Notice

Medical knowledge is constantly changing. Standard safety precautions must be followed, but as new research and clinical experience broaden our knowledge, changes in treatment and drug therapy may become necessary or appropriate. Readers are advised to check the most current product information provided by the manufacturer of each drug to be administered to verify the recommended dose, the method and duration of administration, and contraindications. It is the responsibility of the practitioner, relying on experience and knowledge of the patient, to determine dosages and the best treatment for each individual patient. Neither the Publisher nor the editors assume any liability for any injury and/or damage to persons or property arising from this publication.

Preface to the First Edition

The field of occupational and environmental disease is rapidly evolving. Questions and concerns about the health consequences of exposures to a seemingly endless array of potential hazards in the workplace and elsewhere in the environment are increasingly raised by clinicians themselves or brought to their attention by patients or other interested parties. Yet most practitioners find themselves ill-equipped to recognize, diagnose and treat occupational and environmental diseases. Further, textbooks in the field have not traditionally been dedicated to helping clinicians meet this challenge by presenting clinically relevant information that is both comprehensive yet practical and easily accessible.

The *Textbook of Clinical Occupational and Environmental Medicine* was conceived and written to address the needs of students, trainees, and clinicians who seek a resource to integrate occupational and environmental medicine into routine clinical practice. It evolved in part from our well-received, earlier effort—a concise and less encyclopedic text entitled *Clinical Occupational Medicine*. This textbook, although we hope it benefitted by our experiences with the first, is by intent and necessity markedly different in approach and scope. The role of workplace factors has been broadened to include environmental physical, chemical, and biologic agents that may have adverse effects on human health. Environmental diseases, although in general less well recognized and understood than those arising from the workplace, are integrated throughout the sections of the textbook.

The textbook is divided into four major sections. The first, Principles and Practice, provides a broad overview of the specialized skills central to the successful practice of occupational and environmental medicine, recognizing the strong interrelationship in the field between scientific and ethical, legal, economic, and social issues. The second section encompasses three core disciplines that are necessary complements to the diagnosis, treatment, and prevention of occupational and environmental diseases: toxicology, epidemiology and industrial hygiene. The third and longest section provides an organ system approach that enables the clinician to consider potential occupational and environmental diseases as they most commonly present in an individual patient. The last section, strongly cross-referenced to the third, enables the reader to consider specific toxins or hazards. Each chapter in this section is organized by exposure type (e.g., radiation, biologic factors, metals) and presented to provide an understanding of the environmental and occupational settings where specific agents are likely to be encountered, their acute and chronic health effects, and approaches to treatment and prevention of exposure to them.

The contributors to the textbook are well known and recognized experts from North America and Europe. The editors have worked closely with them to provide a consistent format throughout the textbook. We are extremely grateful for the spirit in which our contributors responded to this objective by accommodating to our evolving effort to achieve for the reader a coherent, comprehensive text. Long periods of silence on the part of some contributors were thankfully rewarded with remarkable chapters. One was preceded by a welcome fax from Greg Wagner, which—like a clear day in Seattle that may follow weeks of rain—served to brighten memories of the recent past. His doggerel is excerpted below

As midnight came
and the bell tolled
off the printer
the pages rolled

Now sitting with the rising sun
I know at least a draft is done!

The editors would also like to acknowledge the outstanding secretarial and editorial assistance provided by Paula Sandler, Rebecca Hubbard, Anne Gienapp, Lanita Stewart, and Marjorie E. Marenberg.

We also want to thank our colleagues at W.B. Saunders for encouraging us to proceed and at all turns strengthening the product, especially John Dyson, Ray Kersey, David Kilmer, Pat Morrison, and Carol DiBerardino.

And finally, we would like to acknowledge the influence of Bernadino Ramazzini, the Italian physician credited as the father of occupational medicine, who taught us many things, but in his extraordinary 1713 treatise, *Diseases of Workers*, understood very well the occupational hazards of authors. He wrote

The Author to His Book

Since you itch and are burning to be published,
First pay heed to an anxious father's warning,
Briefly here's what the fates have destined for you,
Since you bring them something novel,
All the learned at once will run to greet you.
Two short pages, I think are all they'll read through,
Then they'll fling you to factories or by-streets.
Where the poorest buy sausages and fish sauce.
Yes, you're fated to wrap up something greasy.
Still, cheer up, for the same thing often happens
Now to massive imposing legal Pandects.
All-receivers they are; they wrap up mackerel,
Or we screw them to hold the grocer's pennorth,
Pepper, maybe, or smelly seed of cumin.
You must know you were born in grimy workshops
Not in elegant mansions of our betters,
Not in glittering courts where chief physicians
Lay own laws for the cooks but sit down nowhere.
Trust me, then, you will suffer this more lightly
Than do books that can boast of prouder titles.
If they read you and straightway send you packing
Back to workshops, remember—you were born there.

*From Diseases of Workers, translated from the
Latin text De Morbis Artificium of 1713 by
Wilmer Care Wright Publishing Company, New York, New York 1964.*

Preface to the Second Edition

The *Textbook of Clinical Occupational and Environmental Medicine* was originally conceived and written to address the needs of students, trainees and clinicians, as a resource to integrate occupational and environmental medicine into routine clinical practice. We found the response to the first edition extremely rewarding – the text was critically acclaimed and sustained broad national and international distribution. It enjoyed use by many working in different capacities in the occupational and environmental field, not merely clinicians.

In the decade since publication of the first edition, although many of the challenges in diagnosis, treatment and prevention remain, much in the world of occupational and environmental medicine has changed. Workers and others in the United States and abroad face new and emerging threats due to dramatic changes in globalization, technology and demographics. Even the merger of the two components, occupational and environmental – which a decade ago was still being questioned – is now all but taken for granted.

It is against this background that the editors of the first edition have drawn upon the prodigious efforts of two colleagues for this second edition. As with the first edition, we have worked closely with our distinguished contributors to provide a consistent format throughout the textbook and we are extremely grateful for the spirit in which our contributors responded to this objective. We have also undertaken some changes: chapters have been deleted, many more added, and all others significantly updated. In addition to reorganizing the initial four sections, a new section has been added to provide an overview of major workforce sectors, recognizing that an appreciation of the overall health risk in a given setting, such as mining, involves more than an isolated understanding of individual exposures.

Realignments in the publishing world, parallel to consolidations and acquisitions seen in other parts of the economy this past decade, brought us through a series of changes to our London-based publisher, Elsevier. We are grateful to our Elsevier colleagues, especially Rolla Couchman, Hilary Hewitt, Susan Stuart and Amy Head for facilitating this process, and for their support and constant professionalism. The editors would also like to acknowledge the outstanding support and editorial assistance provided by Linda Oliva and Gauri Balani.

As editors, we have in common wondrous appreciation for the support of family and friends – with special recognition by Linda (Lee, Adam and Matthew), Mark (Michele, Zoe and Esme), Drew (Kayla and Naomi), and Carrie (Mara, Joshua, Evelyn and Norman). We also share a deep and abiding respect for workers throughout the world, from whom we have learned so much and to whom we dedicate this book.

Chapter 1

Introduction to Occupational and Environmental Medicine

Mark R Cullen, Linda Rosenstock, Edwin M Kilbourne

Work and economic development are fundamental to the human condition, and have contributed to enormous advancement in wellbeing and health over the centuries. Unfortunately, virtually every aspect of work entails risk of harm as well, both because of the physical nature of the activities involved and the intimate relationship in which workers are placed to natural and man-made hazards in the environment. Moreover, the activities of production themselves and the products generated by work have introduced into the broader environment innumerable hazards of everyday life: in the air we breathe, the food and water we consume, and the material goods we use and ultimately must dispose of. Occupational and environmental medicine (OEM) is an evolving medical specialty that seeks to identify and modify the adverse effects of these hazards on the health of individuals and larger populations.

The focus of OEM differs from many other specialties, which may encompass interest in particular agents (e.g., infectious disease), organ systems (e.g., pulmonary medicine), mechanisms of injury (e.g., immunology) or curative approaches (e.g., surgery). In these more traditional disciplines, the focus of attention is on factors that an individual patient or his/her clinician, or both, can modify to prevent, ameliorate or cure disease or the consequence of injury. In OEM practice, although individuals are of paramount importance, equally important are external factors beyond the direct control of individuals or physicians. The same external factors affecting one person often threaten the health of others. There is a natural tension between the clinical health issues relating to the individual patient and broader public health issues, which transcend the traditional doctor-patient relationship. These broader issues fall very centrally in the domain of OEM practice. The focus of this text, however, is the clinical side, placed in the context of these broader perspectives.

Historically the field of OEM has developed out of two formerly distinct disciplines: occupational medicine and environmental medicine. Though common clinical and public health perspectives, scientific underpinnings, training needs and practice approaches have fostered this 'merger' during the past several decades, there remain differences in the two components by dint of their distinct population foci, divergent societal approaches and distinctive histories. We shall begin here by describing the central principles of disease that irrevocably bind the two; in the sections that follow, unique issues relating to the scope and practice will be introduced.

PRINCIPLES OF OCCUPATIONAL AND ENVIRONMENTAL DISEASE

1. The clinical and pathologic expression of most environmentally caused diseases are indistinguishable from those of non-environmental origin

There is a widely held belief among medical practitioners outside of OEM that diseases of occupational or environmental origin are both rare and distinctive. In reality, diseases caused by work and ambient environment are neither rare nor often distinctive in their clinical presentations and laboratory findings. Most occupational diseases, such as occupational cancers, not only resemble diseases caused by other factors but are otherwise indistinguishable except by careful documentation of a history of a relevant exposure. Other occupational and environmental diseases, like asthma or dermatitis, may be distinguished clinically only through obtaining an exposure history, with or without specialized testing, which presupposes high suspicion for the diagnosis. Only a minority of occupational diseases, such as pesticide and heavy metal poisonings, are sufficiently distinctive that they are likely to be uniquely identified by routine laboratory testing procedures.

2. Many diseases of occupational or environmental origin are multifactorial, with non-environmental factors playing a contributory role

The majority of chronic diseases and even a fair number of acute ones are multifactorial in origin. Coronary artery disease, for example, cannot be simply attributed to hypertension alone in a patient who also smokes. In fact, the discovery of one cause not only does not preclude the possibility of a second, it often makes the effect of an environmental exposure more likely. For example, it has been well established that asbestos exposed workers who smoke have a far higher likelihood of lung cancer than individuals exposed to cigarettes or asbestos singly. Similarly, alcohol consumption is known to potentiate the effects of some environmental hepatotoxins by causing hepatocellular disease.

The most important consequence of this principle in practice is that the potential role of an environmental toxin is not reduced by the presence of another pathogenic factor; in fact, it may be increased. This holds true for

common types of clinical complaints that result from exposure to the environment, such as irritation and sensitization of the skin and respiratory tract. Such problems are too often ascribed to causes such as smoking or viral infection, leaving remediable occupational and environmental causes undetected.

3. The effects of occupational and environmental exposures occur after a biologically predictable latent interval following exposure

Agents or chemicals capable of causing direct and acute injury to the body will typically exert their effects either immediately or soon after exposure. In these cases, because the onset of disease occurs early, possible causal connections are relatively easily identified. On the other hand, the effects of agents that act by sensitizing the immune system, such as those that cause dermatitis or asthma, more often are exhibited only after a period of months to years of exposure.

Other substances initiate insidious disease processes that may become clinically apparent only after a latent interval of many years. For example, carcinogens may not cause cancer until years after the individual's first exposure. Importantly, there is no uniform relation between these late outcomes and any early effects. For example, leukemia may occur in a person exposed to external ionizing radiation at levels far below that which would cause acute radiation sickness or other demonstrable health effect. Indeed, individuals unaffected by early effects may be at higher risk for later effects because they tolerate doses of higher intensity and duration than those who do suffer acute effects, and consequently remove themselves from further exposure, or are removed.

4. The dose of an exposure to a noxious agent is the strongest predictor of the likelihood and type of effect

Although this principle is elucidated in detail in Chapter 5, it is important to recognize that toxins, like drugs, have clear relationships between dose of exposure and subsequent effect, and proportion of exposed individuals affected. Although each host differs from others, knowledge of these relationships and estimation of the amount of each are key to diagnostic decision-making.

In general, higher exposures confer a higher likelihood of being affected (dose–response relationship) and of more serious effects (dose–effect relationship). As shown in Figure 1.1, three distinct patterns can be discerned. For direct acting toxins, such as heavy metals, organic solvents, or pesticides (Fig. 1.1a), there is for each individual a threshold dose below which there is no demonstrable effect. As the dose increases, the severity of effect increases up to a level that ultimately, at least theoretically, would be fatal. In addition, as the dose increases, the proportion of the exposed population adversely affected also increases.

Other harmful agents act by eliciting an immunologic or other hypersensitivity response (Fig. 1.1b). With these agents, such as those that cause asthma, dermatitis, and

allergic alveolitis, many persons experience no untoward effect regardless of dose, presumably based on genetic or other host factors. Increasing dose, however, increases the likelihood of sensitization in those who are susceptible. Once sensitization occurs, however, the severity of reactions is typically independent of subsequent exposure dose and may occur at a very low level.

Finally, there are agents that interact with genetic material to cause mutations or initiate cancers (Fig. 1.1c). With these agents, the administration of even the smallest dose confers a finite chance of a mutation. The risk of disease at the lowest end of the dose–response curve may be only theoretical or unmeasurable (e.g., the risk of lung cancer from smoking one cigarette). In this situation, as with agents inducing hypersensitivity, the dose does not affect the severity of disease once it is present; only the probability of disease increases as the dose of exposure increases.

Although these relationships are different, the importance of dose in arriving at a correct diagnosis, providing treatment, and preventing disease remains crucial in every case. As discussed more fully in Chapter 3, successful evaluation and management of the patient suspected of having a disorder of environmental origin or who has a risk for such a disorder depend on the clinician's ability to assess the patient's recent and past exposure dose, at least qualitatively. Primary prevention, on the other hand, depends on minimizing exposure dose in the first place.

5. People differ substantially in their responses to noxious exposures

Humans sometimes differ remarkably in their responses to environmental exposures. These differences may be due to a wide range of factors, including genetic differences in metabolism, age, gender or size, co-exposures to environmental substances that may interact with agents of interest, coexisting morbid conditions, or complex behavioral factors. The major principles that underlie this variability are discussed in Chapter 11. For present purposes, it is important to recognize such variability, which frequently obscures the relationship between environmental exposures and health effects. For example, a health problem in one among many individuals exposed to a harmful agent may suggest an alternative explanation for the effect when in reality only that single individual was susceptible to that dose of exposure. Similarly, the fact that many workers have functioned without adverse consequence around a chemical or process may wrongly suggest to an employer or susceptible coworker that the environment is equally safe for all. From the practitioner's perspective, it is important to recognize that although the pattern of occurrence of illness in a population may be a vital clue and should always be sought, the absence of an obvious pattern or a confusing pattern may be a function of host variability within the population.

OCCUPATIONAL MEDICINE

In developed countries the vast majority of adults – men and women – are active in the formal economy, inter-

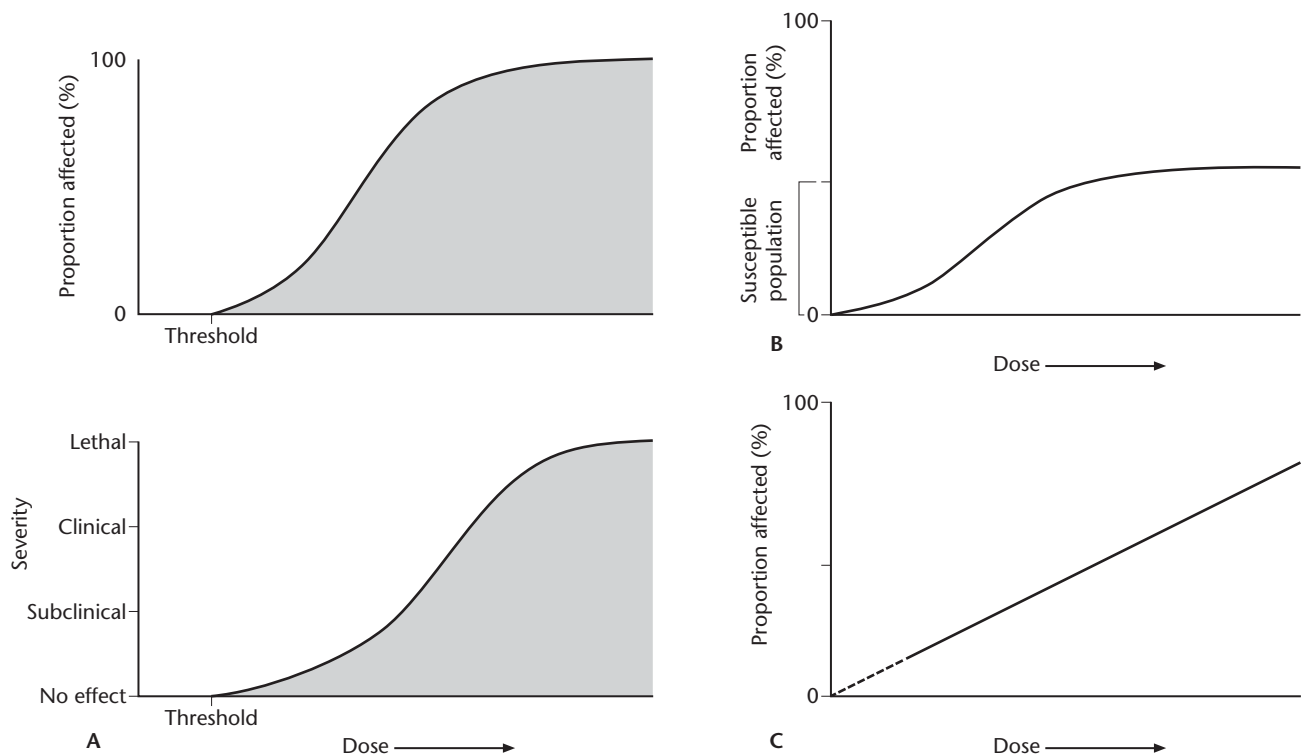

Figure 1.1: Schematic dose–response relations for environmental hazards. (a) For direct-acting agents, there is a threshold for each individual, followed by increasing severity with rising dose. Similarly, a rising fraction of the exposed population is affected as dose rises; eventually everyone is affected. (b) Indirect-acting toxins affect only susceptible individuals. The dose determines what proportion of these individuals are affected. Note that dose may not determine the severity of the reactions, which may be more related to host factors. (c) Carcinogens are believed to cause disease as a linear function of dose. The shape of the dose–response curve at very low doses (dotted line) is difficult to determine directly from studies; it is often assumed to be linear, but this assumption is controversial for some carcinogens.

rupted occasionally for reproduction, medical disabilities and economic dislocations such as layoffs. Virtually every form of work has attendant hazards – physical, chemical, biologic and social; these are discussed in Sections 2 and 4 of this text. Although some work environments are complex, involving many different hazards, and the potential human effects of many hazards remain incompletely studied, the range of possibilities is nonetheless circumscribed and, in theory at least, can be reconstructed and characterized – even quantified – in the effort to assess risk for injury and illness, and evaluate health problems that do arise. For complex historical and social reasons, however, attention to this relationship has been very limited until the past few decades, even in developed countries (Chapter 2). In developing countries, where far higher fractions of the adult population are either unemployed or engaged in informal work, characterization of the health effects of work is far less complete (Chapter 10).

Despite significant recent advances in worker health promotion, there remains as yet no reliable estimate of the magnitude of the medical and economic burden posed by occupational diseases and injuries. Efforts to determine the nature and extent of occupational diseases are more elusive than for injuries; the latter, in general, involving more physically apparent outcomes with more easily traced causes.

Chapter 31 provides an overview of data sources and information about the distribution of both fatal and non-fatal occupational injuries. In this section we review some of the problems defining the extent of occupational disease and injury in developed countries, focusing on what is known and not known in the United States. Readers can find more detailed information about the incidence and prevalence of specific disease entities in the organ system chapters of Section 3 of this text.

Two main factors contribute to the lack of reliable estimates about the extent of occupational diseases: clinical under-recognition that such diseases are in fact occupational and inadequacy of public surveillance systems to capture and summarize those that may be recognized clinically. Under-recognition, in turn, is based on a number of factors, including:

1. inadequate knowledge about the health effects of many hazards among employers, workers and health practitioners;
2. the absence of pathognomonic or even relatively specific findings for many occupational diseases;
3. latency between exposure and disease onset for most chronic conditions;
4. multifactorial causation for many occupational diseases, including those due to both occupational and

environmental factors and non-environmental ones; and

5. marked variations in individual susceptibility to most occupational hazards.

Compounding these complexities in disease recognition are the inadequate attention devoted to occupational diseases in medical education in the United States and the historical isolation that largely excluded attention to occupational factors and conditions from mainstream medical care. Beyond diagnostic difficulties lie fragmented and often biased reporting systems. Moreover, even if reporting systems functioned better, there are a number of significant disincentives for the physician to report an occupational disease. These include: burdensome paperwork and bureaucratic interactions; lack of payment, underpayment, and payment delays if cases are contested by employers; and the wish to avoid litigious involvement.

The burden of occupational injury and disease: sources and limitations of data

The following section provides a brief overview of some of the state and national data sources that have been used in deriving estimates of the nature and extent of the occupational disease burden in the United States. Although data systems in other developed countries differ, the fundamental limitations are common to all to varying degrees. The situation in developing economies is far more intractable, as discussed in Chapter 10.

Annual survey of occupational injuries and illnesses

In the United States the Bureau of Labor Statistics (BLS) program of OSHA, mandated by the 1970 OSH Act, maintains a national employer based system to monitor job-related illnesses and injuries and summarizes these data in annual surveys.¹ The BLS data are obtained by annual compilation of required injury and illness reporting logs from all eligible employers, with substantial penalties invoked for non-compliance. Many shortcomings of this reporting system limit its reliability and completeness including exclusion of many workers (the self-employed; small businesses and farms; and federal, state, and local agency employees); under-reporting of most occupational diseases (especially chronic, multifactorial and latent ones); and the disincentives inherent in any system linking reporting rates to regulatory priorities, however otherwise rational such links might appear. Needless to say, the quality of the aggregate data can be no better than the quality of the data input.

Nonetheless, the most recently available data do provide a broad and staggering picture of the magnitude of the occupational health problem in the US, limitations notwithstanding. In the year 2000 almost 5.3 million occupational injuries were self-reported at covered workplaces alone; 1.6 million of these resulted in lost work time. In addition, 362,000 occupational illnesses were reported, including over 200,000 cases of musculoskeletal disorders attributed by employers to work, over 40,000

skin conditions, and almost 80,000 respiratory cases, poisonings, etc – almost all acute in nature.² In a separate reporting function, 5,344 deaths were reported at work due to occupational causes.

Workers' compensation reports (see also Chapter 57.2)

Workers' compensation records, both state and federal, provide one of the most widely available sources of data about occupational diseases and injuries. There is ample support for the belief that these databases systematically underestimate the extent of occupational illnesses and distort the distribution of types.³ For example, a recent study conducted in the northeastern United States found that as many as 90% of self-recognized musculoskeletal disorders had not been reported to the workers' compensation system.⁴ Workers' compensation systems also vary as to their inclusiveness of coverage; agricultural workers, for example, are excluded from workers' compensation benefits in many states. In addition to problems of incomplete worker coverage and failures to report diseases – especially chronic diseases – to this system (whether because of patient or physician inclination not to do so), many of these systems report only those claims that are accepted; widespread experience suggests many are contested by insurance carriers in virtually every jurisdiction. The reverse also occurs: poorly documented claims are sometimes compensated. Nonetheless, some inferences can be derived from these data which form part of the incomplete whole picture.³

Morbidity and mortality from chronic conditions

In the United States, some states record the individual's usual occupation on death certificates; a smaller number of states include industry as well. These data and accompanying information about cause of death and contributory causes (so-called 'multiple causes of death') have proved useful in estimating excess mortality in different jobs and industries. Since the late 1960s, the National Center for Health Statistics (NCHS) has provided annual summaries of all conditions on death certificates from all states, including information about occupation and industry from the several states which code this; since 1989 more extensive information about industry and occupation has been coded.⁵ These data allow exploration not only of the underlying cause of death but also about other conditions that may have contributed to death. Still, there are many limitations to using death certificates in general and multiple causes of death in particular, including: under- and over-reporting of causes by physicians unknowledgeable about occupational diseases; very limited and poor quality information about job and industry from which to infer exposures; and all those factors leading to under-recognition of occupational diseases alluded to earlier.

Nonetheless, manipulations with these data have led to various estimates of occupational disease mortality in the

US, ranging from 40,000 to 65,000 deaths from chronic occupational disease per year in the US.⁶ Almost 10,000 of these are directly attributable to asbestos.⁷ The majority of cases – cancers, and chronic disease of the respiratory tract, heart, liver and kidneys – have been imputed by comparing proportional death rates in various industries, adjusting as best possible for confounding factors such as tobacco and socioeconomic class. For this reason, caution is suggested in the interpretation of these data.

Canadian estimates of incidence and mortality, derived from similar databases, suggest comparable experience throughout North America, at least, adjusting for differences in the size of the workforces.⁸

National Hospital Discharge Survey

The National Hospital Discharge Survey (NHDS), conducted annually by the NCHS, provides data on hospital stays in non-governmental hospitals.⁹ Information is provided regionally. Data on occupations and industries are not available, but the system does allow capture of diagnostic events that may be occupational in origin, e.g., carpal tunnel syndrome or asthma, or other so-called ‘sentinel health events’ – common disorders that have been linked to occupational causes in some significant fraction of all new cases.¹⁰ These data, despite significant limitations, have been used in helping to derive estimates of the extent of certain occupational diseases in the United States, such as coal workers’ pneumoconiosis, whose prevalence has

resulted in a drop from a peak of 24,000 hospitalizations in 1984 to 11,000 in 1996, and asbestosis, whose prevalence based on these data has increased during the same time period from 6000 a year to 13,000.⁷

Outpatient data

Occupational diagnostic referral clinics developed in the US in the 1970s and have become widespread in medical centers in the 1980s and 1990s.¹¹ These clinics have as their primary goal the identification and management of work-related diseases not readily handled by primary sources of worker care. Although workplace diversity and identified conditions of evaluated patients are limited by local or regional referral practices and patterns, and the availability of such clinics remains extremely limited, data from these clinics provide some insight into common diseases and exposures. Tables 1.1 and 1.2 give an overview of common diagnoses and exposures from 24 clinics, members of the Association of Occupational and Environmental Clinics (AOEC) who submitted case reports to the AOEC database describing patients with work-related diseases or injuries¹² who were diagnosed between January 1991 and December 2000. While not necessarily representative of all patients with work-related conditions, these case reports provide insight into the types of occupational conditions being treated by occupational medicine specialists, as well as into the types of exposures that are causing or exacerbating these diseases.

General diagnosis category	Specific diagnosis	# of cases	% of cases
Respiratory (5814 of 6021 diagnoses)*	Asbestosis/parenchymal disease only	3631	40.1
	Asthma (691 cases) and reactive airways dysfunction syndrome (156 cases)	847	9.4
	Asbestos-related pleural disease only	642	7.1
	Upper respiratory irritation, chronic or NOS	425	4.7
	Silicosis	155	1.7
	Parenchymal and pleural disease	114	1.3
Musculoskeletal (973 of 1755 diagnoses)	Carpal tunnel syndrome or median nerve neuropathy	318	3.5
	Tendinitis / tenosynovitis / bursitis of the forearm, wrist, hand, or fingers	192	2.1
	Epicondylitis	144	1.6
	Low back strain / sprain / tears	133	1.5
	Low back pain / radiculopathy / muscle spasm	98	1.1
	Upper extremity cumulative trauma disorder / musculoskeletal pain	88	1.0
	Noise-induced hearing loss	909	9.7
Sensory organ disorders (909 of 965 diagnoses)			
Symptom-defined and miscellaneous syndromes (443 of 626 diagnoses)	Multiple chemical sensitivity/acquired chemical intolerance	166	1.8
	Sick building syndrome	156	1.7
	Headache (chemical, migraine, tension, or NOS)	121	1.3
Chemical poisoning syndromes (313 of 458 diagnoses)	Toxic effect of lead	181	2.0
	Toxic effects of solvents	132	1.5
Skin (183 of 254 diagnoses)	Dermatitis, all	183	2.0
Psych/Neuro (165 of 395 diagnoses)	Toxic encephalopathy	165	1.8
*Numbers in parentheses represent number of cases with specific diagnoses listed in table, out of total number of diagnoses in category. NOS = not otherwise specified.			

Table 1.1 Diagnoses made in at least 1% of the occupational cases, 1991 to 2000 (*n* = 9044 cases; 10,882 diagnoses)

Exposure	Percent of 5641 occupational cases
Asbestos	49.9
Noise	16.0
Repetitive motion	8.3
Keyboard use	7.7
Indoor air pollutants	7.7
Solvents, NOS	4.8
Inorganic lead	3.3
Lifting	3.1
Crystalline silica	3.0
1,1,1-Trichloroethane	2.7
Tetrachloroethylene	2.5
Fall, NOS	2.5
Acute trauma, NOS	2.1
Dust, NOS	1.9
Smoke, NOS	1.6
Tuberculosis	1.5
Paint	1.4
Chemicals, NOS	1.4
Vibration, NOS	1.3
Isocyanates, NOS	1.3
Coal	1.2
Latex, natural rubber	1.2
Welding, NOS	1.1
Cutting oils	1.0
Formaldehyde	0.9
Ergonomic factors, NOS	0.9
Mold	0.9
Toluene	0.8
Hydrocarbons, NOS	0.7
Xylene	0.7
Pesticides, NOS	0.6
Ammonia solution	0.6
Glutaraldehyde	0.6
Epoxy resins	0.5
Methyl ethyl ketone	0.5
Struck by/against object	0.5

*Exposures contributing to at least 0.5% of the cases are included in table; some cases have more than one contributing exposure.
NOS = not otherwise specified

Table 1.2 Most frequent contributing exposures* associated with occupational conditions, AOEC cases, 1991–2000 ($n = 9044$ cases; 11,239 exposures)

Over a 10-year period, over 9000 patients were diagnosed with work-related diseases or injuries. The AOEC case report records up to three diagnoses and three exposures; therefore, the numbers of diagnoses and exposures exceed the number of patients. As seen from Table 1.1, asbestosis, diagnosed in 41% of all patients with work-related conditions, was by far the most common disease seen in these AOEC clinics; asbestos-related pleural disease was also common. This burden of disease from past asbestos exposures should diminish over time, as asbestos exposures are now well controlled in the US. Noise-induced hearing loss was seen in almost 10% of patients with occupational disease, almost all diagnosed within the patient subgroup with asbestos-related disorders. The AOEC clinics also treat numerous patients with diseases and injuries caused by more recent exposures. Chief among these are respiratory conditions and soft-tissue musculoskeletal disorders. Asthma or RADS (reactive airways dysfunction syndrome) was diagnosed in 9.4% of occupational cases, and upper respiratory irritation in 4.7%. Carpal tunnel syndrome, upper extremity tendinitis/

tenosynovitis/bursitis, epicondylitis, and low back problems together accounted for almost 10% of occupational cases. Table 1.1 also lists several other commonly diagnosed conditions, including dermatitis, lead poisoning, multiple chemical sensitivity, toxic encephalopathy, and sick building syndrome.

Table 1.2 details the occupational exposures most frequently related to patients' injuries or illnesses. Leading the list of associated exposures were: asbestos (49.9%); noise (16%); repetitive motion (8.3%); keyboard use (7.7%); and indoor air pollutants (7.7%). As can be seen from the remaining exposures on the list, occupational diseases and injuries are being caused by very diverse chemical, physical and biologic exposures.

Occupational disease surveillance systems

Both the federal government in the US and some states have developed surveillance systems to track incident cases of all occupational diseases or specific entities. Five states, for example, undertook reporting of occupational asthma under a program sponsored by the National Institute for Occupational Safety and Health: 1100 cases were reported between 1993 and 1995.¹³ Twenty-eight states require reporting by laboratories of blood lead levels for adults as a way of tracking OSHA-mandated blood testing of exposed workers. Results suggest numbers of cases of lead poisoning still occur: Washington State reported almost 2800 levels greater than 25 micrograms/dL between 1993 and 2001;¹⁴ Massachusetts reported 547 during a recent 5-year period.¹⁵ Connecticut requires reporting of all work-related diseases, collecting between 1500 to 2000 reports per year since 1996, mostly musculoskeletal disorders, elevated lead levels, skin and lung conditions.¹⁶

Despite these and emerging efforts both nationally and regionally, it is noteworthy that no comprehensive system exists to capture occupational diseases and non-acute injuries, so all estimates of incidence and mortality must be viewed with caution as likely underestimates of the true burden.

Estimates of the prevalence of occupational conditions in the population

Because incidence data are limited, attempts have been made to estimate the prevalence of occupational effects in the population based on broader measures of the health of the population. The boldest attempt thus far was the Occupational Health Supplement to the National Health Information Survey (NHIS), a periodic populational sample survey conducted every several years by the National Center for Health Statistics.

Unfortunately the supplement has only been done once – in 1988 – limiting any inference about changes. Moreover, since the survey is self-administered, only conditions of which respondents may be aware, such as pain or skin rash, are amenable to study. Interpretation is further

limited by potential bias in respondents' perceptions about what conditions are and are not related to their work.

Nonetheless, analyses of the 1988 survey have resulted in some evidence that the proportion of the population with work-related musculoskeletal disorders such as low back pain, carpal tunnel syndrome and dermatitis may dwarf estimates from BLS and the other sources described above,¹⁷ with literally millions of workers affected by, and to a disturbing extent disabled by conditions perceived to have occurred on the job. While it would be presumptuous to apply these estimates as verified, the extent of positive responses regarding a small number of self-reported conditions further underscores both the large scope of the persisting occupational disease burden in our society, and ultimately the need for more valid, timely and longitudinal data to control it.

ENVIRONMENTAL MEDICINE

Since the birth of occupational medicine and continuing through very recent times, interest in the environmental determinants of non-infectious disease has centered overwhelmingly around the workplace. Substantial concern regarding the potential adverse effects on health of non-occupational environmental exposures has developed only relatively recently. The beginning of this trend is difficult to pinpoint, but in the United States, it has become particularly evident over the last three decades.

Today, the non-occupational environment rivals or exceeds the occupational environment as a source of health concerns among the public at large. Hardly a day goes by without news media coverage of one or more potential environmental health problems. At the national and international level, prominent environmental health issues currently include all of the following and more:

- increased cancer risk from radon in indoor air;
- neurologic dysfunction from exposure to lead in house dust and drinking water;
- respiratory and cardiovascular mortality from particulate and other ambient air pollutants;
- still-to-be-clarified consequences of the accumulation of measurable body burdens of biopersistent halogenated organic compounds (e.g., dioxins and polychlorinated biphenyls) in large segments of the population;
- possible neurotoxic, carcinogenic, and other effects of substances added to foods; and
- potentially devastating health consequences that may arise from global warming and depletion of stratospheric ozone.

Quantifying the precise levels of risk attributable to environmental exposures in a given population presents difficult methodologic problems. Nevertheless, in one major study, an estimated 75–80% of cancers in the United States were judged to be avoidable, and largely due to environmental factors.¹⁸ Tobacco smoke, both actively and passively inhaled, may account for approximately 30% of all cancers in the United States. But other air pollutants are important as well. Over 1000 deaths per year occur in the United States as a result of unintentional exposure

to carbon monoxide, and the prevalence of asthmatic symptoms may double in children as a result of living close to a heavily polluting industrial facility. As many as 10,000 to 20,000 lung cancer deaths occur annually as a result of exposure to environmental radon.¹⁹ A substantial proportion of preschool children in the United States, particularly those living in older housing, are at risk of developing measurable intellectual dysfunction owing to environmental lead.

At the local level, there is concern about the potential danger to people located close to hazardous waste sites and the possible effects of water or air pollution related to nearby industry. At the level of the individual, the practitioner may see patients whose illness or personal health concerns relate either to one of the major issues described earlier or to more unusual exposures or health problems that are specific to that individual.

Purview of environmental medicine

By comparison with occupational health, non-occupational environmental medicine presents both the researcher and the health practitioner with an unusually thorny set of issues and problems. Full consensus has yet to be reached even regarding the boundaries of the new medical discipline, but one could reasonably define non-occupational environmental medicine as that medical specialty involving the prevention, diagnosis, therapy, and study of disease and injury due to external influences but unrelated to the patient's workplace. Nevertheless, the potential problems accompanying such a broad definition of the field should be recognized. There is substantial overlap with extant and established specialties, such as infectious disease medicine and pulmonary medicine. Given the paucity of practitioners of this component until very recently, it would seem most appropriate for practitioners of non-occupational environmental medicine to concentrate both clinical and research activities on those problems and issues not already covered by other specialists.

Some might prefer a more limited (but potentially viable) definition that would exclude essentially all infectious agents from the purview of non-occupational environmental medicine. This limitation in scope would have the added benefit of focusing the specialty area on the effects and potential effects of chemical and physical environmental agents, which are not dealt with comprehensively in any other specialty area except occupational medicine. Whether certain chemical exposures related to lifestyle (e.g., tobacco smoking and ingestion of dietary lipids) should be excluded from the consideration as problems in non-occupational environmental medicine can also be debated. Despite potential overlap with the fields of allergy and clinical immunology, the potential contribution of the environmental medicine practitioner to the amelioration of health problems due to non-infectious biologic agents is large.

There is clearly some overlap between non-occupational environmental medicine and the developing specialty of clinical toxicology. However, clinical toxicologists tend to

deal with sudden, generally well-characterized, chemical exposures for which the resulting clinical picture is often acute, rapidly terminating in death or resolution of clinical abnormalities. They deal less with chronic health effects related to cumulative exposure to relatively low doses of toxicants, whereas this area is a specific focus of environmental medicine. The practice of clinical toxicology is directed toward treating persons for clinical symptoms that are already apparent. Clinical toxicology is less oriented toward risk communication and counseling aimed at preventing adverse health outcomes over the long term. Finally, clinical toxicology does not deal with the physical environmental hazards that form an important focus of research and practice in environmental medicine.

Even if one defined the field in the most restrictive terms possible, the scope of environmental medicine would remain enormous. Potential chemical hazards are particularly numerous with potential human exposure outside of work to more than 50,000 registered with the US Environmental Protection Agency under the Toxic Substances Control Act (see Chapter 57.1) There are fewer physical than chemical environmental agents of concern. This set of etiologic agents requires very different and diverse bases of scientific knowledge to understand the processes involved in the etiology and pathogenesis of the documented and potential health effects produced by such diverse physical agents as ionizing radiation, electromagnetic fields, hot and cold temperatures, high and low atmospheric pressures, and mechanical force.

Differences from occupational medicine

Whereas occupational medicine is a well-established specialty, with a substantial (if still inadequate) number of practitioners focused on reasonably well-defined populations and hazards (earlier cautionary comments notwithstanding), there are relatively few physicians whose practices involve a substantial component of non-occupational environmental medicine. Moreover, many of those who do practice non-occupational environmental medicine do so only as part of a broader practice involving a recognized specialty or subspecialty (e.g., allergy/immunology, otolaryngology, neurology, or pulmonary medicine).

Information bases

For both the practitioner and the researcher, the non-occupational environment presents challenges, many of which are either absent from or present to a lesser extent in occupational medicine. Of these challenges, the frequent absence of quantitative and even certain qualitative information on exposure is particularly troublesome. The worker at a given site is subject to a particular set of exposures that are determined by the industrial process used there. If he or she becomes ill, a relatively rapid determination can, at least in theory, be made regarding whether a workplace exposure could plausibly account for the

illness. Such a determination could be based on the known adverse effects of the specific materials and processes used and the number, duration, and circumstances of contacts the patient has had with them. It is often possible (and always desirable) to conduct environmental measurements of exposures of concern in the workplace to provide quantitative data on both average and peak exposures (see later). Moreover, because a number of workers may share the same exposures, the presence of a pattern of symptoms among workers with common duties can alert one to the possibility that a workplace environmental exposure may be the cause. Workers themselves may have at least some familiarity with the potential adverse consequences of specific exposures in their industry, and, therefore, they may be more likely to report them to the physician.

By contrast, outside of the workplace, peoples' lifestyles and exposures are extremely varied. Patients rarely maintain an encyclopedic listing of the particular products they use or of other exposures that may be relevant to their complaints or illness. Often exposures affect only a single individual or family, substantially lessening the possibility that an association of a disease with a particular exposure could be identified by means of an analysis of the pattern of health effects seen among several persons. The patient may be unable to reproduce or even accurately report the typical pattern of use of potentially etiologic materials, substantially complicating any effort to quantify exposure. Moreover, particular activities (especially hobbies and avocations likely to involve repeated exposures) may or may not lead to exposures recognized by the patient as possibly relevant to symptoms or illness; the patient may fail to consider that his or her non-workplace exposures might be responsible for a health problem and, therefore, may fail to report them to the physician. A careful history that comprehensively reviews possible causative exposures is, thus, particularly important in non-occupational environmental medicine (see Chapter 3).

Comprehensive occupational medical coverage of employees often includes a program of medical surveillance of workers. Such programs are oriented toward the exposure(s) of particular concern in the industry that the program is designed to monitor. Biologic samples (e.g., urine or serum) may be tested periodically to determine whether or not any undue toxicant absorption has occurred. In addition, a worker may receive directed, periodic medical examinations, the purpose of which is the early detection of health effects from the particular substances or processes to which that worker is exposed, hopefully at a stage when those effects can be either mitigated or reversed. If the worker is seen because of a complaint or concern, the surveillance data serve as baseline information that facilitate the evaluation.

Conversely, physicians dealing with patients who are ill or fear they may be ill from environmental exposures incurred outside the workplace are unlikely to have data equivalent to the surveillance data to which occupational physicians may have access. Although testing of biologic specimens from the patient may still be informative, the perspective provided by prior baseline testing is almost

always absent, as are data from previous examinations directed toward documenting information relevant to the particular environmental exposure(s) or health effect(s) of concern.

The practitioner of occupational medicine also may have the benefit of information from periodic environmental monitoring (e.g., air sampling) of substances that may threaten health, typically performed by industrial hygienists or other trained personnel. Such measurements may greatly aid in interpreting patients' complaints or the validity of their health concerns. Even if no measurements were taken before the fact, many industrial processes are performed under conditions that are sufficiently well characterized that they may be reproduced with reasonable precision at a time when the monitoring can be conducted. In contrast, it is rare for environmental measurements relevant to a specific individual to have been taken outside the workplace. Moreover, the patient with a non-occupational, environmental exposure is relatively unlikely to have maintained records on such items as the quantity of a potentially problematic substance used. As an individual, he or she is also much more likely to have varied his or her use of these substances over time in ways that are unlikely to be documented and about which the patient's own memory may be poor. These factors substantially limit the possibility of replicating the exact circumstances of exposure in order to make environmental measurements that may be ideal for clinical evaluation (see Chapter 3).

Scientific investigation of new problems

The complete spectrum of environmentally caused illnesses and their specific environmental antecedents has not yet been fully described. Thus, when one or more patients appear with symptoms that are either novel or unexpected for the set of environmental exposures experienced, it is reasonable to consider the possibility that the illness actually is caused by one or another of the exposures and that the particular disease-exposure link simply has not been described previously. This possibility may be easier to investigate in the workplace than outside it; reasons include specific awareness of the possibility of occupational disease in many populations of workers and the frequent occurrence in the workplace of qualitatively and quantitatively similar exposures among multiple, socioeconomically comparable but unrelated individuals, substantially increasing the statistical power of epidemiologic studies aimed at elucidating the cause of a new syndrome.

On the other hand, there may be situations in which investigations of both new and previously described environmental health effects are problematic in the workplace and more easily completed in the community at large. Such situations may arise, for example, when employees feel substantial pressure either not to report or to downplay their report of symptoms that could reflect negatively on the employer. Alternatively, there may be peer pressure or pressure from employee advocacy groups (e.g., unions)

to report symptoms that the employee might otherwise ignore. Either circumstance can complicate the conduct of an epidemiologic study.

Host populations

The special sensitivities of children and the elderly (i.e., those whose ages are outside the limits of those who typically make up the workforce) to certain environmental agents are more relevant to non-occupational than to occupational medicine (see Chapter 11). Thus, to a greater degree than the specialist in occupational medicine, the non-occupational environmental physician must take such potential differences in sensitivity into account.

Children appear more sensitive than adults to a wide variety of environmental exposures. For example, the developing nervous system of a child appears to be substantially more vulnerable to the toxic effects of lead than that of an adult. Babies tolerate excess nitrate in drinking water far less well than adults. Other potent neurotoxins, such as pesticides (organophosphates and organochlorines) and saxitoxins (the agents of paralytic shellfish poisoning), produce severe illness or death at lower doses in children than in adults. In addition, models for assessing cancer risk generally predict a quantitatively greater risk to children from a given level of exposure to a carcinogen than for adults.

Elderly persons also exhibit different responses to some environmental exposures than do younger adults. The elderly are far more likely to develop clinically apparent illness when exposed to extremely hot or cold conditions than are younger adults. Excretory functions involving renal and hepatic function may be diminished in the elderly, making them more likely to have adverse reactions to certain chemical exposures. In addition, chronic diseases and use of medicines for their treatment are more prevalent among the elderly than among other populations groups and may increase susceptibility to certain environmental exposures. Ambient air pollution, for example, results in excess respiratory and cardiovascular mortality, primarily among such persons. On the other hand, the importance of some environmental exposures may be diminished among the elderly. For example, assessment of exposures to certain carcinogens and counseling in this regard may not be as relevant to elderly persons, particularly if life expectancy is less than the anticipated latent period of the carcinogen. In addition, the adverse effects on reproduction of some environmental agents may be relatively unimportant to patients no longer in their reproductive years.

Thus, to an unusually large extent, physicians involved in non-occupational, environmental medicine must take basic differences in susceptibility into account in the assessment, counseling, and treatment of specific patients, and individual differences in susceptibility demand heavier emphasis in non-occupational, environmental medicine research. A corollary of this statement is that recommended limits for occupational exposure to chemical and physical environmental agents can by no means be automatically

construed as appropriate or applicable to situations of exposure outside the workplace.

Social aspects (see also Chapter 9)

The administrative, regulatory, and economic contexts in which occupational medicine and non-occupational environmental medicine are practiced also create important differences between the two areas. Ethical issues similar to those related to potential conflicts of interest of occupational physicians employed by the same companies whose workers they care for are far less likely to arise among physicians dealing with environmental medicine outside the workplace. Moreover, non-occupational environmental specialists may escape much of the burden of the complex, time consuming, and red tape laden workers' compensation system.

Although they do not necessarily have to confront certain ethical dilemmas faced by occupational physicians, physicians involved in non-occupational environmental medicine – particularly consultants involved in epidemiologic evaluations – share with their colleagues in occupational medicine another set of complex social issues. Environmental physicians are frequently called on by the media – in public meetings, courts of law, or other public forums – to offer expert opinions regarding whether or not specific cases of disease or injury were caused by a specific environmental exposure. Often such opinions must be offered on the basis of few objective data or prior scientific studies and in the context of heated feelings and firmly established, preconceived notions on the part of those affected and their supporters. The expert may be confronted by equally daunting pressure from the party or parties responsible for the environmental exposure, who risk substantial economic losses from an expert opinion supporting a disease exposure link.

Established versus hypothetical hazards

Environmental medicine deals largely with questions of exposure and risk. In this regard it is useful to differentiate clear-cut hazards – those known to cause effects at occupational dose levels, from potential hazards – those known to cause human effects only at much higher dose levels, or those never demonstrated directly to cause harm in humans. Clear-cut environmental hazards can be designated as such on the basis of epidemiologic studies that show a cause-and-effect relationship between exposure to the hazard and the development of a particular illness or injury (usually, but not invariably, done in the occupational setting). For patients exposed to such environmental hazards, the physician's course of action is relatively clear. The exposed patient should be counseled regarding the nature of the risk, along with the likelihood – based on estimated dose and host factors – of possible health outcomes. When appropriate, the patient should be evaluated for the presence of the disease for which he or she may be at increased risk. If the disease is present, appropriate treatment should be instituted.

More problematically, much of the public's current concerns regarding the environment relate to exposures for which harmful effects in human populations have not yet been demonstrated. In general, such potential environmental hazards have been identified as possibly dangerous on the basis of their chemical or physical similarities to clear-cut hazards and/or their apparently harmful effects on animals or in in-vitro systems. Counseling patients about risk in such circumstances is substantially more complicated than for the former class, because the issue of whether or not the risk actually exists at all has to be considered. Quantitative estimates of the extent of possible risk may be lacking entirely. When such quantitative data exist at all, they are typically derived from animal studies or extrapolated from other data on similar (but not identical) compounds. Under these circumstances, some of the important caveats regarding the validity of risk assessment techniques (see Chapter 60) must be incorporated into the patient's counseling on risk related to the environmental exposure.

Data from community-based studies

Nowhere can the occupational roots of much of non-occupational environmental medicine be seen as clearly as in a review of currently recognized environmental hazards. Most such hazards have received their strongest and first scientific support for a causal relationship with human illness on the basis of studies performed on exposed workers. Well-known examples of exposures whose health effects were elucidated in this way include the linking of asbestos to asbestosis, mesothelioma, and carcinoma of the lung; vinyl chloride to angiosarcoma of the liver; and mercury exposure to adverse effects on the nervous system. It is primarily on the basis of these occupational epidemiologic data that practitioners of non-occupational, environmental medicine are aware of the potential risks such exposures pose to persons having non-workplace exposure.

Occupational studies are frequently more useful sources of data than studies of the same agents outside the workplace, because exposure in the workplace is often more intense, more prolonged, more regular, and more easily quantifiable than are comparable exposures outside the workplace. Thus, in a study population of a given size, the numbers of cases of the health outcome of interest are likely to be substantially greater in the occupational than in the non-occupational situation. Moreover, because exposure is generally more easily quantified in occupational studies, the extent of risk is more easily quantified, and the existence and shape of the dose-response curve can be estimated with greater precision.

Nevertheless, data from studies of environmental illness in non-occupational settings are important and continue to be needed to supply information that is missing or unobtainable from occupational studies alone. For example, occupational studies do little to address questions regarding the existence and extent of effects of specific environmental agents on children and others outside the

range of demographic parameters in which workers usually fall. Moreover, what might happen in the home cannot easily be extrapolated from results of studies conducted under industrial conditions. For example, children's exposure to mercury (and consequent health effects) related to 'off-gassing' from household interior latex paint could not easily have been studied in the workplace. Diseases involving severe hypersensitivity to substances arising from industrial operations can sometimes be studied more satisfactorily outside than inside the workplace, because either the workers may be relatively few in comparison to the numbers of persons in nearby areas who are exposed to the substances emanating from the workplace or workers may systematically eliminate themselves from jobs involving contact with substances to which they are hypersensitive and that, therefore, cause them severe discomfort. Thus, non-occupational rather than occupational studies led to the discovery that severe (sometimes fatal) asthma attacks can be elicited in sensitized persons by soybean dust released during the course of industrial operations involving the bean.²⁰

Risk assessment and environmental medicine (see also Chapter 59)

Here, the term risk assessment refers to the use of available data to develop a quantitative estimate of the probability that a given health outcome may result from a specific exposure experienced at a particular point in one's life, for a particular length of time, by a particular route, and at a particular dose level. Although risk assessments may be based on epidemiologic studies (i.e., those involving observation of human beings), they more frequently involve extrapolations based on data obtained from toxicity testing in animals.

Most often, the health outcome of concern is the development of malignant tumors. The test animals are almost always given far higher doses of the test compound than the dose levels for which one wishes to estimate risk, and the test generally lasts a period of about 2 years, the approximate lifespan of small rodents most often used as test animals. Malignant tumors or other health outcomes are assessed histopathologically or by other appropriate techniques. The data obtained from these studies are incorporated into mathematical models that attempt to estimate the maximum dose or concentration of the test chemical to which a human being could be exposed over the course of an approximately 70-year lifetime, while incurring an excess risk – i.e., incremental risk over background – of the health outcome of concern that is less than a particular fraction, frequently 1 per 1,000,000 or 1 per 100,000.

Despite widespread use in regulatory and public health decision making, full consensus has not been reached regarding many issues directly related to the validity of various risk assessment approaches. Some of the most problematic issues relate to:

- extrapolating findings from one species to another;
- adjusting incidence figures from relatively short-lived rodents to relatively long-lived human beings;

- calculating equivalent dosages across species;
- dealing with contradictory results obtained from studies of the effects of the same exposure on different animal species; and
- determining the proper mathematical function for extrapolating high-dose study exposures to the levels of exposure obtained from the environment, which are often several orders of magnitude lower.

Risk assessments based on human (epidemiologic) data are not limited by the problems of extrapolating data from animal models but do suffer from the other problems. Chief among these is quantification of dose. Many human studies of potential use in risk assessment involve retrospective examination of data collected over many years, often from times when the exposure of concern was not thought to be particularly harmful (which is logical, if one considers that large numbers of human beings would have been unlikely to have exposed themselves unnecessarily to a known substantial danger). The attention paid to documenting dose was, therefore, often correspondingly small, and the exposure data are, therefore, frequently imprecise. Human studies yielding positive results also may involve relatively high levels of exposure and, therefore, may suffer from the same problem as animal studies with regard to choice of an appropriate mathematical model for extrapolating data to dose levels more typical of home or community exposure.

All of the problems mentioned earlier lead to uncertainty in the risk estimate. Yet, the results of risk assessments are frequently presented as one or more specific numbers, with no mention of the underlying qualitative and quantitative uncertainties that must inevitably affect the interpretation of such estimates.

However they are derived and with whatever problems, the results of risk assessment are widely applied in formulating environmental regulations regarding the permissible levels of contaminating substances in air, water, soil, and food. The results of risk assessments also guide decisions on risk management made by environmental public health officials (e.g., in determining the extent to which spilled or unintentionally released chemicals must be removed or 'cleaned up' before usual activities in an area can be resumed).

Although the techniques of risk assessment play an important role in the approach to environmental regulation and environmental public health, their appropriate use in physicians' contacts with individual patients remains unclear. It may, in fact, be useful for a patient to be told that a particular exposure to which he or she may be subjected, when incurred constantly over the course of a lifetime, is estimated to lead to approximately a 1 in 10,000 lifetime additional risk of cancer. However, any counseling of the patient in this regard should be accompanied by full disclosure of the types of uncertainties mentioned earlier, all of which potentially affect the validity of the risk estimate. Moreover, to the greatest extent possible, any quantitative risk estimate used in counseling a patient should be set in the context of risks the patient faces frequently and, therefore, is likely to understand. For

example, it may be useful to mention to the patient that 1 in 100 is the order of magnitude of risk for dying over a lifetime in a plane or car crash; by comparison, 1 in 1,000,000 approximates the lifetime risk of being killed by lightning.

Recommending behaviors for risk reduction is complicated by a number of factors, not the least of which is the varying tolerance of particular individuals for different levels of risk. In addition, the risk assessment information commonly available is based on assumptions of constant exposure over a lifetime. Comparable figures for acute exposures that may be of concern to individual patients may be lacking. Other specific features of individual patients' situations (e.g., very young or very advanced age) may result in substantially greater or less theoretical risk for a given patient than that indicated by the estimate used by public health personnel for protecting the general population's health. Currently, the health practitioner does not have easy access to individualized risk estimates fitting the individual circumstances of particular patients as are now readily available for other clinical risks such as cholesterol or body mass index. The best one can do is to emphasize the caveats associated with any quantitative estimate of risk given to a particular patient.

Clinical and public health practitioners and investigators

Close partnership between clinicians and public health practitioners is particularly important in the field of environmental medicine. The need for such collaboration arises, in part, from the fact that although a clinician may effectively treat the deleterious effects on health produced by an environmental exposure, he or she is rarely in a position to change the environmental factors that produced the illness, by contrast with occupational medicine where that relationship may be very much more tenable. For example, it would be senseless to provide chelation therapy for a child with lead toxicity and effectively reduce his or her lead level but then return the child to the same environment that caused the illness in the first place. In this situation, contact with the responsible public health authorities can lead to action that will be of immediate benefit to the patient.

Public health officials also may be a good source of data for health practitioners attempting to counsel patients in a reasonable way about recent highly publicized environmental health concerns. Such episodes of particular concern can be national (e.g., the escalating concern over radon accumulation in buildings and the episode of concern in 1989 regarding residues of daminozide [Alar] and its breakdown products in apples) or local (e.g., concerns of persons living near hazardous waste sites).

A close association with clinicians can provide important information to public health professionals as well. There is currently little formal surveillance for environmentally caused disease. Informal reports from clinicians can alert those working in public health to the presence of a problem that otherwise might have escaped notice

entirely or might have been recognized by them only much later on. In addition, because environmental medicine is a developing area in which previously unrecognized disease exposure associations may be anticipated from time to time, alert clinicians can play an important role in identifying new public health problems. In the early 1980s, clinicians in Barcelona, Spain, pointed out the sudden appearance of clusters of cases of exacerbation of asthma that, from time to time, flooded the city's emergency rooms. That report provided the stimulus for an investigation that eventually led to the discovery that dust arising from ships unloading soybeans in the nearby port was the instigating agent.²⁰ This discovery, in turn, allowed appropriate preventive measures to be taken. Similarly, the eosinophilia-myalgia syndrome was first reported to public health authorities by a group of clinicians who recognized a cluster of patients in New Mexico with similar, peculiar illnesses and a common history of ingestion of L-tryptophan. Subsequent investigation led to the discovery of over 1500 cases nationwide, a clear-cut association with L-tryptophan from a particular manufacturer, recall of implicated products, and an end to the epidemic.²¹ Fostering recognition of such outbreaks is one of the greatest potential roles of practitioners in this emerging field.

Chapter 2

Occupational and Environmental Medicine: the Historical Perspective

Paul Blanc

The history of occupational and environmental medicine is composed of multiple threads continually interwoven over time into a single historical cord. One thread is formed by the key clinicians and researchers who have contributed to the development of this discipline. Most brief summaries of occupational and environmental medical history take this as their limited focus. Yet as important as these biographical elements are in the story of occupational and environmental medicine, other factors have come into play that make the evolution of this discipline distinct from that of other branches of medicine.

First, advances in technology have played a driving role in occupational and environmental medicine that is unparalleled in other fields of health. It is true that advances in diagnostic and therapeutic modalities, from the microscope to the laser, demonstrate the powerful impact that technologic innovation can have on medical practice as a whole. But despite the role that such inventions have played in clinical care, the underlying pathologic processes of concern to practitioners have not changed because of them. Simply put, the microscope did not create illnesses due to new strains of bacteria. In contrast, technologic change continually introduces new occupational and environmental hazards, leading to evolving patterns of established diseases as well as inducing entirely novel conditions never experienced before in human history. Radiation poisoning is an obvious example, but by no means an isolated one.

Second, the history of occupational and environment medicine reflects the impact of larger social movements outside the narrow confines of medicine. This is not to argue that other branches of medicine are immune to such forces. The course of modern medicine still reflects the impact of the French revolution, transmitted down through the influential work of French medical scientists working at the end of the 18th and in the first half of the 19th centuries.¹ So too, the Flexner Report and all that it brought with it for American medicine had a larger sociopolitical context.²

Nevertheless, occupational and environmental medicine, more than any other health discipline in the last 200 years, has tended to wax and wane as a consequence of societal forces. The hygienic movement of the 19th century (particularly in Great Britain), which was linked in turn to wider social reforms, is a case in point. The First World War marked another social-political confluence of forces distinctly impacting occupational and environmen-

tal medicine. More recently, the social movements of the late 1960s in the US coincided with the establishment of OSHA, NIOSH, and the EPA, all of which profoundly affected the field.

The goal of this chapter is to place the story of occupational and environmental medicine within the context of these three disparate, yet inter-related themes: the key historical figures that contributed to the development of the field, the technologic changes that have led to an ever-shifting burden of disease, and the sociopolitical forces that helped set the priorities of the discipline. An overview of this chronology is summarized in Table 2.1. Finally, key resources in occupational and environmental medical history will be summarized in order to direct interested readers further beyond the scope of this brief overview.

OCCUPATIONAL AND ENVIRONMENTAL MEDICINE IN THE ANCIENT WORLD

The remote history of occupational health is fragmentary and largely conjectural.³⁻⁵ In terms of occupationally related illness and injury, as the medical historian Henry Sigerist many years ago pointed out eloquently, the most salient determinant of work-associated morbidity in the ancient world was the widespread use of slave labor.⁵ In a 1936 address to the New York Academy of Medicine, Dr Sigerist remarked:

‘Labor in ancient civilization was primarily slave labor. The pyramids were built by state slaves whose lives had no value whatever, whom every war would replace. We still can see the Egyptian workers laboring under the whip as represented on wall paintings and in reliefs. The lot of the city worker was hardly any better and we can still perceive their voice of rebellion . . . We admire the graceful Greek bronze statuettes that fill our museums but we do not think of the copper miners providing material for these works of art, or the coal miners digging for coal to make the bronze, working ten hours in narrow galleries suffocated by heat and smoke. They were prisoners of war or convicts as a rule.’⁵

As noted by Sigerist, the adverse occupational safety and health impacts of slave labor in the ancient world were most dramatic in mining operations. This industry was also one of the first to manifest the adverse impact on occupational safety and health of technologic advancements in

Historical period	Notable factors	Key documentation
Ancient–Classical	Slave labor Mining and metallurgy Agriculture and crafts	Scattered references in classical medical and non-medical writing
7th–17th Centuries	Early technological change Armaments and metallurgy Alchemical experiments	Ellenbog, Agricola, Paracelsus Chinese technological texts
1650–1800	Large-scale trades Renaissance technologies Coal fuel power pollution	Ramazzini and his translators Evelyn on air pollution
1800–1900	Industrial Revolution Novel exposures to toxins Germ theory predominates	Thackrah and Patissier Annales d'Hygiene Medicine Legale Hirt, Simon, Arlidge, Proust
1900–1950	The New Public Health First and Second World Wars Progressive movements Air pollution emergencies	Oliver, Hamilton, Legge Teleky, Underhill, Drinker Various governmental reports
1950–1970	Nuclear threats, Cold War Petrochemical industry OSHA, NIOSH, EPA	Carson, Brodeur, Berman, Sellars

Table 2.1 A brief chronology of occupational and environmental health

metallurgy⁶ (which increased the demand for a variety of ores) and mining methods (especially pumping systems that allowed mining to delve deeper than ever before).⁷ Such mining operations were important economic forces in Egypt and in Greece, but took place on a truly massive scale in the Roman Empire, particularly in the Iberian peninsula. Rosen's superb *History of Miner's Diseases* provides the most detailed history of this subject.⁷

Allusions by non-medical writers of the classical period to various labor hazards, including risks to miners, constitute some of the earliest written documentation of occupational safety and health problems. Many of these comments are terse references, such as those that have been noted in the epigrams of Martial or the satires of Juvenal.^{3,4} One of the most notable references is the widely cited description of mining by Pliny the Elder (Natural History XXXIII, 40) in which he writes:

'Persons employed in the manufactories in preparing minium (red lead) protect the face with masks of loose bladder-skin, in order to avoid inhaling the dust, which is largely pernicious.'⁵

There are other occasional references to working conditions of artisans or laborers in ancient Western writings, including the Egyptian papyri Eber and Sallier.^{4,5} Similar examples of fragmentary descriptions of working conditions and their inherent risks may also exist in the non-Western early written tradition (especially Chinese medical and technologic writing), but this literature, insofar as it might touch on occupational morbidity, has not been systematically reviewed in the English language.

The concept of 'environmental' health, in the modern sense of the term, is even more difficult to track in early history. A recent review of ancient Roman law makes it clear that statutory and other legal remedies for water and air pollution were indeed undertaken as early as the 1st century AD (for example, a legal opinion by the Roman

Aristo that a cheese maker should not emit smoke into the building above it).⁸ Talmudic commentary provides further indication that legal concepts of environmental and even occupational protection have a surprisingly long history.⁹

Classical *medical* writing (as opposed to general works such as histories or satires) largely ignored occupation in relation to health. Certain vocations were addressed, for example, horseback riding (Hippocrates associated it with impotence and sterility; Aristotle with augmented sex drive).³ This trend continued through Galen, although he may have been the first physician who recorded a personal brush with a significant occupational health hazard. According to one history of the subject:

'In the course of one of his numerous voyages, Galen spent some time on the Island of Cyprus. While there he had visited a mine where copper sulfate was recovered. Unaware of the danger, he himself was nearly overcome by the fumes in the mine. He records that the workmen who carried out a vitriolic liquid ran from the mine with all speed with each load to avoid perishing in the midst of the labors.'³

THE 7TH CENTURY THROUGH THE MID-17TH CENTURY

In the thousand years following the end of the Classical period, the foundations were set upon which modern Western medical science would later be built. Occupational health, as a medical concern, was marginal (at best) throughout most of this long period. Environmental health was given fairly short shrift too, being little discussed beyond a few generalities about climate and good air. This can be contrasted, by comparison, to the subject of diet and health, a topic addressed by many medical writers over these centuries.

During this time there were few, if any, social forces that would have worked to bring such concerns more to the forefront. There were, however, technologic innovations that began to have an impact through changing patterns of morbidity and mortality. These innovations, at first sporadic and isolated, became increasingly important as the Middle Ages drew to a close.

One of the most straightforward examples is provided by technologic developments in armaments, especially the introduction of firearms. The traumatic risks of soldiering, essentially an occupational hazard, were well documented by the famous 16th century military surgeon Ambroise Pare, who gave special emphasis to the novel (at that time) phenomenon of gunshot wounds.¹⁰ From the same period, the introduction of new sea-faring technologies (not only the sailing ships themselves, but as importantly, innovative navigational equipment) led to severe outbreaks of scurvy as an occupational disease of seamen.¹¹

Even earlier than this, mining and metal working technologies became the engine driving the evolution of occupational health as a distinct medical issue.⁷ As was noted previously, this was already true, although to a much lesser extent, in the Classical period. Lead was certainly very widely used during the Roman period and has even been the subject of speculation as to its potential role as a major environmental toxin in that time period.¹²

One of the first, clear-cut medical descriptions of lead colic was noted by the 7th century Byzantine physician Paul of Aegina.¹³ In the Middle Ages, lead, arsenic, and mercury were all employed in the Western pharmacopeia and were the subject of study and misadventure by generations of alchemists. But above and beyond that, the appreciation of novel metals and alloys, and new ways of refining others, brought about the introduction of greater risks and even entirely new hazards to miners and metal workers.⁷ The first publication devoted entirely to the subject of occupational health was Ullrich Ellenbog's fittingly titled, seven-page pamphlet, *On the Poisonous Wicked Fumes and Smokes of Metals (Von den giftigen besen Tempffen und Reuchen der Metal)*.¹⁴ First printed in 1524, it was originally written in 1473 and warns the metal worker of the health hazards of metal, coal, and acid fumes.

Between 1500 and 1650, an increasing number of writers began to address the subject of miners' and metal workers' health. The first book-length treatment of the subject was that of Paracelsus (*Von der Bergsucht under anderen Bergkrankheiten*), written in 1533 but only first published posthumously in 1567.¹⁵ Agricola's *De Re Metallica* (1556), although mainly devoted to the technology of mining and smelting, contains a notable section on occupational health in Book VI. Agricola writes:

'It remains for me to speak of the ailments and accidents of miners, and of the methods by which we can guard against these, for we should always devote more care to maintaining our health, that we may freely perform our bodily functions, than to making profits. Of the illnesses, some affect the joints, others attack the lungs, some the eyes, and finally some are fatal to men.'¹⁶

In addition to Paracelsus and Agricola, during this period authors of note on occupational exposures include Pansa, Ursinus, and Stockhausen.⁷ Early technologic writing, for example, that of Ercker¹⁷ or Birunguccio,¹⁸ is also of interest in relation to likely occupational exposures. Some of the medical writing is straightforward, describing hazards, such as asphyxia, that are clear cut and readily discernible in modern occupational terms. Other writing is terribly obscure (especially Paracelsus).¹⁵ Even Agricola, amidst his lucid descriptions of hazards such as stagnant air, falls from ladders, and cave-ins, warns that in some mines ('although in very few'), there are demons which can be put to flight by prayers and fasting.¹⁶

During this time, another technologic change in Europe that began to impact health was manifest in the environmental rather than the occupational arena. This was the introduction of fossil coal (as opposed to wood, peat, or charcoal) as a fuel.¹⁹ At first, this practice was limited to Britain, with a particularly important industrial application in firing lime kilns. As early as the 13th century, a commission had been established in London to investigate the problem of pollution from coal burning. In 1306, a proclamation was issued banning the practice, albeit to little effect.²⁰ After a brief plateau, the coal market (and with it coal mining) increased logarithmically during the 16th and 17th centuries in Britain.²²

Although fossil coal was employed in China for fuel long before its use in Europe, there has been no systematic review of the history of its use in China and its potential public health impact from an historical perspective. This parallels a general paucity of information on health impacts of early technologic innovations that originated in Asia, although the history of this technology as it pertains to chemistry and metal working is quite rich.²¹⁻²⁴

1650 TO 1800

In 1700, after some years of preparatory work on the subject, Bernadino Ramazzini published the first edition of his landmark treatise, *De Morbis Artificum* ('The Diseases of Artificers', usually translated in modern terms as 'The Diseases of Workers').²⁵ This work is remarkable for its innovations. First, in simply approaching the subject matter as a topic worthy of a complete treatise, rather than by narrowly focusing on a single occupational group or exposure, Ramazzini fundamentally changed the way in which all medical writing would subsequently address occupational illness and injury. Second, and no less importantly, Ramazzini explicitly put occupational risk factors on the agenda in terms of the medical differential diagnosis. In the preface to *De Morbis Artificum*, Ramazzini directly addresses the reader with the following, often cited (deservedly so) admonition:

'The divine Hippocrates informs us, that when a physician visits a patient, he ought to inquire into many things, by putting questions to the patients and bystanders . . . to which I would presume to add one interrogation more; namely, what trade he is of. But I find it very seldom minded in the common course of practice, or if the physician knows

it without asking he takes little notice of it. Though at the same time a just regard to that, would be of great service in facilitating a cure.²⁶

Ramazzini's text was divided into 42 chapters, although the number of occupations covered was even greater (for example, a single chapter covers oil pressers, tanners, lute-string makers, candle-makers and cheese-makers). Even this was not sufficiently comprehensive for the author. In 1713, he published a second edition of the work, adding to it a supplement of an additional 12 chapters to address occupations omitted from the original (including printers, carpenters, and sailors, among others).²⁷

The work practices that Ramazzini documents provide a fairly exhaustive summary of manufacturing technology as it existed in Europe at the turn of the 17th to 18th centuries, just before the advent of the Industrial Revolution that would, by century's end, begin to fundamentally transform the workplace and the risks it entailed. Indeed, there is very little 'recent' technologic innovation driving Ramazzini's observations. Most of the occupations he describes, even those that entail metallurgy and mining, employed materials and methods well established for at least several generations. Other work practices described are virtually unchanged since Roman times, for example, the hazards of fullers (cleaners of cloth). Ironically, one of the few novel syndromes related to an emerging industry was that of nicotine toxicity among tobacco workers, especially for those involved in tobacco grinding.²⁷

Although rapidly changing technology leading to novel illnesses is not a major factor in *De Morbis Artificum*, the work clearly reflects the impact on Ramazzini of the larger social, cultural, and political forces of his day. In broad historical terms, he was very much a product of the late Italian Renaissance. More specifically, he spent most of his career in Modena during the years leading up to the publication of the *De Morbis Artificum* under the patronage of the Ducal House of Este, one of the great liberal benefactors of the age.²⁷ This spirit imbues Ramazzini's work, which emphasizes the lot of the common worker with empathy and compassion on almost every page. Perhaps the most striking passage demonstrating Ramazzini's sociopolitical context is his chapter on the 'Diseases of Jews,' in which he ascribes these disease to the occupations into which the Jews were forced by the restrictions of the period. As odd as the chapter title strikes the modern reader, its actual content underscores Ramazzini's decidedly liberal approach to his subject.

It would be hard to overestimate the impact that Ramazzini's work had on the discipline of occupational medicine throughout the 18th century and well into the 19th. The work was translated from Latin into English within five years of its initial publication (1705); a new English edition in 1746 included the 1713 appendix.^{26,27} More important were two other 18th century annotated translations with significant additions by the translators, one in French (1777)²⁸ and one in German (1780–83).²⁹ The latter is particularly noteworthy, more than doubling Ramazzini's original text. Beyond these translations, Ramazzini was widely cited by his contemporaries and

the generations that followed. His most famous student was the great pathologist Morgagni, whose classic text, *The Seats and Causes of Diseases*, is not only meticulous in documenting the occupations of many of its cases, but also directly discusses possible work-related contributions to the pathology that Morgagni observed in several instances.³⁰

The key medical writers in the 18th century who addressed occupational subjects (although none with as all-encompassing a text) acknowledged their predecessor. One example is Tissot, whose text on the diseases of 'men of letters' was first published in 1768 and widely circulated.³¹ Ramazzini's work on occupational diseases was even the subject of several 18th century doctoral theses,^{32–34} the most well known of which was the work of a Swede, Nicholas Skragge.³⁵ Skragge wrote his thesis under the tutelage of Linneaus, whose lecture notes document that he gave considerable attention to Ramazzini.³⁶

Ramazzini's presence within 18th century occupational and environmental medicine is so dominant that it obscures another pivotal contribution of this time, John Evelyn's *Fumifugium; or, The inconvenience of the aer and smoak of London dissipated*.³⁷ Initially published in 1661, it is the first tract (26 pages only) specifically focused on air pollution and its potential dangers. Although Evelyn's dates (1620–1706) overlap almost entirely with those of Ramazzini (1633–1714), the two could not be further apart. Evelyn, neither a medical practitioner nor a scientist, was a Royalist, a great diarist of the age (as was his contemporary, Pepys), and a colorful polemicist. In *Fumifugium*, railing against the coal smoke polluters of his day, he writes:

'Whilst these are belching forth their sooty jaws, the City of London resembles the face of Mount Aetna, the Court of Vulcan, Stromboli, or the Suburbs of Hell than an Assembly of Rationale Creatures . . .'³⁷

Although it might be tempting to dismiss Evelyn as something of an Enlightenment crack-pot, *Fumifugium* is important in the history of air pollution specifically and environmental health generally. In this context, the unsigned, contemporary preface to a 1772 re-printing of the book is particularly relevant:

'Our Author [Evelyn] expresses himself with proper warmth and indignation against the absurd policy of allowing brewers, dyers, soap-boilers, and lime-burners to intermix their noisome works against the dwelling-houses in the city and suburbs; but since his time we have a great increase of glass-houses, foundries, and sugar-bakers, to add to the black catalogue; at the head of which must be placed the fire-engines of the water-works at London Bridge and York Buildings, which (while they are working) leave the astonished spectator at a loss to determine whether they do not tend to poison and destroy some of the inhabitants by their smoke and stanch than supply with their water.'³⁸

At the beginning of the 18th century, Evelyn stood nearly alone in addressing air pollution in any modern sense of the word.³⁹ By century's end, a series of discoveries had led to an understanding of the precise chemical composition of air. This, in turn, provided a new scientific basis to consider how the contents of air, on a chemical

basis, might act upon the body. The same chemical-analytic attention had not yet been given to water pollution, but was beginning to be applied to food contamination. For example, George Baker's classic ecologic analysis of the regional association between the practice of using lead in apple presses and the 'Devonshire colic' was combined with laboratory experiments demonstrating the lead content in various cider preparations.⁶ Throughout the second half of the 18th century, the potential for systematic application of scientific discoveries to industrial manufacturing was gaining increasing attention. The Diderot's *Encyclopedia*, subtitled an 'Analytical Dictionary of the Science, Arts, and Trades', published its first volume in 1751.⁴¹ The lavish illustrations of the *Encyclopedia*, detailing the mechanical state of the art in industry at the time, heralded the technologic transformations of manufacturing about to occur.

THE 19TH CENTURY

By 1800, 100 years after Ramazzini, the occupational and environmental health equation had been fundamentally altered. First, the Industrial Revolution was in full swing. Second, the French Revolution redefined the rights of the people, and, by extension, those of the worker. Third, medical research was beginning to link toxicology to pathophysiology in ways directly relevant to occupational and environmental as a scientific discipline.

Even after the first flush of the Industrial Revolution, technical innovation (chemical and mechanical) continued to remain a dominant force in occupational health and safety throughout the century. Far more than simply a series of manufacturing changes in the cotton textile industry,⁴² it was introducing both entirely novel exposures as well as increasing old exposures to new levels of intensity.⁴³ Some key examples of novel exposures introduced in this period linked to outbreaks of entirely new syndromes include: chlorine gas inhalation,⁴⁴ work in high barometric pressure environments,⁴⁵ the introduction of white phosphorus ('lucifer') matches,⁴⁶ carbon disulfide-based rubber vulcanization,⁴⁷ aniline and other synthetics in textile dyeing,⁴⁸ and, just at the end of the century, ionizing radiation in medical radiography.⁴⁹

One of the most important established exposures that was greatly magnified through new industrial processes was that of silica dust, especially through the introduction of steam power-driven grinding wheels.^{50,51} Lead is another prime example of a classic exposure with greatly increased exposure levels in the 19th century, particularly in the pottery, glass, and metal-working industries.⁵² Even zinc oxide exposure, which was trivial in 18th century brass manufacturing, burst on the scene with new methods of making the alloy, and with that new technology a novel occupational syndrome – metal fume fever.⁵³

During the 19th century, social forces came to bear on occupational health in important new ways. Despite the revolutionary tradition on the Continent (or perhaps in part because of it), occupational health had its clearest political manifestations in Great Britain, where it was part

of a larger hygienic movement tied closely to a broad agenda of social reform. The key hygienic document of the first half of the 19th century is the famous Chadwick *Report on the Sanitary Condition of the Labouring Population*.⁵⁴ It addresses specific occupational exposures only briefly, although they are included. To a greater extent, the governmental sanitary reports of John Simon underscore the extent to which occupational safety and health was very much on the public health agenda.⁵⁵ Even Florence Nightingale's *Notes on Nursing*, which she intentionally adapted for working men and women, addresses occupational health hazards in general terms.⁵⁶

The most important English language occupational text of the 19th century was that of Charles Thackrah, *The effects of the principal arts, trades, and professions, and of civic states and habits of living*. First published in 1831, Thackrah greatly expanded the work in a second edition in 1832.^{57,58} He was planning a third edition when he died of tuberculosis (most likely occupationally acquired) in 1833.⁵⁹ It is the first text to address the myriad occupational health risks brought about by the new technologies of the Industrial Revolution, especially the health of textile workers. This was a subject of particular interest to Thackrah because he practiced in Leeds, a textile factory center. Thackrah's work had an immediate influence on other hygienists of the period, especially in Great Britain⁶⁰ and in the US.^{61,62} It also had an impact on political reformers. Michael Sadler, rising to speak on pending social legislation in Parliament, is reported to have had a copy of Thackrah's book in his hand and to have quoted from it extensively.⁵⁹

Invoking occupational health as a motivation for more broadly protective legislation was not without precedent: one of the first pieces of child labor legislation in Britain (1778) was for chimney sweeps⁶³ among whom scrotal cancer had been reported by Percival Pott in 1775.⁶⁴ British legislative reforms of working conditions were introduced in a series of landmark statutes promulgated in the second half of the 19th century. As a part of these enabling acts, governmental medical positions as 'factory inspectors' were established. These positions, in turn, provided the training ground for several generations of physicians specializing in occupational disease.^{65,66}

In France, occupational medicine diverged from the discipline that was evolving in Great Britain. Industrial conditions differed between the two countries in significant ways. Although there were some relatively large manufacturing sectors (for example, textiles), production to a much greater degree than in Britain remained in smaller-scale workshops, especially in Paris.⁶⁷ Medicine in France was distinct as well, characterized by a greater emphasis on systematic analysis and characterization of pathophysiologic processes.¹ This was also manifest in occupational medicine.

Patissier in France played a role similar to Thackrah's in Britain. In 1822, Patissier wrote the first original French text on occupational medicine.⁶⁸ Often cited as an annotated translation of Ramazzini, it goes far beyond that. Patissier broke down occupational exposures into

classes of risk, categorized hierarchically consistent with French regulations. Most of the later French writers on occupational health in the 19th century followed Patisier's somewhat didactic schema. Another major text of the early 19th century, Tanquerel des Planches' *Lead Poisoning*, demonstrates even more strikingly the emerging new 'science' of occupational medicine in France during this period.⁶⁹ In more than 1000 pages, it meticulously details over 1200 cases of lead poisoning at the famous Charite Hospital. It remains to this day the largest case series of its kind.

The emerging science of toxicology, dominated by researchers ranging from Orfila⁷⁰ to Bernard,⁷¹ also had a major impact on occupational medicine in France. Indeed, the leading scientific journal of the 19th century for occupational medicine content was the toxicologically oriented *Annales d'Hygiene et de Medicine Legale*. Many of its key occupational articles were also reprinted as separate bound volumes, providing a major source of scholarship on the subject.

In the latter part of the 19th century, German occupational medicine became ascendant, particularly through a series of scientific and medical publications. Of these, the massive textbook of Hirt is the most noteworthy example.⁷² At the same time, the first workers compensation insurance schemes were coming into being, starting with the German 'Accident Insurance Law or Trades and Industry' of 1884.⁷³

Beyond Great Britain, France, and Germany, occupational medicine as a discipline had little presence in the 19th century. In the United States this was especially the case, although clinical reports and scholarly articles on the subject did appear sporadically.⁷⁴ Moreover, there was a subtle, but general decline in the field of occupational health as the century progressed, even in its former centers of strength in Great Britain and France. There were notable textbooks produced in this period, such as those by Aldridge⁷⁵ and by Proust (Marcel's father, who was one of the first to apply the term 'byssinosis' to illness in cotton textile workers),⁷⁶ but these are something of the exception proving the rule.

The explanation for this decline is not clear cut. Technologic innovation was still introducing new hazards and novel syndromes during this period (the association of aplastic anemia with benzene was first published in 1897, for example).⁷⁷ In part, the political climate may have been less conducive. Clearly, social reform was no longer at the forefront.

More importantly, however, occupational disease and, even more dramatically, 'environmental' illness were falling out of scientific favor among the very public health experts who had once touted these concepts. The reason may derive from germ theory and its role in preventive medicine. It became increasingly clear that the major epidemic diseases (acute and indolent), especially those that attacked the poor and working classes, were infectious in nature and attributable to specific, transmissible microorganisms. With these insights came a major paradigm shift which became known as the 'new' public health.

Diffuse concerns over sanitary conditions were replaced with a focused emphasis on controlling contagion or on the innate resistance or vulnerability of the potential host.^{39,78}

Although the discipline of occupational disease was overshadowed to the extent that it could not be illuminated by the new science of microbiology, environmental health concerns beyond bacterial pathogen and vector control were eclipsed almost entirely by the 19th century's end. Any discussion of air quality in terms of chemical or particulate pollution as a direct or proximate cause of disease was likely to be ignored as little more than miasmatic superstition. So too, water- and food-borne illness prevention was approached as if wholly accounted for by microbiological factors.

1900–1970

The 20th century began with a few positive signs of renewed vigor in the discipline of occupational medicine. The first meeting of the International Association for Labor Legislation, the forerunner of the ILO, took place in 1901.⁷³ In the UK, a major multi-authored, state-of-the-art textbook appeared in 1902, edited by Thomas Oliver (later to be knighted for his work in the field).⁷⁹

Workers' compensation legislation spread beyond Germany and Great Britain. During this time, agitation for worker protection and compensation for injury in the US was taking place within the context the larger progressive reform movement,^{80–82} as well as in response to greater labor militancy, particularly among mine workers.^{83–85} In 1909 the first state workers compensation law was passed in the United States.⁷³

Even environmental health, from the standpoint of industrial point-source air and water pollution, began to receive some renewed attention, albeit sparingly. In Britain, alkali works were known to be a major producer of air contaminants since early in the 19th century. Various frustrated attempts at control finally culminated in the Alkali Works Regulation Acts in 1906.⁷³ In Britain and the US as well, smokestack control began to be evaluated, although negative impacts on property were often emphasized over adverse human health effects.^{86,87}

Nonetheless, change was slow. Despite the modest advances noted above, occupational and environmental health was still dominated by the contagion-control agenda of the broader public health movement. In the US, the field was even further constrained by an emerging corporate influence, a history documented extensively in Christopher Sellers' scholarly work, *Hazards on the Job*.⁸⁸

The First World War over-turned the status quo in occupational and environmental medicine. The industrial expansion of armaments production demanded by modern warfare, particularly in the manufacture of munitions and airplanes, led to outbreaks of chemically related illness for which contagion control had no role.^{89,90} Governmental investigation and intervention led to revamping existing units or establishing new ones such as the US Public Health Service Bureau of Industrial Hygiene.^{73,88} Research into the

causes and prevention of ‘industrial fatigue,’ which was subsumed within the discipline of occupational health, was also born out of the same First World War driven needs.⁹¹

More dramatically, the introduction of chemical gas warfare on a mass scale put to rest completely any lingering dogmatic tenet that germs alone accounted for the only large-scale public health threat worth bothering with.^{44,92,93} Ironically, it was research on mines and caissons that provided a key underpinning for the British war gas effort through the work of JS Haldane.⁴⁵

In the years following the First World War, and particularly during the 1930s, renewed attention to occupational illness and injury was infused with a new political awareness. This coincided with the progressive labor movement of the period and drew from its growing strength. In the United States, the apotheosis of this revitalization was Alice Hamilton. Her work in occupational health began at Hull House and she continued to be socially and politically engaged throughout her long career.^{89,94,95} As with past practitioners, Hamilton’s occupational medicine concerns were driven both by old hazards made worse by new technology, such as silica spread by air-powered tools in quarries, and novel problems altogether, such as the outbreak of neurological disease among the workers in the new rayon industry (as with 19th century rubber workers, the disease was caused by carbon disulfide).⁸⁹

Dr Hamilton stands out in this period as a great figure, but she was not alone. In Britain, Thomas Legge stepped down from governmental appointment as the Senior Medical Inspector of Factories in protest over Britain reneging on an international agreement to control lead and took a job as an advisor to the Trade Union Congress (an equivalent of the CIO).⁹⁰ In Spain, a young industrial surgeon named Josep Trueta developed a new system for treating open limb trauma with closed casts. He went on to become a leading Republican military physician in the Spanish Civil War; his closed-cast technique went on to become standard practice for the care of war wounds, saving many lives.⁹⁶

The degree to which explicit occupational health concerns permeated the non-medical literature of the period is also indicative a wider recognition these problems. In the US, Theodore Dreiser’s *Tragic America*, a non-fiction critique of the Depression era, specifically catalogues a number of occupational illnesses, including asbestos-related lung disease.⁹⁷ In fiction, one of the short stories that first brought success to Albert Maltz, later a major Hollywood screenwriter, was an eerie tale featuring a worker dying of acute silicosis.⁹⁸ This was one of the first print notices of the Gauley Bridge disaster, later also treated in a proletarian novel.^{99,100}

Written in a slightly earlier period, but only published widely later, Franz Kafka’s stories of the bureaucratic apparatus were imbued with the first-hand experiences that he gained as a successful operative of the Workmen’s Accident Insurance Institute of the Kingdom of Bohemia.¹⁰¹ In the UK, too, non-medical writing also turned to matters of workplace safety and health. The most remarkable novelis-

tic example may be the following, from A.J. Cronin’s *The Citadel*:

‘He went through the literature on the subject. Its paucity astounded him. Few investigators seemed to have concerned themselves greatly with the pulmonary occupational disease. Zenker had introduced the high-sounding term, pneumokoniosis, embracing three forms of fibrosis of the lung due to dust inhalation. Anthracosis, of course, the black infiltration of the lung met with in coal miners had long been known and was held by Goldman and Trotter in England to be harmless. There were a few treatises on the prevalence of lung trouble in makers of millstones, particularly the French millstones, and in knife and axe grinders ... “grinder’s rot” ... and stone cutters. There was evidence, mostly conflicting, from South Africa upon ... gold miner’s phthisis, which was undoubtedly due to dust inhalation. It was recorded also that workers in flax and in cotton and grain shovelers were subject to chronic changes in the lungs. But beyond that, nothing.’¹⁰²

The Second World War and its immediate aftermath had an effect on occupational medicine, although not as transforming an event as the First World War. Certain sequelae are of note. Women entered the industrial workforce in large numbers, leading to renewed attention to their occupational health hazards¹⁰³ (although this subject had been of some concern since the 19th century).^{104–106} The forced exile of large numbers of physicians and biomedical researchers, which crippled medicine in Germany and Austria generally,¹⁰⁷ had its impact on the disciplines of occupational medicine and toxicology as well. Ludwig Teleky, for example, one of the leading figures in German occupational medicine, was forced to flee to the US.⁷³ Industrial health-related medical research did not cease in Germany, however, particularly in aerospace medicine, where it was directly incorporated into the war effort. The German human research program on low barometric pressure environments, carried out on concentration camp victims, led to several Nuremberg indictments.¹⁰⁸

As in the previous World War, chemical warfare research again was given high priority on both sides, driving toxicologic science to discoveries that would later be to the detriment of occupational health, most saliently through the development of organophosphates.⁹² Paralleling the legacy of chemical warfare research, the birth of the nuclear weapons industry was also to have long lasting health consequences for a new workforce. It would be difficult to argue, however, that this created significant change within the discipline of occupational medicine, with much of the professional oversight of this issue divested to a new specialization of ‘radiation safety.’ Nonetheless, the threat of atomic warfare, and the reality of ongoing, above-ground testing of nuclear weapons, did mean that air-borne pollution was once again destined to be on the public health agenda.

Even as the nuclear age was lending pressure to a reordering of public health priorities, other events supervened to accelerate this process. In Donora, Pennsylvania, from October 27th to 31st 1948, the US experienced its first air pollution disaster.^{39,109,110} Four years later, from the

5th to 9th of December 1952, a larger and even more deadly episode occurred in England, the so-called 'killer-fog' of London.¹¹¹

This was not the very first outbreak of such a crisis. In December of 1930, a similar event had taken place in the Meuse Valley in Belgium. The event was not ignored by scientists, on either side of the Atlantic.^{112,113} Yet data from the event were limited and subject to conflicting interpretation. Moreover, there was a tendency to dismiss the episode as something of an anomaly. For example, Philip Drinker of Harvard, in one of the first scholarly reviews of air pollution in the US scientific literature, wrote in 1939 that:

'Naturally, we want to know whether such an accident could occur in industrial America. Our stacks emit the same gases as did the Belgian, but fortunately, so meteorologists tell us, we have no districts in which there is even a reasonable chance of such a catastrophe taking place.'¹¹²

In the US, Donora did more than simply prove the weather man wrong. It established air pollution control as a newly recognized and critical need.³⁹ Since there were no personnel trained specifically in this area, the early work in the field fell to the discipline of occupational health, largely to engineers in industrial hygiene. By 1957, the US Public Health Service had organized a separate Air Pollution Division, which began to develop criteria documents to address specific pollutants and their potential control.¹¹⁰

In this period there was no matching regulatory movement in occupational safety and health promotion in the US. Not only worker's compensation, but exposure standard-setting, too, was also a matter of state-by-state control. The only national guidelines available were the threshold limit values of a non-governmental organization, the American Conference of Governmental Industrial Hygienists.⁸⁴

Nationally and internationally, this was a time of stagnation, if not retrenchment, in occupational medicine. The ILO, which had predated the League of Nations, joined with it, and then survived its demise, continued on with its work based in Geneva. The United Nations headquartered the World Health Organization there as well, but little effective collaboration emerged from this geographic proximity. In Great Britain, the long line of occupational medicine leaders stretching back to the 19th century hygienists and on down through Thomas Oliver and Thomas Legge appeared to have died off, although in 1955 Hunter did publish the first of what was to become many editions of a dominant text in the field.¹¹⁴ On the Continent, the picture was even bleaker, with the sole exception of Italy. There, the major institute for occupational health research, the Milan University Clinica del Lavoro, had survived the fascist period remarkably intact and its director, Emilio Vigliani, took a leadership role in rebuilding the discipline.¹¹⁵

Cold War politics were not conducive to occupational safety and health promotion. In the United States certainly, in the aftermath of the McCarthy witch-hunts, any collaboration between academics and organized labor would have been suspect, at best. Outside of academic circles,

occupational medicine practice was corporate based and dominated by the Industrial Medical Association (IMA), whose membership between 1948 and 1959 more than doubled to 4000.¹¹⁶ The IMA's presidents over this time included the medical directors of Caterpillar Tractor, Inland Steel, Ford Motor, and New England Telephone and Telegraph.¹¹⁶ This period underscores, once again, the particular responsiveness of this discipline to larger political and cultural forces.

The first major sign of the ice breaking was not in occupational medicine, but rather in environmental health, in this instance primarily in relation to water and soil, rather than air pollution. Rachel Carson's seminal *Silent Spring*, was published in 1962.¹¹⁷ Carson was explicitly concerned with emerging and novel manifestations of environmental damage resulting from a new technology: petrochemical synthetics, particularly chlorinated hydrocarbons. We look back on *Silent Spring* as a landmark publication, but its importance is not merely in retrospect. Immediately upon its release, its impact was widespread and powerful. Strong conservation organizations pre-dated *Silent Spring*, but their evolution into an environmental movement is difficult to imagine without it. The links between the environment, particularly non-human health effects, and traditional concerns of occupational disease were not straightforward to the general public, but were not lost on industry. Only recently has data emerged documenting the degree to which chemical manufacturers and their trade groups viewed with alarm the potential political and especially regulatory implications of Rachel Carson's work.¹¹⁸

The decade in the US that began with *Silent Spring* ended with the establishment of the Occupational Safety and Health Administration, the National Institute for Occupational Safety and Health, and the Environmental Protection Agency. These regulatory advances, made possible by series of enabling legislative acts, did not occur in a vacuum, culturally, politically, or scientifically.

RECENT HISTORY

As the preceding synopsis makes clear, the history of occupational and environmental medicine teaches us that this discipline has a long and complex past. Understanding that past, and the forces that have helped shape it, can better inform our understanding of the issues that face us going forward in an ever-changing world. It is not only convenient, but perhaps prudent as well, to use a cut-off of 1970 for an overview of the historical perspective in occupational and environmental medicine. Nonetheless, it is safe to assume that the interplay of technologic change and social forces continues to exert a substantial effect on the course of the discipline.

In the decades of the 1970s and 1980s, the United States assumed a critical leadership role internationally in key environmental areas such as removal of lead from gasoline, sulfur-containing coal emission reductions, and water pollution remediation. The regulatory evolution of occupational health protection in the US was less robust, although promulgation of a new OSHA lead standard in

the 1970s did represent a major advance. Paralleling these trends, environmental medicine has grown to take on an increasingly prominent role within the discipline, particularly in the US.

Over the past 40 years, multiple exposure-related outbreaks of occupational or environmental disease have occurred worldwide. Some of the most notable episodes include vinyl chloride-caused angiosarcoma of the liver, kepone-induced neuropathy, methyl mercury-related teratogenesis (Minimata disease), and dibromodichloropropane(DBCP)-induced male sterility. Although definitive historical assessments of these events have yet to be written, the importance of technologic and social factors is abundantly clear in the causes, identification, and struggle to control these outbreaks. The same confluence of forces is no less relevant to ongoing issues faced by occupational and environmental medicine.

ADDITIONAL RESOURCES

A complete history of occupational and environmental health is far beyond the limitations of a single chapter in a general text. There are, however, many additional resources that the interested reader can pursue in order to gain supplemental information.

In recent years, a number of excellent historical analyses addressing various aspects of occupational health have been published. These include *Hazards on the Job* (Sellers),⁸⁸ *Deadly Dust* (Rosner and Markowitz),¹¹⁹ *Hawk's Nest Incident* (Cherniack),⁹⁹ *The Bends* (Phillips),⁴⁵ *Workers' Health, and Workers' Democracy: The Western Miners' Struggle, 1891–1925* (Derickson),⁸⁵ and *Occupation and Disease* (Denbe).¹²⁰ In addition to these works, there are noteworthy earlier histories. The two most important books that helped define the field of occupational health history are Rosen's *The History of Miners' Diseases* (1943)⁷ and Teleky's *Factory and Mine Hygiene* (1948).⁷³ In the 1950s, the scholarly work of Meiklejohn was also groundbreaking.^{59,66,121} From a somewhat later period, noteworthy works with considerable historical material include *Death on the Job* (Berman)⁸⁴ and *Expendable Americans* (Brodeur).¹²²

In terms of 20th century memoirs by occupational medicine practitioners, the most important is Alice Hamilton's *Exploring the Dangerous Trades*⁸⁹ (and of related autobiographical interest, Sicherman's *Alice Hamilton: A Life in Letters*).⁹⁵ Another American occupational health memoir of the same period is that of McCord, *A Blind Hog's Acorns*.¹²³

Some of the key library resources in occupational and environmental medicine also should be noted. The greatest single focused collection in the field of occupational medicine was undoubtedly that of Alfred Whittaker, which was later acquired by the Blocker History of Medicine Collections at the University of Texas, Galveston.¹²⁴ This collection includes the only extant copy of Ellenbog's *On the Poisonous Wicked Fumes and Smokes of Metals* (the earliest printed work in occupational medicine).¹⁴ Another small, but important collection in the history of occupational medicine was donated by Robert Legge to the University of California San Francisco.

Occupational health titles are well represented in most of the great medical history collections, although some are particularly noteworthy in this regard, in particular that of the Wellcome Medical Trust (London). In addition to a large number of important printed items, it also holds other material, including the occupational medicine archives of Donald Hunter. The mining collection of Herbert Hoover, housed at Claremont College, contains a number of rare items especially relevant to mining safety and health.¹²⁵ A major resource on microfilm is available through the Goldsmiths'-Kress Library of Economic Literature, which reproduces a 60,000 document collection held at the University of London and Harvard University and includes many items relevant to occupational history prior to 1850.¹²⁶ Finally, the medical bibliography of Garrison and Morton provides an excellent citation listing of many of the key texts (including journal articles) that constitute landmarks in the history of the discipline.¹²⁷

Chapter 3

Approach to the Patient

Mark R Cullen, Linda Rosenstock

As noted in the Introduction, OEM includes both clinical and public health aspects. In this chapter, principles of clinical practice are explored that distinguish the field from the core disciplines of clinical medicine – internal medicine, orthopedics, dermatology, neurology, etc – with which the reader may be more familiar.

One very obvious distinction is that clinical OEM includes two very different components. The bread and butter of the field has come to be known as ‘primary care’ occupational medicine (there is no counterpart on the environmental side) and includes activities that have existed, primarily within heavy industry, long before they were glamorized by this designation or became the subject of scientific scrutiny. Primary care components include, among other things, the conduct of preplacement physical examinations; care of minor injuries and immediately recognized adverse effects of over-exposure in the workplace; return to work examinations and medical screening. Historically these services were deemed sufficiently straightforward that any practitioner of medicine would be qualified to perform them without additional or specific OEM training. Changes in public perception, regulations, rapidly advancing knowledge and legal/economic considerations have rendered each aspect worthy of formal training, now incorporated into the residency requirements for specialty training in OEM in the US.

PRIMARY CARE OCCUPATIONAL MEDICINE

Preplacement evaluation

Preplacement evaluation has superseded the previous construct of pre-employment examination because of societal discrimination concerns; in the US and many other countries, individuals may not be assessed medically prior to being offered provisional employment as a matter of law. Once a job offer has been made, an exam may be conducted – and for jobs entailing any substantial risks undoubtedly should – to determine that the employee is physically and mentally qualified to perform the essential functions of the job safely. The legal aspects of this are discussed in Chapter 57.3. From a medical perspective, the examination must be tailored to the specific physical requirements and hazards of the job; general considerations, such as pre-existing health conditions or disabilities, are irrelevant except insofar as they would interfere with the job. For this reason, primary care occupational medicine practice requires extensive knowledge about the work setting and job requirements for

each position for which any exam may be performed. This knowledge must be sufficiently detailed to address any challenge that an employee has been discriminated against for any reason other than ability to perform the essentials of the job. While it is perfectly acceptable for the examiner – who does not enjoy a traditional doctor–patient relationship with such individuals – to inquire about or evaluate other health issues or behaviors (about which there may be concern from a preventive health perspective) he or she may do so only insofar as three things are borne in mind: such investigations must be voluntary, and the employee aware of that; the information must be maintained confidentially and not used to make employment decisions; and similar investigations must be requested of all new employees, irrespective of the positions for which they have been hired (including managers!).

Management of minor injuries and responses to work hazards

The routine management of minor injuries and acute responses to hazards at work falls into the purview of outpatient emergency medicine or surgery, and is beyond the scope of this text. However, as with preplacement, there are important occupational health components.

First, it is crucial that the underlying causes of the illness or injury be investigated in order to prevent further injuries from occurring. This may or may not be the responsibility of the primary care provider per se, but it is her or his obligation to make sure that all available information from the evaluation relevant to the event is provided to those at the workplace or company who are responsible.

Second, since most employers are now eager to limit lost work time and generally prefer early return to work, even if in restricted roles, the provider must be cognizant of the demands of the patient’s job, to determine whether or not the injury or illness precludes it, unless there are overarching medical reasons for lost time such as the need for hospitalization, work-limiting medications or bedrest. Pressures from employee or his/her supervisor for premature or inappropriate return to work must be resisted, as must the temptation to prescribe time off for convenience or social reasons. Close communication with both the employee and the manager are essential in every case.

Evaluation for return to work

Evaluation for return to work is an extension of the above activities, and requires review of medical reports regarding

any disabling illness – work related or otherwise – and then reiterating the preplacement approach in light of the new information. Even more crucially in this context, information without direct bearing on the patient's specific job is not relevant, and must not be communicated in any way to the employer.

Medical screening

Finally there is medical screening. This activity involves the collection of information from the patient – it may be a questionnaire, a hearing test, a blood test etc – to assess either level of exposure to a hazard or a possible preclinical health effect. The primary purpose is to protect the individual worker, although results are often scrutinized for other purposes, such as part of a surveillance program to prevent adverse workplace effects more generally (discussed more fully in Chapter 4.3). The first level of interpretation, however, pertains to the wellbeing of the individual tested. In this way, results may demonstrate an over-exposure or a work-connected effect. In either case the practitioner is obliged to inform the worker explicitly of that fact, and assure appropriate response such as reduction of exposure, removal, compensation and/or treatments as necessary. Often, however, abnormalities detected on screening exams are not job related in origin, nor directly affect the ability of someone already doing the job to continue doing it (although occasionally they might, and in that situation must be addressed). When non-work connected abnormalities are suspected, two things become essential: the provider must inform the employee of the abnormal finding and her/his opinion regarding its origins, and the provider must share responsibility that the findings are appropriately followed up.

TERTIARY CARE OCCUPATIONAL AND ENVIRONMENTAL MEDICINE

Unfortunately, despite all of the preventive aspects of those charged with making the workplace and outside environment free of excess hazard, some adverse consequences of exposure continue to occur; many more are suspected. Evaluation of such patients constitutes the 'tertiary' aspect of OEM practice, one that prior to a few decades ago could not be said to exist in organized form in the US or most other parts of the world. It is to that aspect that the rest of this chapter is devoted.

Patients, physicians, and third parties typically prompt diagnostic consultation with an OEM specialist for one of four reasons:

1. the patient (or referring party) suspects that symptoms, signs, or laboratory abnormalities may be due to some environmental or occupational factor;
2. a disorder has been diagnosed where the cause may not be evident: the question arises as to whether it may be due to an environmental or occupational factor;
3. exposure to a suspected harmful agent has raised concern that early manifestations of disease may be

present or that the patient may be at high risk for subsequent occurrence; and

4. assessment of disability and/or potential for work rehabilitation.

In the sections that follow we will concern ourselves with the first three scenarios; assessment of impairment and disability is the subject of Chapter 8.

CLINICAL EVALUATIONS IN OEM

In addition to the usual methods of clinical diagnosis, three tools are special to OEM practice: the occupational and environmental history, the environmental evaluation, and the use of specialized tests to establish causal associations. Despite variations in applicability, the principles are common to every case.

Occupational and environmental history and evaluation

The occupational health history is fundamental to the assessment of the work-relatedness of health problems; as such, even in abbreviated form it should become a routine component of every comprehensive health history, not exclusive to OEM referral care.^{1,2} The environmental history complements the occupational health history by probing for the presence of non-occupational factors and their possible role in the disease process.

The occupational and environmental history has multiple purposes.

1. *To increase awareness of occupational and environmental factors.* It is more the exception than the rule that clues to the potential role of these factors emerge from the physical examination or routine laboratory testing. Unless this history is specifically elicited or otherwise offered by the patient, the opportunity will be lost to consider occupationally and environmentally related disease or risk.
2. *To make accurate medical diagnoses.* Failure to obtain the history in the setting where occupational and environmental factors have played a role inevitably results in at least a partial misdiagnosis. For example, if fatty liver disease is correctly diagnosed but is attributed to alcohol over-consumption when solvent exposures have also played a role, then the diagnosis of alcoholic fatty liver disease is not correct and important treatment interventions may be overlooked.
3. *To prevent the development of occupational and environmental disease.* By using the occupational and environmental health history as a screening tool, identification of exposures to potentially hazardous factors can result in the reduction or elimination of these exposures. This factor may be beneficial in the setting where exposures cause diseases of long latency, as well as those responsible for acute and recurrent conditions. Identifying past asbestos exposure, for example, may render counseling about smoking cessation more effective when this counseling is

provided in the setting of education about the synergistic effect of exposure to both carcinogens. In the case of exposures causing acute conditions – for example, pulmonary allergens – interventions to decrease exposure are likely to reduce the person's risk of subsequently developing hypersensitivity.

4. *To prevent the aggravation of underlying medical conditions by occupational and environmental factors.* The smoker with chronic bronchitis who is exposed to respiratory irritants in the workplace will, regardless of effectiveness of smoking cessation interventions, benefit by reducing his or her exposure to identified respiratory irritants. Similarly, in addition to optimizing glucose control in the individual with diabetes mellitus, avoidance of exposure to agents that may cause peripheral neuropathy is also an important intervention, because the individual predisposed to a peripheral neuropathy of any cause may be at increased risk for damage from environmental peripheral neurotoxins.
5. *To identify potential workplace hazards.* In addition to using the occupational and environmental history as a screening tool to identify and ameliorate the risk of exposure to hazards, the history can help identify factors that would otherwise not be suspected as injurious. For example, the worker who presents with a persistent nocturnal cough may have been exposed to an irritating or sensitizing agent, initiating bronchial hyper-responsiveness manifested as cough.
6. *To detect new associations between exposures and disease.* The field of occupational and environmental medicine is rapidly evolving. As more interest and attention are paid to environmentally induced illnesses, more is learned about the nature and extent of adverse effects of specific agents. Perhaps no other field offers the potential to uncover, through the evaluation of an individual patient, a previously unknown association between exposure and disease. Examples include adding to the list of now over 200 agents known to induce specific asthmatic responses, identifying new neurologic syndromes as chronic sequelae of past intoxications, and discovering new renal and hepatic toxins.
7. *To establish the basis of compensation for occupational and environmental disease.* Whether for workers' compensation for occupational disease or liability claims, the physician plays a key role in determining the likelihood that an environmental exposure has caused a given medical condition. The patient's history of exposure, its onset, intensity, and duration – sometimes alone or in conjunction with other available exposure information – is fundamental to this assessment.
8. *To establish rapport with patients.* This last benefit of the occupational and environmental health history in many ways is a secondary and unexpected bonus to the original objectives. In our experience, it is remarkable how often encouraging an otherwise taciturn person to describe the details of his or her job

facilitates a more relaxed and congenial medical evaluation. Demonstration of a physician's interest in activities fundamentally important to the patient can lessen anxieties attendant with first time physician-patient encounters.

Components of the occupational and environmental history

The occupational and environmental history can be obtained in several ways. One approach is to integrate a series of key questions directly into the routine health history. Another approach is to incorporate a screening history with all new visits, selectively updating this procedure as indicated. In either approach, however, the occupational and environmental history has two main components: the employment and exposure history and the occupationally and environmentally related health history. The first component contains information about current and past jobs as well as non-occupational environmental exposures. The health history component uses questions to elicit information about health problems and symptoms in relation to specific exposures and work settings, and about the existence of symptoms or illnesses in coworkers, household members, or community residents.

A sample history form that can be self-administered and maintained as part of the patient's database is shown in Figure 3.1. This form can serve as a screening tool; clinical judgment will determine when it is appropriate to take a more comprehensive history. Because in some clinical settings even this shortened form may not be readily administered, we are often asked what few questions should be asked of all new patients. A survey of members of the United States Association of Occupational and Environmental Medicine Clinics (AOEC) found the following three questions essential.

1. Please describe your job.
2. Have you ever worked with any health hazard, such as asbestos, chemicals, noise, or repetitive motion?
3. Do you have any health problems that you believe may be related to work?

The following section describes the elements of the two core components of the occupational and environmental health history in greater detail, as would be appropriate to OEM tertiary evaluation.

Work and exposure history

This component of the occupational and environmental health history extends beyond what might be routinely obtained in the clinical setting. Nonetheless, the objectives of the work history are similar to many other aspects of social history, particularly those that include identifying in an individual risk factors that indicate the need for prevention or intervention strategies.

The following discussion is relevant to information about the current or most recent job or, in some instances, a previous job of concern regarding the problem under evaluation. For example, if a patient is being evaluated for

suspected occupational asthma, the key to a successful diagnosis is to focus on the job when the patient first began having symptoms. In addition to asking for the patient's job title (or occupation), it is important to ascertain the specific nature of the job. This information can be obtained by asking additional questions about the industry. For example, a painter in a shipyard is subject to different exposures from a painter in a residential setting. Hence, the key questions are: 'What product or service does your employer make or produce?' and 'What aspect do you do on your job?' If the job is already familiar to the physician, then the question may be modified; for example, one may ask 'Is there anything you do now that is different from past jobs where you've been an electrician?'

The screening history inquires about the use of personal protective equipment (PPE). Although the provision of good protective equipment should mitigate risks of exposure, it must be kept in mind that those who use protective equipment are often at increased risk for work-related illnesses. The protective equipment serves as a clue that hazardous materials are present, and exposure at least possible. For this reason a candid appraisal of the equipment's actual use is invaluable as well.

The patient should be asked directly about potentially hazardous exposures that are present at work, whether of biologic, chemical, physical, or psychologic origin. A

checklist approach (as illustrated in Fig. 3.2) can be used to direct this inquiry. If a patient gives a positive response within any category, then further information can be obtained about specific exposures. For an overview of the patient's occupational and environmental history and for an evaluation of those conditions of long latency, such as cancer or pneumoconiosis, the history must include information about past jobs and exposures and potential important exposures in the non-work environment. An abbreviated history of all employment is provided in the sample history form (Fig. 3.1). Sometimes an individual omits information about employment during military service; therefore, this information, which may indicate that the individual was subject to other toxic exposures, should be specifically sought.

Many workers are well informed about specific exposures. In other instances, however, the exposure history requires further investigation to identify specific constituents of products and exposure levels. Consideration of the exposure dose is important in identifying, preventing, and managing occupational diseases; the history is an important first step in establishing the level of exposure. Although it is by no means precise, the patient's assessment of relative levels of exposure (i.e., low, medium, high) for specific agents can be valuable. One way of eliciting this information is shown in Figure 3.2, a portion of a comprehensive occupational and environmental history that can also be self-administered. Here, the patient is given an opportunity to report potential exposure to various widely prevalent hazards that appear or have appeared in the current or any past job. For physical

List of exposures	A. Current or most recent job (paid work)				B. Any previous job				C. Any activity outside paid work			
	Yes	If yes check one			Yes	If yes check one			Yes	If yes check one		
		Low	Med	High		Low	Med	High		Low	Med	High
Example Asbestos	✓	✓			✓			✓				
1. Fumes and dust												
Asbestos												
Plastic fumes												
Welding fumes												
Fumes (other)												
Glass (e.g. fiberglass)												
Silica (e.g. sand)												
Plaster												
Wood (specify type(s) if known: _____)												
Other (specify if known: _____)												
2. Elements and metals												
Aluminum												
Arsenic												
Cadmium												
Chromium												
Copper												
Lead												
Mercury												
Nickel												
Zinc												
Other (specify if known: _____)

	A. Current or most recent job (paid work)				B. Any previous job				C. Any activity outside paid work			
List of exposures	Yes	If yes check one Low Med High			Yes	If yes check one Low Med High			Yes	If yes check one Low Med High		
3. Solvents												
Alcohols (e.g. methyl, wood)												
Benzene												
Toluene, xylene, naphtha												
Paint, varnish, degreasers												
Tri-, tetrachloroethylene												
Other (specify if known: _____)												
4. Other chemicals												
Acids												
Alkali (caustics)												
Ammonia												
Herbicides and pesticides												
Dyes												

Figure 3.2 (cont'd): Sample of detailed self-report form for specific occupational and environmental exposures.

hazards it is often best to have the patient compare levels to common comparisons, such as 'loud as a subway'. Sometimes acting out an activity or task may be useful for demonstrating potential risk, especially for musculoskeletal effects.

As noted, the nature and use of protective equipment may provide an additional clue about levels of exposure, as would information about the general cleanliness of the workplace and the adequacy of ventilation. Finally, for some exposures that have acute as well as chronic effects, such as organic solvents, the description of immediate symptoms in relation to exposure – e.g., acute intoxication or headache – may provide evidence that excessive exposure levels have been encountered; the absence of these symptoms would suggest more modest exposure levels.

Environmental history

The non-occupational environment, while generally less hazardous in terms of the number and dose of chemical, physical, and biologic hazards, is paradoxically more complex to query. Often the patient has a particular focus or concern, and detailed attention can be directed to that,

for example the consequence of a leaky furnace, or the installation of a new carpet in the home. However, in every OEM referral examination at least a survey of possible environmental contaminants should be made, covering at least a question about outdoor air, environment inside the home (e.g. heat sources, chemical use) hobbies and avocations, sources of toxic pollution in the community, drinking water and diet. Occasionally, patients are referred with cryptogenic signs or symptoms, such as recurrent hives or respiratory complaint, or an elevated body burden of some heavy metal, the source of which is obscure, rendering it necessary to probe all of these aspects in some detail.

The home is the source of most referrals and concerns. Wells may be contaminated with organic hydrocarbons, metals or pesticides. Exposure occurs during consumption or, in the case of volatile chemicals, from the air during bathing. Most people will be unaware of whether there are contaminants in their water, unless these have already been tested for a reason. From a history-taking perspective, the major issue is whether they use well or city water; if the former, whether there is reason to suspect contamination. Rarely the water will have an odor or abnormal appearance, but it's not a very discriminating question. An unre-

lated water concern is old plumbing, from which lead and copper may leech after water stands overnight.

Boilers, furnaces, fireplaces and stoves provide opportunities for carbon monoxide, gas, particles and fuel exhaust exposure if flues or other devices leak or are clogged. Carpets, a source of irritation when installed, harbor molds and mildew (as do ceiling and wall board) after exposure to moisture. Furnishings, computers, pets, cleaning materials or services and other merchandise may introduce chemical hazards, allergens or, occasionally, infectious risks. Radon gas occurs primarily in homes built on hard rock, but can only be evaluated by measurement – there are no other clues to be gleaned from the patient. Many, if not all of these hazards are enhanced by indoor tobacco use.

Questions about outdoor sources of contamination should focus on recognized point sources, since major air pollutants such as ozone and sulfate and oxides of nitrogen are more regionally distributed: the patient is unlikely to know what levels are, though these can be obtained from regulatory authorities. Of more usual concern are local polluters, which may include neighbors using chemicals on lawns and trees that patients find noxious or disconcerting.

Many people engage in hobbies or avocations at home or in their garage, involving hazardous risks. These should be specifically queried, since they may involve exposures to very dangerous materials at levels at or even above those seen in comparable occupations, usually without appropriate controls. Examples may include gardening, painting cars, sanding (lead) paints from old furniture, building models with glues and solvents, home renovations or virtually anything which for another patient would be an occupation. Not rarely, people do at home something similar to their work, so that this line of questioning is crucial for screening all patients.

Finally, it is worth asking every patient at least briefly about their diet. The most important issues revolve around imported or unusual foods, a heavy portion of the diet coming from a single source (e.g. swordfish, an important source of environmental mercury exposure) or the use of non-commercially sold dietary supplements. Cookware of distant origin may also be a source of metal or other hazards. These factors are discussed at length in Chapter 53.

Health in relation to work and environment

The traditional part of the health history, including the chief complaint and review of systems, needs to be appropriately expanded to assess a possible relationship between occupational and environmental exposures and health problems. In each of the chapters in Section 3 of this text, specific questions pertinent to disorders under discussion are highlighted. But a few questions should be asked of all patients; others are specific to particular conditions. If nothing else, patients should be asked whether they feel their health problems are occupationally or environmentally related. In many instances, the first suspicion about an occupational or environmental disorder arises from the patient's concern about the effects of an exposure.

Although this suspicion may well prove to be unfounded, such concerns should always be taken seriously.

The presence of similar symptoms or complaints among coworkers or others exposed may be an important clue. Particularly for agents acting as direct toxins (see Chapters 1 and 5), the presence of symptoms among others similarly exposed may indicate that a common exposure is responsible and that the exposure levels are generally above typical 'thresholds'. Even for substances producing sensitization, such as chemical asthmagens, finding other persons in the workplace with similar symptoms may help identify the offending agent. The report of the presence or absence of symptoms in coworkers or others in an ostensibly contaminated environment should, however, be interpreted with caution. Sometimes an exposure affects only a single person, due to unique opportunities for exposure, an idiosyncratic reaction, or differing host susceptibilities. Conversely, 'epidemics' may seem to be occurring where common complaints are exhibited, whose causes turn out to be quite unrelated.

An important component of this part of the history, particularly for symptoms reflecting acute and recurrent conditions such as dermatitis or asthma, is the relationship between symptoms and time of work shifts or specific exposures. In the occupational setting, patients should be asked whether anything different at work preceded the onset of their symptoms, such as handling a new task, new product, or new job assignment. Patterns of symptoms in relation to time at work may provide helpful hints to both the diagnosis and the etiologic agent. Several patterns are described below; these patterns may occur alone or in combination in an individual patient. Inquiry about timing of symptoms in relation to non-workplace environmental exposure is essentially no different from inquiry about workplace exposures, and questioning should proceed along the general lines described below.

Change in symptoms during the work day

For a number of substances that induce their effect as direct acting toxins, such as solvents or non-specific dusts and respiratory irritants, the patient may arrive at work free of symptoms only to experience their onset in a predictable fashion after arriving at work. A person with building-related illness (Chapter 50), for example, may report the onset of headache and dizziness within 1 to 2 hours after arriving at work; abatement of these symptoms occurs within a few hours after leaving work. For agents causing immediate hypersensitization responses, such as flour in bakers sensitized to it, the patient often describes the onset of symptoms consistent with asthma (whether exhibited as cough, chest tightness, shortness of breath, or wheeze) within minutes of exposure. Common upper respiratory and mucosal symptoms, including coryza, eye discomfort, and itching, precede or occur concurrently.

Symptoms may not occur similarly on all work days, and they may vary depending on the level of exposure (e.g., when ventilation is on or off, climatic conditions,

specific job responsibilities) and other host factors (e.g., extent of recent exposure, medication use).

Change in symptoms over the work week

For several agents, of which cotton dust exposure is the classic example, there may be a higher level of symptom intensity on first returning to work after several days away ('Monday morning fever'), although symptoms (and concomitant pulmonary function decline) may worsen gradually as the week passes. In some instances, symptoms may be apparent only at the beginning of the work week. In metal fume fever, for example, the symptoms of this flu-like illness are most likely to occur on a Monday or Tuesday, with the individual exhibiting loss of the tolerance acquired during the previous work week. On the other hand, workers exposed to nitrates may get headaches both in the beginning of the work week and on weekends. Weekend flare-ups are associated with a withdrawal syndrome from these potent vasodilators, with associated vasospastic coronary or cerebral events occurring most commonly on weekends.

Change in symptoms on weekends and on vacations

A number of work-related syndromes result from exposures that have immediate or early effects, such that associated symptoms resolve within hours or days and occasionally with longer periods away from work. The effects of overexposure to solvents are examples of this type of temporal change. Because some solvents have longer half-lives than others, it may take days for the acute effects of solvent intoxication (characterized by headaches, lightheadedness, dyspepsia, and irritability) to resolve. For individuals who are chronically exposed to these agents, these effects may persist longer but should gradually resolve unless permanent sequelae, such as chronic encephalopathy, have supervened.

Trials of removal of the individual to assess the effect of withdrawal from exposure have an important diagnostic role in OEM. Examples include: removing a worker because of exposure to potential hepatotoxins to determine whether or not several weeks or months away from work may result in resolution of dysfunction; removing a student with respiratory symptoms from a problem classroom; removing a worker with carpal tunnel syndrome from exposure to repetitive motion; and removal of the patient with contact dermatitis from consumption of suspect water. Occupation-related trials must be conducted in close cooperation with employers, to prevent unwanted economic sequelae or misunderstanding about the reason for work absence (see Chapter 9).

Onset of symptoms away from exposure

A few agents are known to have unique patterns of inducing effects in relation to time of exposure. Some occupational asthma-inducing agents, for example, cause as the most common pattern of sensitization a delayed reaction from 4 to 12 hours after exposure, often initially exhibited as nocturnal asthma. The diisocyanates (TDI, MDI, HDI)

and Western red cedar are two well-studied agents associated with this pattern, which is characteristic of exposure to low molecular weight compounds. Often, the patient presenting with new onset asthma from these causes describes first awareness of wheezing or cough on nights following days at work; over time, with the emergence of non-specific bronchial hyper-reactivity, this clear-cut association with time at work may be lost.

As mentioned earlier, some agents such as nitrates may not exert their effects until their levels are lowered, so that symptomatic vasoconstriction may occur on removal of the individual from exposure. Some solvents, notably trichloroethylene, may cause a reaction similar to that of the drug Antabuse; affected individuals experience a flushing response when consuming even modest amounts of ethanol, even hours after solvent exposure has ceased.

Other experiences with work-related events

The last component of the modified general health history is to inquire about previously diagnosed work-related injuries or environmental illnesses, including any experience with workers' compensation. In addition to completing the historical database, this information may be helpful in recognizing previous hazardous exposures and the patient's clinical and emotional response to these.

The validity of the occupational and environmental health history

As noted previously, the occupational and environmental health history can be obtained by using a self-reported questionnaire or by interview. In either case, the question of the accuracy of exposure information provided by the patient is often raised, particularly if the information is likely to be used in settings that may have adversarial connotations such as workers' compensation or litigation.

Several investigators have studied the reliability and validity of this part of the health history. In the occupational and environmental history, self-reported exposure information has been evaluated in comparison with other measures, including personnel records; outcome measures, such as vital status, chest x-ray studies, and cancer registries; and information obtained by interviews with individuals knowledgeable about workplace assessments. Studies have found varying degrees of association between self-reported information and data obtained from other sources.³ Results are nonetheless reassuring when the occupational and environmental history is the main or only source of exposure data.

Wherever possible, however, self-reported exposures should be supplemented by other information, discussed in more detail in the next section. The need for additional data about the nature and extent of specific exposures varies on a case by case basis. In practice, the information obtained directly from the patient often is sufficient to raise suspicion, but adequate for diagnosis only when corroborating information cannot be obtained after appropriate effort.

Strategies for further evaluating occupational and environmental exposure

Unfortunately for the practitioner, for many reasons the history by itself is insufficient for an accurate diagnosis. These reasons include: lack of specificity about the identity of hazards; inadequate information about exposure levels; recall biases (greater attention to exposures that were at the time bothersome or otherwise perceived as being harmful); and other biases, e.g., patients fearful of possible job loss may under-report exposures, whereas litigants may exaggerate the intensities of exposures and purported effects. For these reasons, an essential component of the work-up is obtaining additional exposure information whenever possible. This additional information serves several purposes: to learn the specific identity of chemical or physical hazards to which the patient has been exposed; to establish information about dose; and to corroborate or modify the information that has been obtained directly from the patient. This includes both environmental and prior medical information that may clarify perceptions or reports of the relationship between the two.

The section that follows is a summary of avenues that may be used to obtain environmental and related health information. Strategies for obtaining this information are variable, and issues about confidentiality must always be considered (see Chapter 9). A further discussion of some of these sources is provided in Chapter 4.1.

Prior medical records

These records tend to be accessible and obtainable without risk of any disclosure for the patient. Although these records may not further etiologic assessment, they can confirm the patient's complaints on previous occasions and provide objective measures of his or her previous physiologic status. This information can help corroborate or modify the history and may be useful in applying one of the cardinal principles of occupational and environmental diseases: the biologic plausibility inherent in the time between exposure and effects (see below).

Exposure records from an employer

Under current regulations in the United States and most other developed countries, employers are obligated to maintain material safety data sheets (MSDS) for each potentially hazardous material with which employees may come in contact. The employer must make this information available to the employee or his or her physician in a timely fashion, together with any available information about exposure doses (e.g., air sampling information, blood tests). Despite this, there remain numerous problems. The MSDS themselves are often of limited quality. Much potentially useful information is lacking, such as information on minor ingredients that may be responsible for important health effects, especially allergic ones. In addition, the health information is often presented uncritically and without adequate discussion, much as the way adverse effects are uncritically listed in the Physician's

Desk Reference. In fact, for many of these MSDS, the most useful information is the telephone number listed to call for additional help. Employers or others working directly for them (e.g., physicians) may be able to provide more useful information, including the results of past workplace assessments, although other biases may be at play in such informational requests.

Health and regulatory agencies

Often, a workplace or environmental hazard has been inspected by an agency with regulatory authority. The results are generally available to physicians and, if so, may be an excellent source of information. Nonetheless, one limitation is that workplace inspections are generally conducted by industrial hygiene or safety personnel for the sole purpose of ascertaining whether or not there has been adherence to various regulations; the regulations may not reflect the possible harm that can occur at levels lower than the 'acceptable limits.'

Unions and community groups

Although they are not in the same position as current or past employers, who have direct access to exposure information, many such organizations take environmental health issues seriously and have substantial amounts of information, often of good quality, that is relevant to their members or residents of a community. On the other hand, the role of adversarial relations among parties may slant or bias information from these sources (see Chapter 9).

Direct site visit

When the issue is a current or recent exposure, there is perhaps no more satisfactory way to evaluate the environment than onsite inspection. This practice offers the advantages of contacting employees at the site, relating the history to observable facts, and directly assessing exposure and dose. The opportunity to correlate illness with the work environment is one of the special advantages of clinicians who are based at the workplace. Lack of this capability puts the diagnostician at a considerable disadvantage. Whether he or she is based inside or outside the plant, however, the clinician must recognize that the direct assessment of exposures is a highly complex and specialized process, requiring assistance of an industrial hygienist or a comparably trained professional (see Chapter 4); not every relevant exposure possibility may be evident to the untrained eye.

DIAGNOSTIC DECISION MAKING

Specialized use of the laboratory

Clinicians without experience in OEM diagnosis and practice may imagine that the laboratory could be used to compensate for the difficulties in obtaining reliable information about exposure or putative effects. This is not surprising, given the remarkable progress of clinical toxicologists in quantifying xenobiotics and the burgeoning array of technical capabilities that now allow measurement

of many contaminants down to the level of parts per trillion in numerous body tissues. Unfortunately, at this time, the overall role of the laboratory in OEM remains limited. In this section, the role of the laboratory in tertiary OEM practice is described. Each of the organ system (Section 3) and exposure chapters (Section 4) in the text further details the role of the laboratory in the assessment of particular hazards and diseases.

Despite some overlap, laboratory tests can be conceptualized in one of three ways.

1. Tests that elucidate pathophysiology

These tests include almost all of the routine 'medical' tests, such as imaging studies, chemistry panels, and hemograms. Also included are tests that play more specific roles in OEM diagnosis, such as non-specific inhalational challenge tests (e.g., methacholine challenge test) or measurement of enzyme levels (e.g., cholinesterase or aminolevulinic acid dehydratase [ALA] test). The net effect of this kind of study is to clarify what is or is not wrong pathophysiologically with the patient. Some such studies, of course, may be invaluable for assessing causality, but the primary role is to evaluate effects, not exposures or causes.

2. Tests that elucidate or quantify exposures

Other tests may be performed to establish the presence of a suspected causal agent in an organ or body tissue. Such tests are often referred to as biologic monitoring because, in effect, they use the body as a sampling device to assess exposure. Examples include measurement of the whole blood lead level, which documents that lead at a given concentration is present in red cells, or polarizing light microscopy on a lung biopsy to quantify crystalline silica particles. These kinds of studies may lead to inferences about health effects, but they do not measure them, only exposures. Although there may be some rationale in using a measure of exposure as a surrogate for identifying 'cases' of disease (e.g., identifying an adult with a lead level over 40 g/dL as 'lead poisoned') for surveillance purposes, the identification of the toxin is not tantamount to demonstration of a causal health effect for clinical use.

3. Tests that directly assess the relationship between an exposure and an effect

A few tests are 'dynamic' in the sense that they inherently capture causal information. An example is determining the presence of a specific antibody to a sensitizing agent. The presence of the antibody in such a case confirms both that exposure has occurred and that it has generated an immunologic reaction (which may or may not prove to be related to a presenting symptom or sign!). Similarly, patch testing and specific inhalational challenge tests are types of tests that document that an exposure and sensitization have occurred and may even document the relation between the level of exposure and a specific health effect.

At times, a test of one of these three types may be used appropriately to establish information about another type. For example, zinc protoporphyrin (ZPP) in red cells, a

measure of lead effect in the blockade of the enzyme heme synthetase, is a test commonly used as a surrogate measure of lead exposure because of its dose-response characteristics. Similarly, while measurement of urine cadmium level is a good index of recent absorption in workers exposed to the metal, in another setting – long after exposure has ceased – it may serve as a good measure of the renal effect of cadmium. In individuals who have not had recent cadmium exposure but who have suffered impaired renal function, the affected kidney leaks stored cadmium, whereas the intact kidney will not. In this case, an apparent measure of an exposure is used to measure an effect.

Even when the logic for ordering a laboratory test is clear to the clinician, there remain several problems with the application of results to diagnosis.

1. Limitations inherent in the laboratory itself

The clinician must always be alert to the factors that limit the quality of any data that are returned from the laboratory. These include (1) the ability of the laboratory to detect a substance or an effect, (2) the reliability of the laboratory at measuring such substances, (3) the validity of results, (4) the precision of the results, and (5) the standardization of the results. Notably, for example, the indiscriminant use of hair analysis to detect heavy metals has undergone scrutiny; in all but a small number of research labs, hair analysis has been found wanting in almost every one of these dimensions.⁴

2. Strategies for obtaining tests

Although many tests in clinical medicine do not vary significantly according to the time they are obtained (e.g., chest x-ray studies), others can be interpreted only on the basis of careful planning of how and when samples are obtained (e.g., plasma triglycerides). In many clinical situations in OEM, the strategy for sampling is crucial to interpretation of results. For tests of effects, the timing must be planned to avoid either missing the effect or confounding one effect with another. An example of the first situation is the use of spirometry to detect bronchospasm; even an individual with severe occupational asthma may have normal spirometry if the test is not timed to coincide with an expected effect. On the other hand, an audiogram performed within several hours of noise exposure is likely to document the temporary effects of noise but is incapable of establishing baseline hearing function.

Failure to consider testing strategy may also limit the interpretation of tests that directly assess the relationship between exposure and effect. For example, it is now well recognized that early in the course of occupational asthma, sensitization to agents such as isocyanates may rapidly reverse after removal of the individual from exposure. Therefore, even in a previously sensitized individual, a specific challenge with the agent may fail to produce bronchospasm if that person has been away from the exposure for a period of time before testing.

3. Interpretation of normal and abnormal results

Laboratories commonly supplement reports with statements as to whether or not a result is 'normal'. By convention, the term 'normal' usually means that a test result falls within the range of results for 95% of the healthy population. For a few tests, other guidelines are used by convention, such as within 20% of the mean result of a reference group. In OEM, unlike general medical practice, laboratory test results need to be placed in their appropriate context. For example, a young worker exposed to a known respiratory tract toxin may have 'normal' lung function on spirometry, yet comparison with a previous value from the same individual documents that loss in function has occurred. The laboratory's interpretation in this case is falsely reassuring. Conversely, a lead battery worker may be identified by the laboratory as having an 'abnormal' whole blood lead level of 20 µg/dL. Although this level is indeed higher than that found in any general population, it is unlikely to reflect significant lead toxicity, nor is it an unexpected value in a well-controlled battery plant. Recognition that this level of exposure is higher than that seen in other adults may have some utility, but cannot be used as the basis for the diagnosis of lead poisoning.

Further, as with all tests, the likelihood that an individual with an abnormal test in fact has the disease under evaluation (positive predictive value) is influenced not only by the test's sensitivity (that those with disease will test positive) and specificity (that those without disease will test negative) but also by the prevalence of the disease in the specific population from which the individual comes. For example, a minimal finding of interstitial fibrosis on a chest radiograph in an asbestos-exposed worker is, in itself, more predictive of disease than is the same finding in someone who has not been exposed to a fibrogenic material (see further, below).

The available databases for diagnostic inference

Having completed the basic evaluation, including the history, environmental exposure assessment, physical examination, and basic laboratory evaluation, the information needs to be integrated to answer three central questions.

1. Given everything already known about the patient, is it plausible that he or she has a disease or health effect related to environmental exposure?
2. If it is plausible, how likely is it, based on the exposure assessment and clinical pattern?
3. Given the exposure assessment and clinical setting, how should various laboratory tests be interpreted? What further studies or tests offer the possibility of substantially altering the likelihood that any clinical abnormality(ies) is (are) related to the environmental exposure?

In this section, we address the task of identifying existing sources of information and establishing how these sources can be used to assist in arriving at a working diagnosis.

Many different types of resources are available to address questions about disease plausibility and likelihood. Most, but not all, rely on a review and assessment of the scientific literature related to the exposures and the health effects in question. The most important are as follows.

1. Exposure assessment databases

For a variety of reasons, it is often not possible to confirm directly the occurrence of an exposure of interest or to obtain a reliable estimate of dose. Fortunately, there are many available resources for translating historic information into at least semi-quantitative estimates about exposure and likely dose. Texts, including this one, often summarize the hazards associated with particular kinds of activities and the range of doses to which such workers are potentially exposed. Large surveys, such as the ones performed periodically by the National Institute for Occupational Safety and Health (NIOSH), allow determination of the jobs and industries where certain hazards are likely to be found.⁵ Scientific papers, often from the industrial hygiene literature, can frequently provide valuable summaries that may be relevant to a particular clinical problem. Such papers are easily searched using National Library of Medicine and related databases such as Medline or Toxline.

2. Epidemiologic databases

When there is some basis for estimating exposure and dose, epidemiologic studies often provide the most compelling data relating exposure to risk for disease. Epidemiologic studies can provide direct evidence that an exposure causes an effect in humans. Moreover, such studies often establish certain limits for biologic plausibility of an association between exposure and disease, such as the timing between exposure and emergence of increased disease risk. These kinds of data are often helpful in the quantitative assessment of individual risk. If individuals who do precisely the same activity have been studied, quantitative determination of risk is relatively straightforward. Even if the patient's exposure setting differs from groups that have been reported, one can often learn enough about the patient's exposure to fit him or her into the range of exposures that have been studied.

Access to epidemiologic studies is readily achieved by using available texts and computerized literature searches. Unfortunately, occupational epidemiology studies vary dramatically in quality and applicability to the patient under evaluation. Issues related to the quality of epidemiologic studies are discussed in Chapter 6. The relevance of epidemiologic studies to the patient at hand is no less important.

First, the exposure dose in the patient should be reasonably similar to the exposure dose of at least a portion of the study population. Study findings can be extrapolated to results at higher and lower doses, but this approach is not always valid biologically and requires complex scientific judgements (see Chapter 5).

Second, the population under study ideally should resemble the patient's demographic characteristics, such as age and gender. Unfortunately, most studies historically

have been limited to white males, so there is often little choice other than to use the data on white males and modify the interpretation as needed. Whether this is a meaningful limitation depends on the particular health effect and the likelihood that host susceptibility plays an important modifying role.

3. Toxicologic databases

Epidemiologic data are often inadequate alone for determining the likelihood that a patient's health problem can be related to an environmental exposure. Alone or in combination with epidemiologic data, the results of animal studies performed under experimental conditions may be helpful. One advantage of these studies is that they often provide very strong evidence of dose-related effects of hazards. Further, animal studies may provide information about certain laboratory findings, such as the presence of toxins in diseased organs, biochemical changes, and histopathology. Modern toxicologic studies of this kind are plentiful and are easily identified by computer searches of the scientific literature. Good summaries are often available as well in texts and in monographs such as the toxicologic profiles compiled by the United States Agency for Toxic Substances and Disease Registries located in Atlanta.⁶

Serious limitations of toxicologic studies include differences between species and routes of exposure. For example, gavage (tube feeding) differs greatly from the routes by which patients typically have been exposed. In addition, animal studies almost invariably depend on use of relatively high doses of single toxins, and invariably require extrapolation to be applicable to clinical situation. As with epidemiologic studies, such extrapolation sometimes requires complex scientific judgment. Additional limitations to the use of toxicologic studies for clinical purposes are identified in Chapter 5.

4. Clinical studies and case reports

Clinical reports and case studies, although of limited value for establishing cause and effect *per se*, often are exceptionally useful for clinicians in OEM. Compared with epidemiologic studies, very rich information is often provided regarding the actual characteristics of the patients being reported and the specific nature of their exposure and dose. Specific clinical information of importance may include the results of a wide array of tests and descriptions of the patterns of illness, clinical course, and responses to treatment. At their best, clinical case reports and studies may be sufficiently applicable to provide a rational basis for all subsequent steps in diagnosis and management. At their worst, clinical reports may create the illusion of a causal relationship between an exposure and an outcome that cannot be substantiated. Case reports relevant to an exposure, therefore, should be carefully reviewed, but strong weight should be given to them only if corroborating evidence (e.g., toxicologic or epidemiologic) is also available.

5. Clinical experience

Although direct clinical experience may create certain biases of perception because exposed individuals with prob-

lems are far more likely to have been seen than those without problems, relevant experience should be drawn upon whenever feasible. Specifically, when possible, physicians should consult those who may have previous experiences with patients like their own, such as physicians practicing in workplaces where relevant exposures are commonplace, or those caring for such workers. Such databases, while not 'scientific' in the usual sense of the term, have obvious relevance.

Quantitative clinical reasoning

Once the patient's health status has been evaluated, and the exposure history obtained and supplemented to the extent feasible, the task remains to establish a final diagnosis. In particular, it is necessary for the OEM practitioner to address the specific question regarding the suspect occupational and environmental cause. In most cases, despite every effort, this determination requires dealing with at least some uncertainty. Not only will the diagnosis often fail to be unequivocally established by information at hand, in many instances there is no single further test or source of information that could provide certainty even were patient safety, cost or practicality not at issue.

Going back to the principles outlined in Chapter 1, for many situations there are no discriminatory tests to resolve, for example, whether a bladder cancer was or was not caused by exposure to benzidine dye, or asthma by exposures in an aluminum potroom. For other situations, extensive quantitative data regarding former exposure might theoretically resolve the matter, or a test might in theory exist to assist, but the information or test cannot be obtained. Unfortunately, though in many domains of medicine such specific answers are not required – physicians treat such disease all the time without establishing their causes – this luxury does not extend to OEM where preventive and therapeutic efforts, as well as appropriate assignment of medicolegal benefits, require such a diagnosis. In this section we discuss the use of Bayesian reasoning to reach a diagnosis in the face of uncertainty. A fuller discussion of this subject can be found in various texts.^{7,8}

Whether they do it explicitly or not, all clinicians rely on Bayesian reasoning in everyday practice, when deciding that a fever in a young adult is most likely mono, or a rash in an elderly patient most likely a reaction to a medication – and which medication is the most likely culprit. The theory, based on Bayes theorem, is straightforward: the probability of any diagnosis being correct is the mathematical product of two probabilities. The first probability is the 'risk' for the patient (given his/her age, race, gender, background, the season, etc) getting such a disorder, sight unseen. This is referred to as the 'prior' probability, and refers to the frequency with which such a diagnosis occurs in the population from which the patient comes.

For example, the prior risk of an adolescent getting mono in a given year is very high – perhaps as high as 1 per 100 – based on incidence in that age group. Likewise, the risk of an elderly patient on antibiotics getting a skin

rash is also high, depending on the antibiotic. Contrarily, the risk of a young patient in otherwise good health getting tuberculosis in the US is very low – perhaps 1 per 100,000 – compared to the same person in South Africa, where the background rate is several orders of magnitude higher. Obviously, some knowledge of disease rates in the appropriate population is necessary for estimating this prior probability, but even in the absence of such detail, almost all practitioners should have enough experience to know what is common and what is rare. More detailed information comes from medical texts, periodicals like MMWR and descriptive epidemiologic studies. In occupational and environmental medicine practice, the sources may be the same, or knowledge is available from some of the sources of exposure information described earlier in this chapter.

The second factor in the calculation of the probability of each diagnostic consideration is the probability that some major finding – typically a physical sign or laboratory anomaly – would be expected in patients with that diagnosis. For example, 80–90% of all patients with mono have persistent fever. On the other hand, less than 1 in 10 with mono will be expected to be negative on the mono-spot test. Determining these ‘posterior’ probabilities depends on performing the most appropriate exams and/or tests for the major diagnostic possibilities dictated by knowledge of the patient’s (prior) risks. The sources for this information, at least for diseases of OEM concern, are discussed in Section 3 of this text in relation to each of the major disorders.

Once these two probabilities are estimated for each major diagnostic possibility, comparison should yield either a clear ‘winner’ – the most likely – or leave a small number, usually two, about equally possible. In the former instance, the work-up is essentially complete, unless one of the more remote possibilities has health consequences that mandate exclusion. For example, even if metastatic cancer is a very unlikely possibility for a young coal miner with diffuse nodules on chest x-ray (unless he/she had a melanoma removed the year before!), consideration of cancer might dictate additional tests to further exclude this possibility if only because of the harm to the patient of overlooking it. More important is the use of additional tests when there remain competing probabilities, as the following case examples illustrate.

The first example is a 60-year-old African-American male, a foundry worker who has been a ‘chipper-grinder’ – a job entailing the grinding of sand off metal castings – for 35 years. He complains of cough and shortness of breath and has a symmetric reticulo-nodular infiltrate on his x-ray (Fig. 3.3). The ILO grade of the infiltrate is 2/2 (see Chapter 19.1 for a discussion of the ILO rating system for x-rays). The complaint and the x-ray are compatible with silicosis, but also with sarcoidosis, chronic beryllium disease, disseminated tuberculosis and other rarer diseases. Using the approach suggested above, it is first important to learn roughly how likely a chipper-grinder of this era (1968–2002) would be to get silicosis, i.e., the prior probability of that diagnosis.

Figure 3.3: Abnormal chest x-ray for both hypothetical patients. The x-ray shows symmetric, bilateral reticulo-nodular opacities in the mid and upper lung zones, rated 2/2 by a B-reader using the ILO scale (see Chapter 19.1).

Based on review of the literature or, better yet, a call to the company or physicians caring for workers there, you learn that as many as 1 in 5 long-term workers have developed this common outcome of daily, historically uncontrolled exposure. Next, reviewing Chapter 19.9 of this text, you learn that his x-ray is typical of the disease, present in almost all cases, let’s say 90% for the calculation purposes. Applying Bayes theorem, his likelihood of having silicosis is proportional to:

$$0.2 \text{ (prior)} \times 0.9 \text{ (posterior)} = 0.18.$$

The absolute number is unimportant, only its value compared to other possibilities. Compare it, for example, with his risk for sarcoid, the next most likely consideration from a clinical perspective. Sarcoid has a prevalence in this patient’s ethnic group of about 1 per 1000. Even assuming the x-ray is seen in all such cases, the likelihood of sarcoid would be proportional to:

$$0.001 \text{ (prior)} \times 1.0 \text{ (posterior)} = 0.001.$$

Crudely estimating, silicosis is 180 times more likely than sarcoid in this case. For all of the other possibilities the prior would most likely be lower still, even though tuberculosis occurs more frequently in silica-exposed men than in the rest of the population. Although it makes sense to exclude tuberculosis because of the gravity if this were missed, the overwhelming likelihood is that this man has silicosis. Unless his illness takes an unexpected turn, no biopsy or further tests are easily justified, especially not for medicolegal reasons.

Now consider a second patient with the same complaint and the same x-ray from the same foundry. This second man, however, is only 35, and has worked in this environment only since 1995. For him, the prior probability of silicosis, by comparison to the previous case, is very low –

he has worked fewer years, all in the more modern period since environmental controls have been instituted (you learn using the approach above) and in a less exposed job category (other facts you could confirm). With silicosis far less likely a priori, his likelihood of having sarcoid, or even one of the rarer causes of this x-ray picture (Fig. 3.3) become greater by comparison. So likely, in fact, that additional tests, up to and including lung biopsy, would be justified to reach the correct answer, whereas in the first case the risk of such a test may exceed the risk of initially missing an alternative diagnosis (as might occur very rarely, of course).

Not every case is as clear as these, nor in every case is there an obvious test available to break 'ties'. Consider, for example, the elderly painter with heavy solvent exposure who develops depression, or mild dementia. There are numerous possibilities and no trivial test to distinguish chronic solvent intoxication. Another concern in many cases is the possibility of no disease at all. This must often be factored in as a possibility, when signs or laboratory findings are minimally deranged (not really a possibility in the previous examples). In such a case one calculates the probability of no disease in much the same way as a particular diagnosis, e.g., what is the (prior) probability that a 60-year-old foundryman is free of any respiratory disease? Having said that, and with full appreciation of the difficulty of providing estimates of many prior probabilities with great confidence, the overall approach is itself very robust, and OEM practitioners, whether in training or highly experienced, are well advised to make such estimates as explicitly as information allows, the more so the more complex and uncertain the case may be.

PATIENT MANAGEMENT

There are four conceptual stages in the management of patients suspected of occupational or environmental disease. Although actual treatment choices depend on the particular hazardous exposure, clinical disorder, and relevant social issues, the conceptual framework remains uniform.

The diagnostic period

In every case, there is a period of time from the first contact with the patient until the best possible working diagnosis can be achieved. Although this period may be as short as a single visit in cases of clear-cut exposure and a well-delineated physiologic response (or its absence), often this period spans days to weeks and occasionally even longer, during which relevant records of medical and exposure history are obtained, environments evaluated, and additional tests performed. Several important aspects of management should be kept in mind during this period.

1. Formulate the diagnostic plan at the outset. For reasons already given, it must be anticipated that many potentially knowable facts may remain unlearned. Therefore, at the outset, it is important to decide how the diagnostic process will proceed,

whether or not one succeeds in obtaining desired information. This is another way of saying that the patient cannot be held hostage to impediments in getting access to information.

2. Use the diagnostic period to the fullest. An advantage of small delays in achieving best clinical diagnosis is that it facilitates ascertainment of various social issues, such as the agendas of all parties and likelihood of reactions if certain choices are proposed (see Chapter 9).
3. Do not initiate management decisions until a sound working diagnosis is achieved. Although a few occupational and environmental illnesses are true medical emergencies, the vast majority are not. In fact, many diagnostic issues, such as the temporal relationship between physiologic responses and exposures or the measurement of biologic exposure dose, are best studied while a patient remains in an exposed situation. Further, given the ramifications of certain courses of action, such as removal of a worker from a job or the designation of a particular health problem as occupational, it is important not to take such steps prematurely when there is a reasonable likelihood that subsequent facts may alter diagnostic thinking. Although further exposure may seem on the surface to place a patient at unnecessary additional risk, it is important to place that risk in the context of exposures that have already occurred and the very real risk of taking mis-steps that may be harmful in themselves, especially if they are premature and wrong.
4. In certain circumstances, diagnosis itself depends on the individual's response to a therapeutic trial, such as whether or not the symptoms abate on removal of the individual from an environment. Although such trials are sometimes necessary or desirable, they must be conducted as trials, with the explicit understanding that the goal is to establish a diagnosis and not misconstrued as treatment based on a putative or tentative diagnosis. Only in this way can future confusion be avoided and, with it, the attendant social costs to the patient.

Formulation of treatment plans

Once the diagnosis has become sufficiently clear, treatment plans can be developed. Sometimes the choice is strongly dictated by clinical circumstances, as in cases of disabling chronic diseases. More often, however, there are alternatives. Although one choice or another may seem preferable from a strictly medical perspective, it cannot be presumed that this choice satisfies the needs of the patient, or that it is included among the options offered by the employer or other relevant circumstances. Whenever feasible and safe, it is ideal to consider alternative possibilities for the management of every case. On other occasions, though, medical realities dictate clearly one course of action, such as discontinuing exposure of a patient with heavy metal or pesticide poisoning when the documentation is clear-cut.

Establishing and communicating the therapeutic plan

However limited or diverse the options considered, the actual choice of a treatment plan cannot be made without discussion with all parties who must participate, first and most importantly the patient. The benefits, costs, and health risks associated with each option must be identified so the patient can make an intelligent decision based on all the facts, including social factors (see Chapter 9). If necessary, he or she should be encouraged to include a spouse or other family member who may be affected by the choice. Advice from other advocates, such as a social worker, union representative, or advisor, may be invaluable – especially when one choice or another may disrupt the individual's normal life activities, work, or income.

Once the patient has agreed to a plan, it is reasonable to communicate that plan to the other parties who must cooperate, especially in the occupational setting. In every case, the patient should be aware of the planned communication and it should be limited to issues that are within the purview of the doctor's relationship with non-medical parties. Once an approach has been selected, it is important that results of the evaluation be put in writing for the patient, his or her personal physician, and others who need to have this information. Dissemination of this information can often be best accomplished by a single letter, which is sent to everyone. Although this method may limit communication of certain private issues and require use of language not technically ideal for every reader, the use of a single letter reduces the likelihood of anyone misunderstanding what has been found and recommended.

Therapeutic follow-up

Whatever plan is chosen, clinical and non-clinical consequences that arise during the initiation of the plan may lead to reconsideration by patient, physician, or both. For example, the impact of altered life circumstances, such as joblessness, or homelessness in environmental cases, may provoke re-evaluation of options, however strongly they are indicated from a clinical perspective.

By planning visits for no grander purpose than a progress update and plan re-evaluation, the physician offers the most flexible and supportive milieu in which the patient can accommodate to changes demanded in the management of occupational and environmental health problems.

Where does the physician's responsibility end?

One of the most inescapable realities of modern OEM practice in most parts of the world, including the United States, is that many hazardous situations will be recognized about

which little can be done. Reasons include: limitations of resources available in the professional community, corporate sector, and governmental agencies; technical uncertainty about the solution; economic incentives to ignore or resist recognition of the problem or solution; inadequate regulatory, technical and administrative structures to resolve the matter; and last, but not least, widespread ignorance.

None of these factors should form the basis for physician apathy or reluctance to consider and act on the public health implications of a serious occupational or environmental disease or injury. At a minimum, the record should clearly indicate the physician's opinion that others may be at risk. The choice of strategy should be well documented in the patient's record. Finally, although various approaches may best be carried out verbally or informally, in the end it is important that the individuals who control the environment in question be formally notified that concern has been raised. This notification may come directly from the physician or, more often, indirectly through a government agency or their consultant. The physician's effort should be documented in writing, which is far more effective in motivating action than informal approaches.

Once these steps have been taken, the practitioner can and should return to the care and needs of the patient, whose OEM problems and their clinical and social sequelae may take months, often years, to resolve. This is the same timetable that public intervention may follow. Clinicians may choose early in the process of public health actions to turn responsibility over to others. Regardless, the often delayed but sometimes highly effective link between clinical evaluation and resultant greater public health good is one of the great satisfactions of OEM practice.

Chapter 4

Principles of Industrial Hygiene

4.1 Occupational Hygiene

Robert F Herrick, John M Dement

Occupational (industrial) hygiene is the health profession dedicated to the anticipation, recognition, evaluation and control of hazards in the workplace environment. The scope of interest includes chemical, physical and biologic hazards as well as ergonomic and human factors, that cause or contribute to impaired function, disease, disability, injury and discomfort resulting from work. As the profession grew up with the Industrial Revolution, it has been known as industrial hygiene, but the term occupational hygiene more accurately describes the field and the practitioner's range of activities. In fact, the term occupational hygiene is prevalent everywhere except in the United States. The term industrial/occupational hygiene is derived from the Greek Hygieia, the goddess of health and prevention, daughter of Asklepiose, god of medicine. Its roots trace back to Bernardino Ramazzini (1633–1714), considered the father of occupational medicine.

The modern history of occupational hygiene starts with the industrialization of the United States and western Europe. This process was chronicled by Theodore Hatch, who summarized the 'Major Accomplishments in Occupational Health in the Past Fifty Years' on the 50th anniversary of the Division of Occupational Health of the Public Health Service in 1964.¹ Hatch recounted that prior to the First World War (about 1914), societies were predominantly rural and based upon agriculture. Industrial processes were few, and conducted by manual labor. The only plastic available was celluloid, petroleum refining discarded most product as waste, and Henry Ford had just introduced the radical concept of a \$5 daily wage. This was the industrial world Alice Hamilton found when she began to trace health problems among immigrant families back to the workplace. Pioneers like Hamilton and Hatch identified important problems, but they also had the vision to develop interdisciplinary approaches to solve them.

Occupational hygienists share responsibility with physicians and other occupational health practitioners and researchers in the identification of adverse health effects associated with the workplace environment. The occupational hygienist focuses upon the factors that are potential causes of work-related conditions, providing information on workplace processes, and exposures to physical, chemical and biologic agents that result from those workplace processes and conditions. The evaluation of those hazards frequently includes measurements to identify and quantitate contaminants in the workplace, as well as measurements of physical factors such as noise, radiation, heat and ergonomic conditions. In the practice of

occupational hygiene, the evaluation of hazards leads to the selection and application of an appropriate exposure control strategy. These strategies include engineering controls, improvements in work practices and materials, and personal protective equipment to reduce workplace risks.

In addition to the occupational hygiene practice of hazard recognition, evaluation and control, research on exposures as potential causal factors for occupational disease advances the goal of promoting worker health and safety. Exposure assessment in epidemiologic research and hazard evaluation is a vital role for occupational hygienists. These assessments frequently involve current and past exposures, so occupational hygienists apply familiarity with workplace processes, controls, and exposure information in conjunction with the work histories of employees, to reconstruct exposures in retrospective epidemiologic studies and risk assessments.

Occupational hygienists integrate information and knowledge from disciplines including engineering, chemistry, physical science, toxicology and medicine. While occupational hygiene practitioners are usually trained in one of these disciplines, the majority have graduate degrees in occupational (industrial) hygiene, environmental health, or an allied field. There are programs for professional certification of occupational (industrial) hygienists in several countries, requiring demonstration of proficiency in the following technical areas: basic science; biohazards; biostatistics and epidemiology; engineering and other controls; ergonomics; ethics and management; analytical chemistry; sampling, monitoring and instrumentation; noise and vibration; ionizing radiation; non-ionizing radiation; regulations, standards and guidelines; thermal and pressure stressors; toxicology; and general topics including community exposures, hazardous wastes, risk communication, indoor environmental quality, and others (unit operations, process safety, and confined spaces). Certification is achieved through a combination of work experience and a comprehensive written examination. In the United States, approximately 6500 industrial hygienists are certified by the American Board of Industrial Hygiene.

OCCUPATIONAL HYGIENE AND DISEASE PREVENTION

Prevention of environmental diseases may be thought of as a two-stage process involving primary prevention

and secondary prevention.² The ultimate objectives are: (1) to avoid the establishment of disease, (2) to reduce the likelihood of disease recurrence or progression and (3) ameliorate the morbidity associated with the disease. Prevention of environmental diseases involves hazard recognition, hazard evaluation, and hazard control/intervention.

Hazard recognition: The hazard associated with a given exposure is a function of both the toxicity of a material and the extent of human exposure. Surveillance of both exposure and disease provides clues and hypotheses for further evaluation. Health data may be generated through environmental/occupational medicine and surveillance programs or through epidemiological studies. Toxicology often provides valuable information with regard to hazard recognition.

Hazard evaluation: Prevention strategies require knowledge of the effects caused by exposures as well as the dose levels where effects occur. These data allow development of risk assessment and strategies to reduce or eliminate significant human exposures. Toxicology, occupational medicine, and epidemiology provide the means for identifying chemical, physical, or biologic hazards. Toxicology testing in animals is an important component of early hazard recognition as well as hazard evaluation.

Hazard control/intervention: Primary prevention involves identification of environmental hazards which are factors or co-factors in disease development, followed by application of methods to reduce or eliminate human exposures. This represents the classical public health approach. Figure 4.1.1 depicts the components of the pathway from the source of a contaminant in the environment, through exposure, dose, and adverse health outcomes. The opportunities for intervention at various steps along the pathway are also shown. Principles and methods for controlling occupational hazards are discussed more fully later in this chapter.

RECOGNITION OF OCCUPATIONAL AND ENVIRONMENTAL HAZARDS

Classification of hazards

Workers may be exposed to contaminants by inhalation, absorption through the skin, ingestion, or injections (e.g., through accidental puncture wounds). Inhalation and skin absorption represent the predominant routes of exposure for most materials in the occupational environment. Ingestion may be an important source of exposure where poor hygiene practices, such as consumption of food and beverages in a contaminated work area, is allowed. Workers in healthcare facilities often are exposed to infectious agents through punctures with contaminated needles. Mucous membrane exposures to infectious agents from blood and body fluids may also be an important route of exposure in healthcare facilities.

Environmental agents are broadly classified by the Occupational Safety and Health Administration (OSHA) in the Hazard Communication Standard.³ The following is a summary and elaboration of hazards listed in the OSHA standard.

Physical hazards

Materials such as explosives, flammable or combustible liquids, oxidizers, compressed gases, organic peroxides, pyrophoric materials, unstable (reactive) chemicals, or water reactive chemicals are regarded as physical hazards by OSHA. Other exposures in the workplace, such as excessive noise, ionizing and non-ionizing radiation, and temperature extremes are further examples of physical hazards.

Ergonomic hazards include repetitive and forceful movements, vibration, temperature extremes, and awkward postures that arise from improper work methods and improperly designed workstations, tools and equipment.

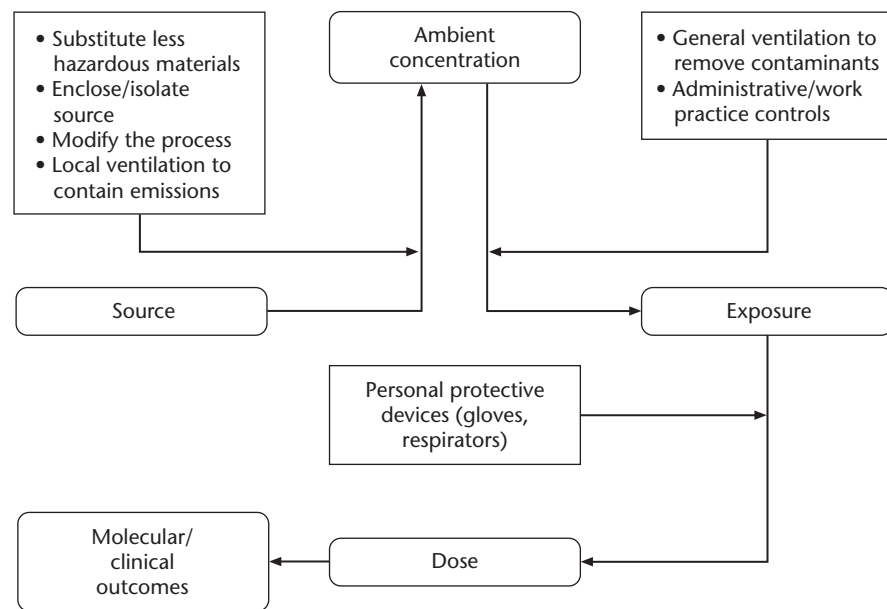

Figure 4.1.1: Hazard recognition, evaluation, control.

Ergonomic factors are increasingly important causes of injury in the workplace. Collectively, the term musculo-skeletal disorders (MSDs) refers to conditions that involve the nerves, tendons, muscles, and supporting structures of the body. Carpal tunnel syndrome is an example of a well-recognized work-related MSD of the wrist.

Chemical health hazards

Many chemicals are capable of producing adverse acute or chronic health effects. Chemical hazards include exposures to chemical mists, vapors, gases or particulates (dust and fumes) through inhalation or by absorption through the skin. OSHA defines hazardous chemicals to include carcinogens, reproductive toxins, irritants, corrosives, sensitizers, hepatoxins, nephrotoxins, agents which act on the hematopoietic system and agents which damage the lungs, skin, eyes or mucous membranes. Certain biologic materials are health hazards.

Biologic health hazards

Biologic hazards include bacteria, viruses, insects, plants, birds, animals and humans. Most biologic health hazards can be classified as infectious or immunologically active. As an example, accidental injection of blood-borne viruses is the major hazard of needlestick injuries, especially the viruses that cause AIDS (the HIV virus), hepatitis B, and hepatitis C. Anthrax is an example of a bacterium (*Bacillus anthracis*) that can affect the skin, the lungs, as well as the mouth, throat, and gastrointestinal tract. The infection sometimes can spread to other parts of the body, especially if treatment is not started early. The anthrax bacteria can form spores under certain conditions when, for example, body fluids infected with the bacteria are exposed to the air. The bacteria cannot live for long outside an animal; however, the spores can survive in soil and some other materials for decades.

Types of air-borne contaminants

Aerosols: Aerosols are composed of liquid droplets or solid particles fine enough to remain dispersed in air for a prolonged period of time. Aerosols may also be referred to as air-borne particulate matter with a wide range of particle size. Typical size ranges for aerosols are shown in Figure 4.1.2.

Dusts: Dusts are solid particles suspended in a gaseous medium. Dusts result from the mechanical disintegration of materials, such as grinding, with enough mechanical energy to propel particles into the air. Air-borne dust particles vary widely in size from approximately 50 μm to less than 1 μm . Only the larger particles may be seen without the use of a microscope. Most dusts produced from industrial operations as well as non-industrial operations such as construction or demolition consist of particles that vary widely in size, with the small particles greatly outnumbering the large ones. In general, when visible dust is noticeable in the air near a dust-producing operation, exposures to large numbers of smaller particles can be anticipated. The presence of a visible dust cloud, under typical indus-

trial lighting conditions, may represent a serious overexposure condition for substances such as asbestos and silica.

Air-borne dusts show wide variability in particle shape. Figure 4.1.3 shows typical dusts from a rubber-processing operation using industrial talc. The particles vary from flat to rounded and compact. In comparison, Figure 4.1.4 shows a microscopic photograph of dusts from an industrial operation generating talc contaminated with asbestiform minerals. The photograph demonstrates greatly elongated asbestiform fibers, similar in appearance to fibers seen with commercial asbestos minerals.

Fumes: Fumes are formed when the material from a volatilized (evaporated or vaporized) solid condenses in cool air. The solid particles that are formed make up a fume that is extremely small, usually less than 1 μm in diameter. In most cases, the freshly generated fume reacts with the oxygen in the air to form an oxide. Welding, metalizing, and other operations involving heating of metals to high temperatures produce vapors from the molten metal which produce fumes. Arc welding volatilizes metal to form a vapor that condenses, usually as the metal or its oxide. Fumes, because they are extremely fine, are readily inhaled.

Smoke: Smoke is usually produced by the incomplete burning of carbonaceous materials such as coal and oil. The resulting aerosol consists of carbon or soot particles less than 0.1 μm in size. Smoke, such as tobacco smoke, generally contains droplets as well as dry particles.

Mists: Mists are finely divided liquid droplets which are air-borne. Mists may be generated by condensation of liquids from the vapor back to the liquid state, or by breaking up a liquid into a dispersed state, such as by splashing, foaming, or atomizing. In industrial operations, mists are produced during paint spraying, spray application of pesticides and herbicides, and during cutting and grinding operations. Acid mists are produced during metallurgical pickling operations and during electroplating.

Particle respiratory deposition

The hazard associated with air-borne particulate matter is a function of: (1) the biologic activity of the material, (2) concentration of the air-borne material, and (3) air-borne particle size. Particle size determines the site of deposition within the respiratory system. Many occupational diseases such as silicosis and asbestosis are associated with material deposited in particular regions of the respiratory tract. Criteria have been developed to define critical size-fractions most closely associated with various health effects.⁴ The various critical fractions established by the American Conference of Governmental Industrial Hygienists (ACGIH) are shown in Figure 4.1.5 and are defined as follows.

Inhalable fraction: This is the fraction of air-borne particulate matter which can be hazardous when deposited anywhere in the upper or lower respiratory tract.

Thoracic fraction: Those particles which are hazardous when deposited anywhere within the pulmonary airways and the gas exchange region.

Respirable fraction: Those particles which are a hazard when deposited in the gas exchange region of the lungs.

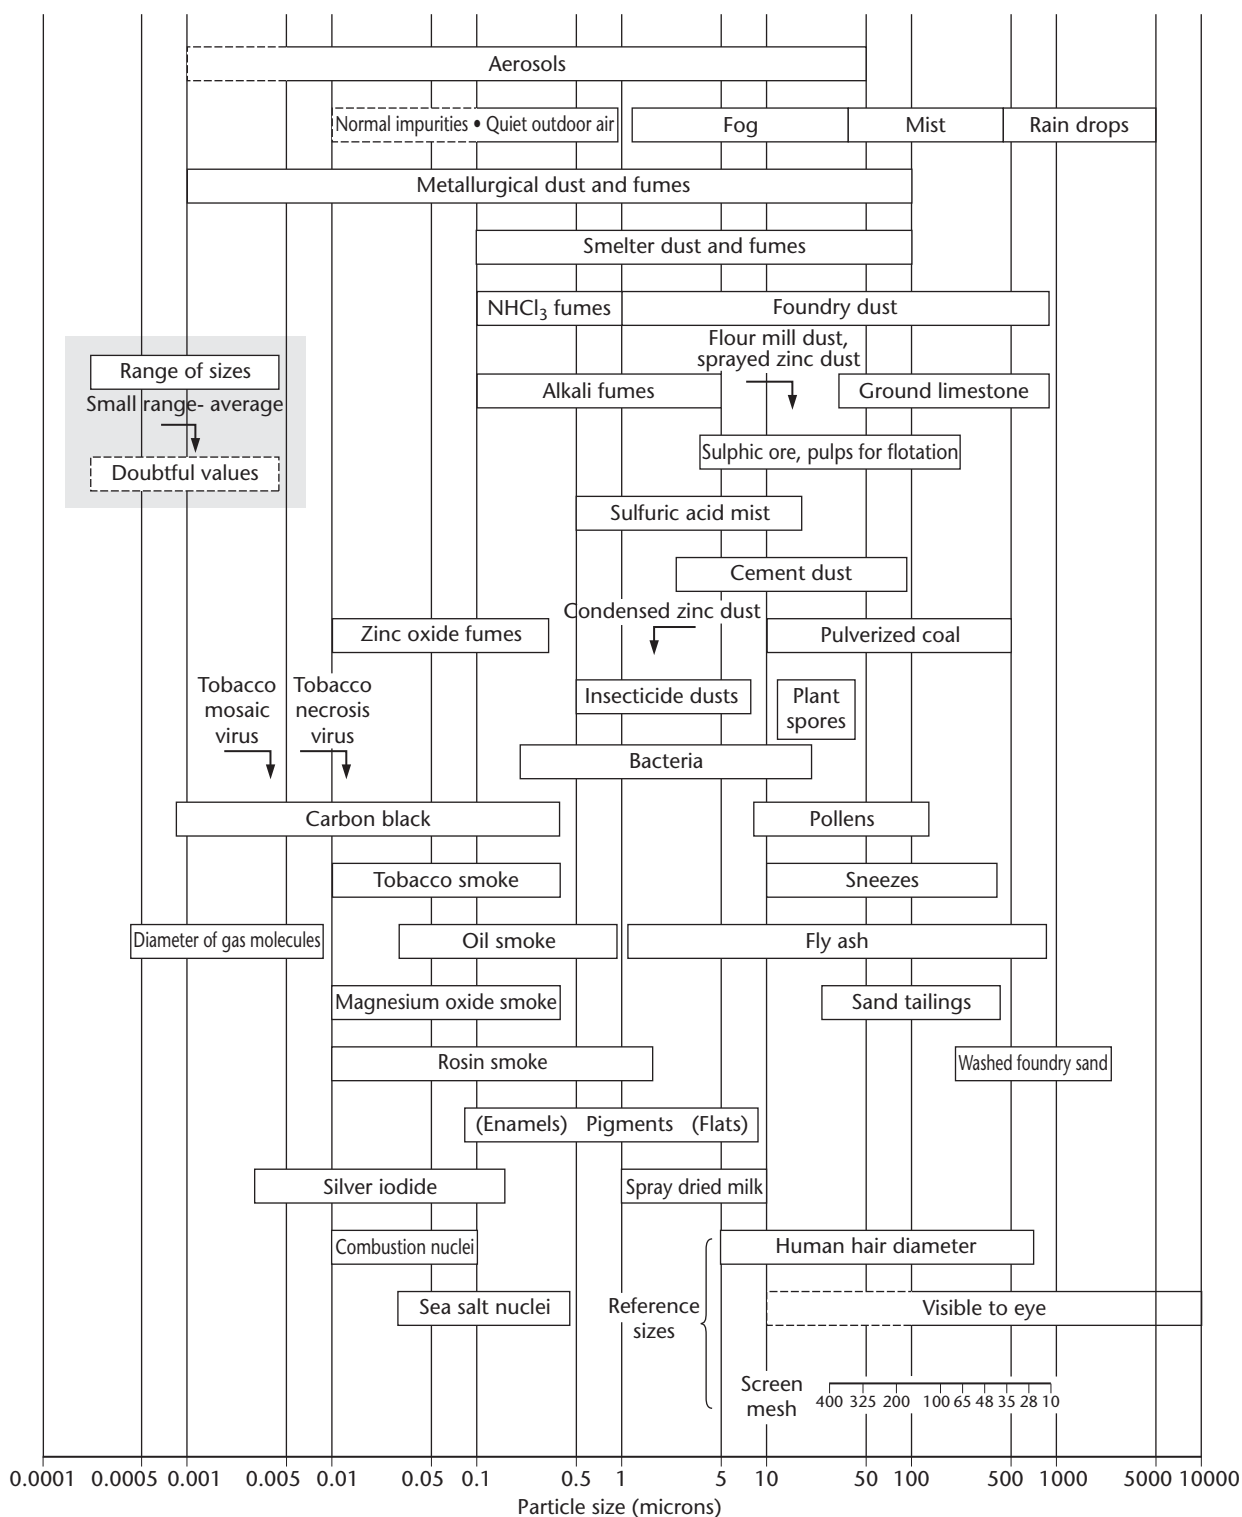

Figure 4.1.2: Size ranges for airborne contaminants, and comparisons with reference sizes.

Gases: Gases are formless fluids that expand to occupy the space or enclosure in which they are confined. The gaseous state is restricted to temperatures and pressures which would normally be present in the ambient or occupational environments.

Vapors: Vapors are the gaseous form of substances that are normally in the solid or liquid state at room temperature and pressure. Evaporation is the process by which a liquid is changed into the vapor state and mixed with the surrounding atmosphere. Many solvents will volatilize

Figure 4.1.3: Electron microscope image of airborne particles from an industrial rubber operation using non-fibrous talc.

Figure 4.1.4: Electron microscope image of airborne particles from a talc mine and a mill processing talcs contaminated with asbestiform minerals (seen as long, thin fibers).

to form vapors at normal temperatures and pressures. In addition, application of heat in many industrial operations produces more vapor. In general, the higher the vapor pressure of a liquid, the greater the potential for

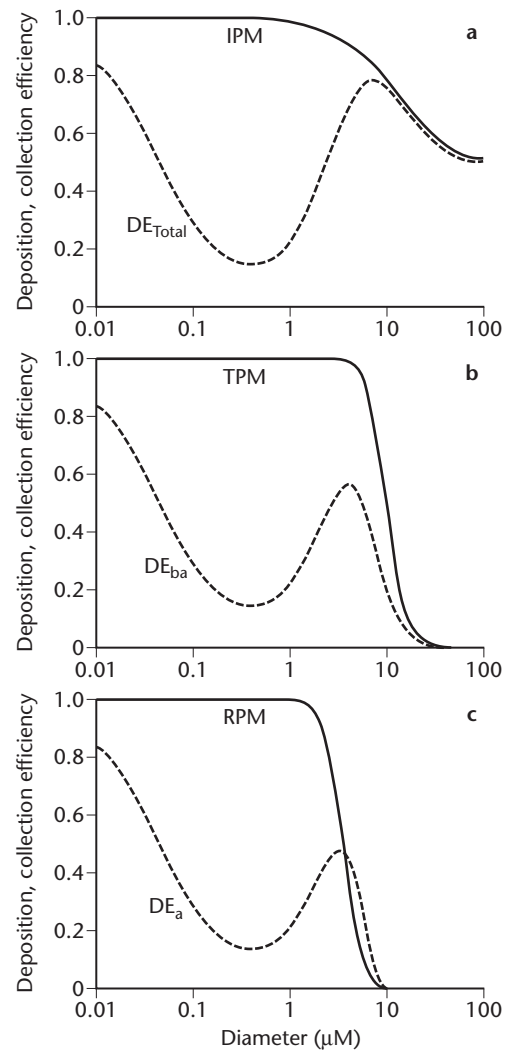

Figure 4.1.5: ACGIH reference curves for inhalable (a), thoracic (b), and respirable (c) fractions of airborne particulates. In (a), total inhalable fraction, or IPM, demonstrates that most particulates under 100 μm are *inhalable*. The DE_{total} curve reflects the fact that all but particles between 0.1 and 1.0 μm are well retained in the respiratory tract. In (b), it is apparent that particles under 10 μm are able to enter the bronchial tree and are called *thoracic*, or TPM. DE_{ba} shows the proportion of particles of each size deposited in the bronchoalveolar compartments. Particles of smaller size (<5 μm) are *respirable*, labeled RPM in (c). Alveolar deposition is indicated by the DE_a curve.

generation of elevated vapor concentrations near open sources or containers.

Fire and explosion hazards

Under appropriate conditions, gases, vapors and dusts present fire and explosion hazards. Fires and explosions account for a large majority of catastrophic industrial accidents resulting in injury and death. Health and safety personnel and workers must be trained to recognize fire and explosion hazards and their control. The following are key definitions and concepts.

Flash point: The flash point is the lowest temperature of the liquid at which the vapor/air mixture above the surface

will propagate (spread) a flame away from the source of ignition through the vapor/air mixture. A vapor/air mixture whose concentration is below the lower limit of flammability may burn in the zone immediately surrounding the source of ignition, without spreading away from the source of ignition. The flash point is an important concept with regard to fire hazard recognition. If a liquid has no flash point, it is not flammable or combustible, and conversely the presence of a flash point indicates flammability or combustibility. In finely divided forms, such as mist or spray, liquids can be ignited at temperatures below their flash points.

Flammable (explosive) limits: Vapors of a flammable or combustible liquid must be mixed with air in the proper proportions, in the presence of a source of ignition, for combustion or an explosion can occur. The proper mixture with air is called the flammable range and is also referred to as the explosive range. The flammable range includes all concentrations of flammable vapor or gas in air, in which a flash will occur or a flame will travel if the mixture is ignited. The minimum concentration of vapor or gas below which propagation of flame does not occur on contact with a source of ignition is called the lower flammable or explosive limit (LEL). Conversely, the maximum concentration of vapor above which propagation of flame does not occur is called the upper flammable or explosive limit (UEL). A vapor/air mixture below the lower flammable limit is too 'lean' to burn or explode, and a mixture above the upper flammable limit too 'rich' to burn or explode. As an example, the lower explosive limit of gasoline is 1.4% and the upper flammable limit or upper explosive limit is 7.6%.

Ignition temperature: The minimum temperature required to initiate or cause self-sustained combustion independent of the heating source is called the ignition temperature. Ignition temperatures may be changed substantially by a change of conditions, including composition of the vapor or gas-air mixture, shape and size of the space where the ignition occurs, rate and duration of heating, and temperature of the ignition source.

Autoignition or ignition temperature: The temperature at which a material self-ignites without any obvious sources of ignition, such as a spark or flame. Most common flammable and combustible liquids have autoignition temperatures in the range of 300°C (572°F) to 550°C (1022°F). Some have very low autoignition temperatures. For example, ethyl ether has an autoignition temperature of 160°C (356°F) and its vapors can be ignited by hot surfaces such as steam pipes.

Flammable liquids: The National Fire Protection Association, Flammable and Combustible Liquids Code, Standard No. 30,⁵ defines a flammable liquid as any liquid having a flash point below 100°F (37.8°C), and having a vapor pressure not exceeding 40 psi at 100°F.

Combustible liquids: Combustible liquids are those with flash points at or above 100°F. Combustible liquids do not ignite as easily as flammable liquids, although they can be ignited under certain circumstances.

Explosive dusts: Many industrial dusts may be explosive when air-borne. Notable examples are finely divided parti-

cles of aluminum and magnesium. Many air-borne organic dusts are explosive. Fire and explosion hazards may be present in grain elevators, woodworking plants, feed, cereal, flour, and paper mills, and fertilizer plants. The particle size and the density of the dust cloud produced are factors which govern the potential fire and explosion hazards.

Many materials are themselves capable of detonation or of explosively decomposing, some may be sensitive to mechanical or local thermal shock, or react only at high temperatures. Some materials need only be slightly contaminated to produce a violent reaction. Materials such as peroxides, perchlorates, fluorine, and chlorine support combustion directly or by evolution of oxidizers.

Boiling point: The boiling point of a liquid is the temperature at which the liquid's vapor pressure is equal to the atmospheric pressure at its surface. The boiling point is highly dependent on the pressure of the liquid. Liquids such as solvents will evaporate to form vapor at lower temperatures. As the temperature of an organic liquid increases vapor formation will occur more rapidly. Liquids with low boiling points have relatively high vapor pressure at room temperature and will volatilize readily, whereas those with high boiling points will usually volatilize more slowly.

Vapor pressure: When a liquid of a substance is exposed to the atmosphere there is a continuous movement of molecules from the liquid into the atmosphere. The vapor pressure of a substance is the pressure at any given temperature at which equilibrium between the vapor phase and the liquid or solid form occurs. The vapor pressure of a solvent is an important parameter to be considered in predicting fire and inhalation hazards. The vapor pressure also determines the tendency of a substance to become air-borne and pose an inhalation hazard.

Organic liquids with high vapor pressures are potentially hazardous because they evaporate readily into the air to produce high vapor concentrations. The saturation vapor concentration (i.e., highest attainable) for a liquid at a given temperature and pressure can be calculated as follows:

$$ppm = \frac{P_v}{P_{atm}} \times 10^6$$

where: ppm = parts per million by volume, P_v = vapor pressure in mmHg, P_{atm} = atmospheric pressure in mmHg.

Measures of air-borne concentration

Air-borne concentrations of contaminants are expressed in several ways, depending on the form of the contaminant and the sampling and analytic method used to determine air-borne concentration. Terms used to describe degree of exposure are as follows.

Ppm: Parts of vapor or gases per million parts of contaminated air by volume at room temperature and pressure.

Mpp/cf: Millions of particles of a particulate per cubic foot of air. This concentration measure is used to express dust concentrations measured with an impinger.

Mg/m^3 : Milligrams of a substance per cubic meter of air. This measure can be used for gases and vapors as well as dusts. For gases and vapors, mg/m^3 can be converted to ppm by volume using the following expression:

$$ppm = \frac{mg / m^3 \times 24.45}{m.w.}$$

where: ppm = parts per million by volume, mg/m^3 = gravimetric concentration of the vapor, m.w. = molecular weight of contaminant.

Vapor %: Part of vapor or gas per 100 parts of contaminated air by volume at room temperature and pressure.

Fibers/cc: A measure of the numbers of fibers longer than 5 μm in length per cubic centimeter of air. This measure is used for asbestos and man-made fibers when concentrations are measured by the membrane filter sampling method, using phase contrast microscopy.

CFU/m³: A measure used to express the concentration of bacteria or fungi in an air-borne sample. The foci of growth of viable organisms on culture plates are counted and expressed as the number of *colony-forming units* (CFU).

PFU/m³: A measure used to express the concentration of viruses in an air-borne sample. Virus-infected cells in culture produce changes in appearance, or the cells may burst and produce *plaques*. The foci of virus-infected cells in cultures are counted and expressed as the number of *plaque-forming units* (PFU).

Occupational exposure standards and guidelines

REL: NIOSH recommended exposure limit. RELs are generally time-weighted average concentrations for up to a 10-hour workday during a 40-hour workweek.

STEL: Short-term exposure limit. A STEL is normally a 15-minute (or other specified time period) TWA that should not be exceeded during any time of the workday.

TWA: Time-weighted average. A method of calculating a daily or full-shift average exposure by weighting the different short-term average concentrations by exposure time:

$$TWA = \frac{C_1T_1 + C_1T_2 + \dots C_nT_n}{T_1 + T_2 + \dots T_n}$$

where: C_1 = concentration of contaminant measured during time period, T_1 = time for average concentration C .

PEL: OSHA permissible exposure limit. PELs are regulatory levels (usually TWAs) that must not be exceeded during any 8-hour work shift of a 40-hour workweek.

Ceiling Concentration: Maximum OSHA concentration which must not be exceeded during any part of the workday.

TLV: Non-regulatory exposure recommendations by the American Conference of Governmental Industrial Hygienists (ACGIH). There are TLVs for approximately 750 chemical compounds and materials. These are usually 8-hour TWA concentrations but STELS or ceiling values are recommended by the ACGIH for approximately 150 compounds.⁶

General principles of occupational hazard recognition

Hazard recognition involves a systematic review of a worker's occupational environment to identify exposures and potential exposures.⁷ This review should provide the following types of information:

- Materials produced or stored and the process involved.
- Raw materials used or added to the process.
- By-products formed during the production process.
- Types of industrial equipment used.
- Cycle of operation and/or frequency of exposure, with attention to specific work tasks.
- Operational methods and work practices used.
- Health and safety controls in place.
- Use of personal protective equipment.
- Levels of exposure to harmful agents.
- Frequency and duration of worker exposure.
- Number of workers exposed.

Although the most useful data for hazard identification are the magnitude and frequency of exposure, such data are rarely available for all contaminants of interest. The health professional is then faced with estimating the *potential for exposure* using other surrogate data sources. Information concerning plant processes, hazardous raw materials and by-products, work practices, types of control measures, use of protective equipment and duration of exposure can often be obtained from plant personnel or through interviews with workers.

For many types of jobs, such as maintenance and construction work, worker exposures are often highly dependent on specific work tasks and related work practices. In evaluating worker exposure, it is important to recognize the wide variability in individual worker exposures, even when workers are doing the same or comparable jobs.

The OSHA hazard communication standard provides a valuable information resource for hazard identification.³ This standard requires employers to:

1. develop a written hazard communication program
2. maintain a list of all hazardous chemicals in the workplace
3. make available to workers material safety data sheets (MSDS) for each hazardous chemical
4. place labels on containers as to the chemical identity and precautions in handling, and
5. provide workers with education and training in the handling of hazardous chemicals.

A material safety data sheet (MSDS) is a short document (several pages) which provides summary information concerning a hazardous material. The OSHA hazard communication standard does not require a standard format for MSDS; however, the types of information which must be provided are specified. Figure 4.1.6 is a non-mandatory MSDS format suggested by OSHA. The following is a summary of information to be provided by an MSDS.

Section I: Contains general information – (a) chemical identity, (b) manufacturer's name and address, and (c) emergency telephone numbers

Section V- Reactivity Data			
Stability	Unstable		Conditions to Avoid
	Stable		
Incompatibility (<i>Materials to Avoid</i>)			
Hazardous Decomposition or By-Products			
Hazardous Polymerization	May Occur		Conditions to Avoid
	Will Not Occur		
Section VI – Health Hazard Data			
Route(s) of Entry:	Inhalation?	Skin?	Ingestion?
Health Hazards (<i>Acute and Chronic</i>)			
Carcinogenicity:	NTP?	IARC Monographs?	OSHA Regulated?
Signs and Symptoms of Exposure			
Medical Conditions Generally Aggravated by Exposure			
Emergency and First Aid Procedures			
Section VII – Precautions for Safe Handling and Use			
Steps to Be Taken in Case Material is Released or Spilled			
Waste Disposal Method			
Precautions to Be Taken in Handling and Storing			
Other Precautions			
Section VIII – Control Measures			
Respiratory Protection (<i>Specify Type</i>)			
Ventilation	Local Exhaust	Special	
	Mechanical (<i>General</i>)	Other	
Protective Gloves	Eye Protection		
Other Protective Clothing or Equipment			
Work/Hygienic Practices			

Figure 4.1.6 (cont'd): OSHA-suggested format for material safety data sheet, or MSDS. Although required in the United States under the Hazard Communication Standard, many different formats are used by different companies.

Section II: Lists the hazardous ingredients and identification information. Includes any synonyms, TLVs or recommended occupational exposure limits.

Section III: Lists the physical/chemical characteristics that are applicable. Can include boiling point, vapor pressure, vapor density, specific gravity, melting, evaporation rate, and appearance and odor.

Section IV: Contains fire and explosion hazard data. This section includes flash point, flammable limits, extinguishing media, special fire fighting procedures, and any unusual hazards.

Section V: Provides data. States conditions of stability, any incompatibilities, hazardous decomposition products, and hazardous polymerization conditions.

Section VI: This section lists those health hazards which may arise from acute or chronic exposure, the route of entry, target organ, signs and symptoms of exposure, emergency first aid procedures, and whether the chemical is classified as a carcinogen.

Section VII: Lists the precautions for safe handling and use. Included are steps to be followed in case of a spill, waste disposal methods, and handling or storage precautions.

Section VIII: Contains control measures that are to be utilized when the chemical in question is used. This includes what type of respiratory protection is required, ventilation requirements, other personal protection devices/clothing, and specific work practices.

While MSDS are valuable for hazard identification, they must be used with a degree of caution for several reasons. Firstly, quality and completeness vary considerably between chemical producers. Secondly, the OSHA standard does not require chemical producers to conduct further toxicological studies to define the hazard of a chemical – the standard requires only the disclosure of a known hazard. Thus the quality of an MSDS is greatly dependent on published literature concerning the hazard of a substance.

In addition to information concerning raw materials used and by-products formed, information concerning the type of industrial process and jobs performed by workers is often helpful in hazard identification. In most industrial processes and occupational environments, several hazards will be present. Occupational hygienists have training and experience in identifying process and job specific hazards. Table 4.1.1 provides a brief summary of typical plant processes and the types of hazards that may be present. In considering possible exposures to workers, it is important to recognize exposures during non-routine tasks such as maintenance and cleaning. Maintenance workers may be exposed to most chemical hazards in the plant environment in addition to other materials such as asbestos, man-made mineral fibers from insulation materials, cutting oils, and lubricants. Cleaning operations, especially by dry sweeping, may re-suspend materials creating significant potential for particulate exposures.

The National Institute for Occupational Safety and Health (NIOSH) has conducted several national surveys to identify potential exposures and hazards by industry and

job.⁸ Data from these surveys are often helpful in identifying potential occupational exposures when a worker's job title and industry of employment are known. There are several sources of guidance which are very useful in the recognition and evaluation of workplace hazards.^{1,9-24} These are included in the References, and should be consulted as sources of further information.

Occupational exposure limits and information sources

OSHA air contaminant standards

The goal of the US Occupational Safety and Health Act of 1970 is 'To assure safe and healthful working conditions for working men and women. . .' (Public Law 91-596). In order to achieve this goal, the Act authorizes the Secretary of Labor to issue occupational health and safety standards. In the case of air contaminants, the Act requires that these standards be set as exposure limits 'which most adequately assure(s), to the extent feasible, on the basis of the best available evidence, that no employee will suffer material impairment of health or functional capacity even if such employee has regular exposure to the hazard dealt with by such standard for the period of his working life. . . .'. In accordance with this mandate, in 1971 OSHA promulgated approximately 425 permissible exposure limits (PELs) for air contaminants, derived principally from the American Conference of Governmental Industrial Hygienists Threshold Limit Values (ACGIH-TLVs) of 1968.

The Act also describes mechanisms for updating these standards, which include the requirements that OSHA must provide notice of proposed rulemaking, give interested parties an opportunity to comment, and hold a public hearing if requested. As of 2001, OSHA had issued 30 substance-specific and three 'generic' health standards under these provisions. In 1989 OSHA published a final rule for general industry, revising 212 existing exposure limits and establishing 164 new ones. However, in 1992 the 11th Circuit Court of Appeals ruled that OSHA did not sufficiently demonstrate that the new PELs were necessary or that they were feasible. The Court's decision to vacate the new limits forced the Agency to return to the original 1971 limits. While the updated standards were vacated, the substance-specific reviews do provide some additional guidance to health professionals. NIOSH scientific reviews in support of the PEL update project are available on the NIOSH Website.

OSHA may issue Emergency Temporary Standards under section 6(c) of the Act when it determines 'that employees are exposed to grave danger from exposure' to toxic substances. Once OSHA has published an emergency standard, proceedings must commence for issuance of a regular standard under section 6(b).

OSHA also has regulations on access to medical and exposure records. Under these regulations (29 CFR 1910.20), health professionals may obtain access to medical records, and exposure information from employers and former employers. Other OSHA generic health standards address

Process of operation	Nature and description of hazard
Abrasive blasting	Abrasive blasting equipment may be automatic or manually operated. Either type may use sand (free silica), steel shot or artificial abrasives. Excessive noise exposures may occur
Agricultural and food science technicians	Bioaerosols, caustics, acids and other agents causing contact dermatitis
Animal breeding/handling	Allergenic animal proteins, bioaerosols, dusts from bedding, grains, feeds, infection hazards Gases from fecal decomposition in animal confinement housing
Assembly operations	Improper positioning of equipment and handling of work parts present ergonomic hazards due to repeated awkward motion resulting in excessive stresses
Automotive repair/mechanics	Solvents and degreasers, asbestos and other fibers, automotive exhaust, lead, glues and sealants, benzene from solvents and automotive exhausts
Automotive body repair & painting	Paint aerosols, solvents, isocyanates, epoxy, dusts from body fillers, lead
Babbitting	Fumes and dusts of oxides of antimony, lead, tin and zinc
Bagging and handling	Conveying, sifting, sieving, screening, packaging, or bagging of any dry material may present a dust hazard. The transfer of dry, finely divided powder may result in the formation of considerable quantities of airborne dust. Inhalation and skin contact hazards may be present
Bakers	Flour dust, bioaerosols or biological enzymes
Cement cutting/grinding	Excessive dust, silica, and noise
Ceramic coating	Ceramic coating may present the hazard of airborne dispersion of toxic pigments and metal oxides plus hazards of heat stress from the furnaces and hot ware
Coal mining	Coal mine dust, silica, noise
Coal handling	Dusts and gases of carbon monoxide, coal, free silica, and sulfur dioxide
Coke handling	Coke and free silica dust
Coking	Contaminants encountered include ammonia, benzene, carbon disulfide, carbon monoxide, cyanamides, hydrogen sulfide, naphthalene and other polycyclics, phenols, pyridine, and sulfur dioxide
Dry grinding	Dry grinding operations may produce airborne dusts and ergonomic hazards
Dry mixing	Mixing of dry material may present a dust hazard
Earth moving, drilling, or boring	Elevated dusts exposures, potential high exposures to silica
Electro-tinning (alkaline and halogen)	Mists of caustics, chromates, fluorides, and sulfuric acid
Electron beam welding	Any process involving an electric discharge in a vacuum may be a source of ionizing radiation. Such processes include electron beam equipment and similar devices
Fabric and paper coating	The coating and impregnating of fabric and paper with plastic or rubber solutions may involve evaporation into the workroom air of large quantities of solvents
Farming & ranching	Pesticides, wood preservatives, bioaerosols and animal-derived proteins, grain dusts, hydrogen sulfide from manure pits and decaying organic matter, molds
Ferromanganese handling	Dust and gases of ferromanganese and hydrogen
Firefighting	Smoke, dusts, carbon monoxide, gases such as hydrogen chloride, from burning plastics
Forming and forging	Hot bending, forming, or cutting of metals or non-metals may have the hazards of lubricant mist, decomposition products of the lubricant, skin contact with the lubricant, heat stress (including radiant heat), noise, and dust
Furnace operations	Dusts, fumes, and gases of carbon monoxide, iron oxide, metal oxides, sulfur dioxide, and other combustion products
Galvanizing	Production of fumes, gases and mists of ammonium chloride, chromates, hydrochloric acid, hydrogen chloride, lead oxides, and zinc oxide
Gas furnace or oven heating	Products of combustion that may be released into the workroom atmosphere. Burner noise may be excessive
Grinding	Grinding, crushing, or comminuting of any material may present the hazard of contamination of workroom air due to the dust of the material being processed or of the grinding wheel
Healthcare workers	Blood-borne pathogens, tuberculosis, and other biological hazards, latex, drug exposures, chemotherapeutic agents, waste anesthetic gas, laser hazards, hazards associated with laboratories, radioactive material, ionizing radiation, formaldehyde, ethylene oxide and paracetid acid used for sterilization, patient lifting injuries, job stress, workplace violence
High temperatures	Any process or operation involving high ambient unlagged steam pipes, process temperatures (dry-bulb) temperature, radiant equipment, etc, heat load (globe temperature) or excessive humidity (wet-bulb temperature) may produce heat-related problems
Janitorial work/cleaning	Caustics, solvents and other agents causing contact dermatitis, dusts, bioaerosols from fleas, mites and rodents, asbestos from old insulation, potentially infected human wastes
Leaded steelmaking	Dusts and fumes of iron oxide and lead oxide
Industrial maintenance operations	Exposures to typical hazardous materials in the process plus asbestos, man-made mineral fibers, cutting oils and lubricants. Cutting and welding hazards and frequent solvent exposures
Materials handling, warehousing	Carbon monoxide and oxides of nitrogen arising from internal combustion engine fork-lift operations. Secondary spills from spills and re-suspended dusts

Table 4.1.1 Hazards associated with jobs, processes and tasks

Process of operation	Nature and description of hazard
Metalizing	A high-temperature coating of parts ('spraying') with molten metals presents hazards of dust and fumes of metals and their oxides, fluxes, carbon monoxide, in addition to heat and non-ionizing radiation
Microwave and radiofrequency	Microwave heating operations or induction heating may produce heating effects, electromagnetic field exposures and, in some cases, noise exposures
Molten metals	Melting and pouring of molten metals may produce toxic gas, metal fume or dust. Acrolein often is produced
Ore handling	Dusts of fluorides, free silica, and iron oxide. Some ores may contain other toxic metals as well as mineral fibers
Paint spraying	Paint spraying operations produce hazards from inhalation and skin contact with toxic and irritating solvents and inhalation of toxic pigments (cadmium, chromates and lead). The solvent vapor evaporating from the sprayed surface also may be source of hazard, because ventilation may be provided only for the paint spray booth
Pesticide application	Exposure to pesticides, herbicides, fungicides, or insecticides through sprays, dusts, vapors, soil incorporation or chemical application on trees, handling of agents causing allergic or contact dermatitis
Pickling (steel)	Gases and mists of hydrochloric acid, hydrogen chloride, hydrogen fluoride, oxide of nitrogen, and sulfuric acid
Plating	Electroplating processes involve risk of skin contact with strong chemicals and a respiratory hazard if mist or gases from the plating solutions are dispersed into the workroom air. Most commonly, these can be acids, alkalis, chromic acid mist, etc
Plumbers, pipefitters & steamfitters	Asbestos, man-made fibers, polyurethane, epoxy, styrene, glues, solvents, lead, coal tar, welding and soldering fumes
Punch press, press brake, drawing	Cold bending, forming, or cutting of metals or non-metals may involve hazards of contact with lubricant, inhalation of lubricant mist, and excessive noise
Refractory handling	Free silica dust as well as asbestos fibers
Sheet metal fabrication	Welding and cutting fumes and gases, glues, solvents, soldering fume, asbestos, man-made mineral fibers, urethane foam
Sintering	Dusts and gases of carbon monoxide, fluorides, free silica, iron oxides, and sulfur dioxide
Solvent degreasing	Vapors of perchloroethylene, trichloroethylene, vapor decomposition products (e.g., phosgene) and other solvents
Steelmaking (material handling)	Dusts of fluorspar, graphite, iron oxide, limestone, mill scale, and ore
Tandem rolling mills	Oil mist
Tool grinding, filing & sharpening	Tungsten-carbide, cobalt, beryllium alloys, abrasives containing silica, cleaning solvents
Vapor degreasing	The removal of oil and grease from metal products may present hazards
Veterinarians & technicians	Animal pathogens including hepatitis A from primates, animal proteins, therapeutic agents
Welding, gas or electric-arc ('brazing')	Processes involving the melting and joining of metal parts may produce exposures to fumes and gases. Oxides of cadmium, chromium, fluorides, iron, manganese, nickel, nitrogen, and vanadium may form, as well as pyrolysis by-products from fluxes and coatings. Welding on painted surfaces (e.g., lead-based paint) may produce a lead vapor hazard
Wet grinding	Wet grinding of any material may produce possibly hazards of mist, dust, and noise
Wet mixing	Mixing of wet materials may present possible hazards of solvent vapors, mist, and possible dust. Elevated noise levels also are possible
Woodworking/cabinet making	Hard and soft wood dusts, allergenic dusts such as Western red cedar, glues, epoxies, coatings, formaldehyde-resin adhesives, isocyanate

Table 4.1.1 (cont'd) Hazards associated with jobs, processes and tasks

blood-borne pathogens and occupational exposures to hazardous chemicals in laboratories.

Material safety data sheets (MSDS) are an important tool for communicating information about potentially hazardous chemicals in the workplace. The OSHA Hazard Communication Standard, 29 CFR 1910.1200,³ mandates that employers inform employees of potentially hazardous materials. The regulation specifies requirements for the labeling, and communication of information on the hazardous properties of chemicals. It applies to chemical manufacturers, importers, and distributors. The standard includes a basic list of substances which must be treated as hazardous, and the term 'hazardous chemical' is defined as any chemical that is a physical hazard or a health hazard.

The OSHA hazard communication standard requires employers to: (1) develop a written hazard communication program, (2) maintain a list of all hazardous chemicals in the workplace, (3) make available to workers MSDS for each hazardous chemical, (4) place labels on chemical containers as to the chemical identity and precautions in handling, and (5) provide workers with education and training in the handling of hazardous chemicals.

OSHA also has issued a generic standard for respiratory protection (29 CFR 1910.134). OSHA's revised Respiratory Protection Standard became effective in 1998 and replaced the respiratory protection standards adopted by OSHA in 1971. The standard provides guidance for employers on how to establish and maintain a respiratory

protection program to protect their respirator-wearing employees.

NIOSH recommendations

The NIOSH develops and recommends criteria for preventing disease and hazardous conditions in the workplace. These recommendations are issued in several forms, including exposure limits for physical and chemical hazards published as criteria documents and current intelligence bulletins. Information on recommended methods for prevention, including engineering controls, guidelines for selecting personal protective equipment such as respirators, and safe work practices are published in documents such as hazard alerts and occupational hazard assessments.

The NIOSH recommendations are not themselves legally enforceable; however, they are transmitted to OSHA and the Mine Safety and Health Administration (MSHA) for use in promulgating legal standards. NIOSH has recommended exposure limits for over 600 chemicals and compounds, as well as for physical hazards including hand-arm vibration, heat, noise, radon progeny, and ultraviolet radiation. Safety and health standards have also been recommended for industries, processes, and work environments including foundries, confined spaces, and logging operations.

Toxicological reviews

Reviews and evaluations of information on the toxicity of hazardous substances are prepared by several governmental and private organizations in the United States and internationally. The Agency for Toxic Substances and Disease Registries (ATSDR) (<http://www.atsdr.cdc.gov/>) of the US Department of Health and Human Services prepares toxicological profiles for compounds which are commonly found at hazardous waste sites, and may pose the most significant threat to human health. The profiles identify and review the key literature on each substance's toxicological properties. Each profile includes a public health statement which summarizes the compound's toxicological properties, a review of the information on human exposure, and known information on human health effects. The reviews are intended primarily for the use of health professionals, as well as private organizations and members of the public.

The National Institute of Environmental Health Sciences (NIEHS) of the US Department of Health and Human Services prepares an Annual Report on Carcinogens, which reviews and evaluates information on evidence of carcinogenicity. The report provides a listing of chemicals classified on the basis of the strength of the evidence of carcinogenic risk. Chemicals may be classified as 'known carcinogens' based upon sufficient evidence of a causal association between the chemical and cancer in humans. Chemicals for which less available evidence exists may be classified as compounds 'reasonably anticipated to be carcinogens'.

The American Conference of Governmental Industrial Hygienists (ACGIH) prepares a listing of Threshold Limit Values (TLVs) and Biologic Exposure Indices (BEIs) which is updated annually.⁴ The TLVs are recommendations

intended to be used as guidelines for limiting occupational exposures to more than 700 chemical and physical agents. They are prepared by technical committees of the ACGIH, which is an association of occupational and environmental professionals largely from academia and governmental agencies. In addition to the annual TLV listing, the ACGIH publishes a companion volume of documentation for the TLVs, which summarizes the pertinent scientific information and data that was used as the basis for the recommended exposure limits or indices.⁶

Several international organizations review scientific information for purposes of evaluating risks resulting from human exposure to chemicals. The International Agency for Research on Cancer (IARC) prepares a critical review of information on evidence of carcinogenicity for chemicals. The result of these reviews is a set of monographs which include several hundred chemicals, mixtures, processes and occupations.²⁵ The IARC classification of the evidence on carcinogenicity ranges from category 1 (carcinogenic to humans; sufficient evidence of carcinogenicity) to category 4 (probably not carcinogenic to humans). The International Programme on Chemical Safety (IPCS) is a joint venture of the United Nations Environment Program, the International Labor Organization, and the World Health Organization. This program develops Environmental Health Criteria Documents, which are summaries and evaluations of the information on toxic effects of specific chemicals and groups of chemicals. Over 200 chemicals have been reviewed, and are published in the criteria documents,²⁶ that summarize available information and include recommendations for further research.

Computerized databases and internet resources

Many excellent computerized databases and internet-based information sources are available. Only a few of the more important sources are highlighted in this section. These data sources are expanding rapidly. In addition to the primary information sites on the internet, links with other useful information sources are provided. As with all internet-based information, users should be careful to rely on information provided by reputable sites such as the various Federal and State agencies.

The National Library of Medicine (NLM) is an excellent starting point for research on agents and health effects (<http://www.nlm.nih.gov/>). The major bibliographic resource available through the NLM is MEDLINE/PubMed. MEDLINE/PubMed provides public access to over 12 million MEDLINE citations back to the mid-1960s and additional life science journals. PubMed includes links to many sites providing full text articles and other related resources.

In addition to bibliographic data resources, the NLM provides public access to a number of peer-reviewed databases concerned with chemical agents and health. These databases are briefly summarized below based on description provided by the NLM.

Hazardous Substances Data Bank (HSDB). HSDB is a toxicology data file that focuses on the toxicology of potentially hazardous chemicals. It is enhanced with

information on human exposure, industrial hygiene, emergency handling procedures, environmental fate, regulatory requirements, and related areas. All data are referenced and derived from a core set of books, government documents, technical reports and selected primary journal literature. HSDB is peer reviewed by the Scientific Review Panel (SRP), a committee of experts in the major subject areas within the databank's scope. HSDB is organized into individual chemical records, and contains over 4500 such records.

Integrated Risk Information System (IRIS). IRIS is a toxicology data file that contains data in support of human health risk assessment. It is compiled by the US Environmental Protection Agency (EPA) and contains over 500 chemical records. IRIS data, focusing on hazard identification and dose-response assessment, is reviewed by working groups of EPA scientists and represents EPA consensus. Among the key data provided in IRIS are EPA carcinogen classifications, unit risks, slope factors, oral reference doses, and inhalation reference concentrations.

GENE-TOX. GENE-TOX is a toxicology data file created by the US Environmental Protection Agency (EPA) and contains genetic toxicology (mutagenicity) test data, developed from expert peer review of the scientific literature, on over 3000 chemicals. The GENE-TOX program was established to select assay systems for evaluation, review data in the scientific literature, and recommend proper testing protocols and evaluation procedures for these systems.

Chemical Carcinogenesis Research Information System (CCRIS). CCRIS is a scientifically evaluated and fully referenced databank, developed and maintained by the National Cancer Institute (NCI). It contains some 8000 chemical records with carcinogenicity, mutagenicity, tumor promotion, and tumor inhibition test results. Data are derived from studies cited in primary journals, current awareness tools, NCI reports, and other special sources. Test results have been reviewed by experts in carcinogenesis and mutagenesis.

TOXLINE. TOXLINE is the National Library of Medicine's extensive collection of online bibliographic information covering the biochemical, pharmacologic, physiologic, and toxicologic effects of drugs and other chemicals. It contains more than 3 million bibliographic citations, almost all with abstracts and/or indexing terms and CAS Registry Numbers. TOXLINE references are drawn from various sources grouped into two major parts – TOXLINE Core and TOXLINE Special – both of which operate under versatile search engines offering a variety of search and display capabilities.

Developmental and Reproductive Toxicology/Environmental Teratology Information Center (DART/ETIC) Database. DART/ETIC is a bibliographic database that covers teratology and other aspects of developmental and reproductive toxicology. It contains over 90,000 references

to literature published since 1965. DART/ETIC is funded by the US Environmental Protection Agency, the National Institute of Environmental Health Sciences (NIEHS), the National Center for Toxicological Research of the Food and Drug Administration, and the NLM.

EPA's Toxic Chemical Release Inventory (TRI). TRI is an annually compiled series of databases that constitute the toxic releases files on the National Library of Medicine's (NLM) Toxicology Data Network (TOXNET). This series, which includes 1995–1999 reporting years, contains information on the annual estimated releases of toxic chemicals to the environment and is based upon data collected by the Environmental Protection Agency (EPA). Mandated by the Superfund legislation, TRI's data cover air, water, land, and underground injection releases, as well as transfers to waste sites, and waste treatment methods and efficiency, as reported by industrial facilities around the United States. TRI also includes data related to source reduction and recycling.

ChemIDplus. ChemIDplus is a free, web-based search system that provides access to structure and nomenclature authority files used for the identification of chemical substances cited in National Library of Medicine (NLM) databases. ChemIDplus also provides structure searching and direct links to many biomedical resources at NLM and on the Internet for chemicals of interest. The database contains over 350,000 chemical records, of which over 114,000 include chemical structures, and is searchable by Name, Synonym, CAS Registry Number, Molecular Formula, Classification Code, Locator Code, and Structure.

All of the major Federal agencies concerned with occupational and environmental health, including NIOSH, OSHA, EPA, and NIEHS, provide excellent internet-based information resources. NIOSH (<http://www.cdc.gov/niosh/homepage.html>) provides many of their publications online as well as a number of useful data sources including:

NIOSH Certified Equipment List (CEL): A database of all certified respirators and coal mine dust personal sampler units.

NIOSH Manual of Analytical Methods: A collection of methods for sampling and analysis of contaminants in workplace air, and in the blood and urine of workers who are occupationally exposed.

NIOSH Pocket Guide: Provides a concise summary of physical and chemical properties of agents, health effects, exposure limits, recommended personal protective equipment including respirators, and sampling methods.

NIOSH has developed an electronic data source (NIOSTIC-2) consisting of bibliographic databases of literature in the field of occupational safety and health. NIOSTIC-2 is updated quarterly and is available online and on CD from several vendors. NIOSTIC-2 covers the following subject areas: toxicology, occupational medicine, epidemiology, pathology, physiology, engineering, industrial hygiene, health physics, behavioral sciences, ergonomics, hazardous waste, chemistry, and control technology.

NIOSH also developed the Registry of Toxic Effects of Chemical Substances (RTECS) which is a compendium of data extracted from the open scientific literature concerning the toxicology of a chemical or chemical compound. RTECS is intended to be a comprehensive source of basic toxicity information for the assessment of hazards posed by exposure to chemical substances.

OSHA (<http://www.osha.gov/>) provides a comprehensive resource for standards, standard interpretations, and Electronic Products for Compliance Assistance on its internet site. This site also provides hundreds of links to other useful documents and technical resources. Medical Tests for OSHA Regulated Substances are included, providing specific information on medical tests published in the literature for OSHA regulated substances.

The Agency for Toxic Substances and Disease Registry (ATSDR) has developed the Medical Management Guidelines (MMGs) for Acute Chemical Exposures (<http://www.atsdr.cdc.gov/mmg.html>). These guidelines were developed by ATSDR to aid emergency department physicians and other emergency healthcare professionals who manage acute exposures resulting from chemical incidents. ATSDR also has developed ToxFAQs which serve as a quick and comprehensible guide regarding exposure to substances found around hazardous waste sites and the effects of exposure on human health.

EXTOXNET (<http://ace.ace.orst.edu/info/extoxnet/pips/ghindex.html>) is a cooperative effort of University of California-Davis, Oregon State University, Michigan State University, Cornell University, and the University of Idaho. EXTOXNET provides Pesticide Information Profiles (PIPs) which provide specific pesticide information relating to health and environmental effects. PIPs are not intended to be exhaustive literature reviews concerning a pesticide.

Resource hotlines

A number of emergency response services are in operation, some of which are primarily intended to provide information on environmental aspects of chemical hazards. These services are good sources of information on the toxicity and risk of exposure to a wide range of chemicals, regardless of whether exposure takes place in an environmental or an occupational setting. NIOSH operates a toll-free technical service to provide information on workplace hazards. The service is staffed by technical information specialists who can provide information on NIOSH activities, recommendations and services, or any aspect of occupational safety and health. The number is not a hotline for medical emergencies, but is a source of information and referrals on occupational hazards. The NIOSH toll-free number is 800-35- NIOSH (800-356-4674).

CHEMTREC (<http://www.chemtrec.org/>) is a 24-hour hotline to the Chemical Transportation Emergency Center operated by the Chemical Manufacturers Association (USA 800-424-9300; outside USA 703-527-3887). CHEMTREC assists in the identification of unknown chemicals, and provides advice on proper emergency response methods and procedures. It does not provide emergency treatment

information other than basic first aid. CHEMTREC also facilitates contact with chemical manufacturers when further information is required.

The National Pesticides Information Center (<http://npic.orst.edu/>) is operated by Oregon State University and the US Environmental Protection Agency (800-858-7378). The hotline provides information on pesticide-related health effects, toxicity, and minor cleanup procedures to physicians, veterinarians, fire departments, first responders, and the general public. It is also a source of information on pesticide product formulations, basic safety practices, health and environmental effects, and cleanup and disposal procedures.

Several hotline and information lines are available for response to information requests on toxic materials and environmental issues. The US Environmental Protection Agency (USEPA) (<http://www.epa.gov/>) has several hotlines and information sources. The Center for Environmental Research Information is a central point for distribution of USEPA research results and reports (513-569-7562).

EPA also operates the Emergency Planning and Community Right-to-Know Act (EPCRA) hotline (800-424-9346) to provide information regulations and programs implemented for the Resource Conservation and Recovery Act (RCRA); the Comprehensive Environmental Response Compensation and Liability Act (CERCLA, or Superfund); and the Emergency Planning and Community Right-to-Know Act and the Toxic Substances Control Act. In addition, each of the ten USEPA Regional Offices has a hotline telephone number. ATSDR also operates an emergency response hotline manned 24 hours a day (404-498-0120). The ATSDR hotline staff is composed of toxicologists, physicians, and other scientists available to assist during an emergency involving hazardous substances in the environment.

EVALUATION OF HAZARDS

Occupational hygiene includes assessment of the nature and extent of human contact with biologic, chemical and physical hazards in the work environment. In the study of occupational disease, occupational hygiene techniques are applied to identify, evaluate and control the factors that cause work-related disease. While the techniques for evaluation are tailored to each type of hazard, the principles of evaluation can be generalized.

Over the range of types of air-borne exposures (e.g., gases and vapors, aerosols, biologic or physical agents), there are two general classes of measurement techniques. One class may be termed the extractive methods, in which the contaminants of interest are removed from the environment for laboratory analysis. With these methods, an air sampling device is used to collect the contaminants, usually from air in the vicinity of the worker's breathing zone. This sort of measurement of exposure is termed a personal sample, as it attempts to characterize the composition of the environment at the point the worker contacts it by inhalation. Most measurement methods assess air-borne contaminants due to the importance of inhalation

exposures; however, methods to measure contamination of surfaces, as well as the exposure of the skin, are available.

The second general class of measurement techniques are those which determine the analyte directly in the atmosphere. These techniques are described as monitoring methods, and they are usually derived from instrumental methods first used in the laboratory. Devices which perform automated chemical analysis, or make measurements based upon chromatographic or spectrophotometric methods are common. These monitoring methods can measure continuously and report results immediately, which allows the examination of the pattern of exposure as it changes over time. This often represents substantial improvement over the information provided by extractive sampling methods, which accumulate material over the time of sampling, and give a result which is time integrated over that period.

Evaluating current hazards

Gases and vapors

Over the range of exposures which are found in the work environment, the greatest number are typically present in the form of a gas or vapor. Of the 567 chemicals and materials for which there are OSHA Permissible Exposure Limits (PELs), approximately 300 are usually found as gases or vapors in the workplace. As these materials pose a hazard primarily due to inhalation (although skin contact or ingestion may also be significant routes of exposure), exposure measurement methods typically involve the collection of air near the point of inhalation. These measurements are called personal breathing zone samples.

Most gas and vapor sampling is performed by using a sampling medium which removes the contaminants from air, and concentrates them for laboratory analysis. These sampling devices are small enough to be placed in the breathing zone of the person being sampled and they usually contain solid materials which adsorb the contaminants from air and retain them for analysis (materials such as activated charcoal, silica gel, and porous polymers are typically used). Other sampling devices contain liquids, which absorb contaminants based upon solubility or a reaction of the contaminant with the sampling solution. Air comes into contact with the collection media in these samplers either by active movement of air through the medium by a small portable pump, or by natural diffusion of the contaminants into the sampler to the collection medium. In both types of sampling devices, the total amount of contaminant collected during the sampling period is determined by removing the contaminant from the media (usually by chemical or thermal desorption), with analysis using a laboratory instrument such as a gas chromatograph, or a high performance liquid chromatograph. These devices may be coupled with a mass spectrometer to provide positive identification of contaminants.

An alternative method for air sampling is to collect a sample of air directly from the atmosphere using an evacuated container or a flexible bag. The composition of the

air collected in this sample may be analyzed directly. Measurements made by these methods are described as grab samples. As the absolute quantity of material collected by these direct, or grab sampling techniques is small, these methods are generally limited to cases where very small amounts of contaminant can be accurately measured. Materials for which other methods are not applicable, such as highly reactive or unstable contaminants which cannot be preserved for later analysis, may be best measured by grab sampling.

Monitoring devices that can measure contaminants directly in the atmosphere are available for many gases and vapors. The simplest type of these are indicator or detector tubes, containing a chemically treated material that changes color in response to exposure to a contaminant. These devices are small and extremely simple to use, and can provide semiquantitative determination of a range of air-borne contaminants, such as carbon monoxide, mercury, and many organic solvents. At the next level of complexity are portable instruments that directly measure a single contaminant, such as oxygen, or provide a composite measurement of all combustible gases in an atmosphere. These latter two measurements are commonly made in the workplace to determine the safety of entering a confined space, such as a manhole or a storage tank.

The most sophisticated monitoring equipment is a set of instruments which are derived from devices previously used only in the laboratory. Instruments such as gas chromatographs with a range of detection systems, spectrophotometers, electrochemical monitors, and mass spectrometers have been miniaturized and made transportable for field use. These devices can provide the sort of detailed identification and analysis of air-borne contaminants which until recently has been only available by using extractive methods of sampling and analysis. Many of these devices are capable of providing continuous measurement of the concentration of air-borne contaminants, and displaying and recording results in real time. This capability allows observation of the change in level and composition of exposure through time, which is a powerful tool in the analysis of sources of exposures. This detailed information about the characteristics of exposure is also useful in the development of methods to control exposures.

Particulate material

A wide variety of solid and liquid materials suspended in air may be important as causes of occupational disease. These suspensions of particles in air can be collectively described as aerosols, a term which includes air containing solid particles (dusts), fine particles formed by condensation (fumes), and liquid particles (mists). The evaluation of exposure to these aerosols must consider the mass quantity and number of particles present in air (the concentration), as well as the size distribution, and chemical composition of the particles. As in the case of gases and vapors, exposure measures can be made by methods which remove the particulate materials from air for subsequent analysis, and by devices which measure the particulate content directly in air. Measurement methods which remove particulate

material from air usually operate on the basis of the physical properties of the material, e.g., the particle size, mass, or electrostatic charge of the particles. Once the particles are removed from air, they can be subjected to a variety of chemical analyses to determine their composition, and they can be examined microscopically to evaluate their shape and size.

These methods for collecting particles for analysis operate in a fundamentally different manner from the techniques used to extract gases and vapors from air. Even the smallest particles in an aerosol are many times larger, and more massive than the molecules in the mixture of gases which comprise air. Particles which can be seen with an unaided eye are approximately 200 μm in diameter. (For comparison, a red blood cell is about 7.5 μm in diameter.) Particles large enough to be seen are generally too large to penetrate beyond the extreme upper oral and nasal passages, while most of the particles 100 times smaller (2 μm diameter) will enter, and be deposited in the respiratory tract. Even these 2 μm diameter particles, while far too small to be seen, are vastly larger and heavier than the gas molecules in air, which have an average diameter of 0.0004 μm . Most particulate sampling methods, therefore, utilize this difference in size and mass between aerosol particles and molecules in air to remove aerosol particles for analysis.

The method most commonly used for personal measurement of aerosol exposures is filtration. As is the case for gas and vapor sampling, small filters can be placed in the breathing zone, and the aerosol particles are collected from air approximately at the point of inhalation. Several types of filtering media are used, depending upon the type of analysis which will be performed, and the properties of the contaminant being measured. For example, the particulate material collected from air can be measured by chemical analysis for metals using a method such as atomic absorption spectrophotometry, or the organic fraction may be extracted from the filter and analyzed by a chromatographic method. Dusts such as those found in mining atmospheres may be analyzed for their mineralogic composition. Where the shape and size of the particle are important factors in evaluating the hazard, such as is the case for asbestos and other mineral fibers, the collected particulate material is analyzed by counting and sizing the individual particles using optical or electron microscopy.

The hazard from air-borne particulate material varies greatly, depending in large part on the site of deposition within the respiratory tract. The size of the particles, expressed as the aerodynamic diameter, is the major factor which determines the region of the respiratory tract where a particle may be deposited. Most aerosols found in the workplace contain mixtures of particles of widely varying sizes. It is not unusual, for example, to find particles ranging in size by a factor of 100 (i.e., an average diameter of 2 μm , but individual particles ranging from less than 1 to 100 μm) within an aerosol in a workplace such as a coal mine, a bakery, or a construction site.

When a worker is exposed to a mixture such as this, the inhaled particles are distributed throughout the respiratory

tract on the basis of the particle aerodynamic diameter. Since the toxic effect of a particle may depend on the region of the respiratory tract in which it is deposited, exposure measurements are made using methods which classify aerosol particles on the basis of their size. There are many types of air sampling devices which are designed to separate particles into fractions that correspond to the region of the respiratory tract in which they are likely to be deposited. Particle size selective samplers include devices that are designed to effectively capture particles in several size ranges. Inhalable particle samplers efficiently collect particles up to 100 μm in aerodynamic diameter; which includes materials that are hazardous when deposited anywhere in the respiratory tract.

Samplers that are optimized to collect particles with aerodynamic diameters of 10 μm and smaller measure the thoracic particle mass fraction; these include particles that are hazardous when deposited in the pulmonary airways and the gas exchange region. Respirable particle samplers are optimized to efficiently collect particles with aerodynamic diameters of 4 μm and less; these particles are hazardous when deposited in the gas exchange region of the lung. This information about the size of the particles, along with the chemical analysis provides the data needed to fully evaluate the hazard which an aerosol exposure may present. For example, it has been shown that humans absorb lead differently depending on whether uptake is from inhalation or ingestion.

Depending upon the size of an inhaled aerosol particle, it may be deposited in the deep alveolar region of the lung, or it may be retained in the upper airways. The location of deposition is critical for a material such as lead, since virtually all the lead retained in the alveolar region is absorbed, while lead in the upper airways is cleared to the gastrointestinal tract where it is absorbed with an efficiency ranging from 10% to 30%.⁹ The amount of lead contained in these small (less than 1 μm in aerodynamic diameter) aerosols may make a much greater relative contribution to the blood lead than larger particles which are deposited in the upper airways. Air sampling to assess a hazard such as this would be conducted using a device which separates the particles into two or more fractions based upon their aerodynamic diameter. Air samplers such as miniature cyclones, or impactors are used to separate aerosols in this way, so that the size fractions can be analyzed separately.

There are a variety of instruments which directly measure the atmospheric concentration of aerosols. These instruments depend upon the physical properties of the particles in air to provide the means of detecting and measuring aerosol concentration. For example, the tendency of particles to scatter light provides the basis for a family of instruments known as optical particle counters. In these devices, air is drawn into a chamber and a light source is focused on the air sample. Particles suspended in the air scatter a portion of the light, and this amount of light is proportional to the quantity of air-borne material in the sample. Instruments incorporating lasers as the light source are capable of directly measuring the size, as well as the concentration of the particles in an air sample.

Another type of direct reading instrument operates by subjecting the aerosol particles to electrical charges, and measuring their movement in a charged field. These instruments are also capable of directly measuring the mass of material present in air, and providing information about the size characteristics of the particles. A third type of instrument measures the mass of aerosol in a sample by collecting the particulate material on a surface which is placed between a source of beta radiation and a beta radiation counter. The attenuation of radiation is proportional to the mass of particulate material from the sample, allowing the direct measurement of aerosol mass concentration in air.

Biologic hazards in air

Methods for evaluating biologic materials in air are a specialized set of techniques derived from the methods for measuring air-borne particulate material. In terms of methods for air sampling, there are two general classes of biologic hazards: those considered viable, which pose a risk through their capacity to grow and multiply in an exposed host, and the non-viable particles, which are hazardous due to the ability to produce an allergic response, regardless of whether the exposure agent is viable. The methods for measuring exposure to these hazards tend to be specific to the agent being evaluated, and are not standardized to the degree of other aerosols. The importance of methods to measure biologic hazards is apparent in studies of indoor environments, particularly in buildings with outbreaks of respiratory complaints, and in healthcare facilities.²⁷

Methods for measuring viable materials in air use equipment which is similar to that used for other air-borne particles, including filters, impactors, impingers, and open settling surfaces. The difference in these methods from the general aerosol sampling methods is in the need to preserve the viability of the collected material. The techniques for detecting and enumerating viable organisms require that conditions be suitable for the collected material to grow into observable colonies or plaques. The sampling devices therefore include a growth medium, in which the collected micro-organisms are retained, or can be preserved in a viable state so they can be transferred to a growth medium after sampling. Depending upon the purpose of the sampling, the growth medium can be tailored to support general growth, or it may be selective to favor the organisms of interest. In some investigations, the overall level of biologic contamination, measured in terms of total colony-forming units may be important.

Other investigations seek to address more specific concerns, such as the contamination originating from an air conditioning system in an office building. A study of this sort of problem would use selective media to evaluate particular types of micro-organisms. The range of collection and culturing techniques for air-borne micro-organisms, as well as the specialized nature of investigations of biologic hazards usually require expertise in microbiology for quantitative measurements and interpretation. Unlike other chemical and physical contaminants, there are no generally accepted standards for viable micro-organisms in air.

The second type of biologic hazard is an air-borne particle which produces an allergic response, regardless of whether the particle is viable. These particles are described as aeroallergens, and include pollens, some bacteria, fungal spores, and insect body parts. These materials are collected from air using techniques including filtration, impaction, and gravitational settling. The properties of the collected material may be determined by microscopic examination, culturing for the viable fraction, and immunoassay for the antigenic component of the air-borne material. These assay techniques are tailored to the property of interest, and investigations of air-borne allergens are usually designed to address specific exposures.

Measures of hazards in tissue or body fluids (biologic monitoring)

The use of exposure information in the investigation of occupational disease requires the assumption that exposure is a reasonable indicator or marker for the quantity of a toxic material which reaches a site in the body and elicits a response. Under some circumstances, this is a valid assumption, and useful exposure response associations can be observed. There are, however, many factors which can compromise the value of exposure measures as predictors of health effects. Exposure is a measure of the concentration of a contaminant in the environment external to the body. As was mentioned in the discussion of air sampling procedures, measurements can be made as close to the actual point of inhalation as possible (the breathing zone sample), but the air collected at this point is not identical to that which is inhaled. Once the air enters the respiratory tract, contaminants may be removed, distributed and metabolized by many possible mechanisms. There can be a great deal of variability in these mechanisms between individuals, resulting in very different quantities of an active material at sites where toxic effects occur, even though the individuals may have had the same measured level of external exposure.

Another factor which complicates the assessment of exposure is the ability of many toxic materials to enter the body by several routes. In addition to pulmonary absorption, materials may be cleared from the respiratory tract and swallowed, resulting in uptake from the gastrointestinal tract. Many industrial materials can also be absorbed directly through the skin. Measurement of contaminants in biologic media reflects the contributions from these multiple routes of exposure, as well as the variability in absorption, distribution, and metabolism between exposed individuals. Progress in biologic monitoring has been driven by the uncertainties in the relationship between measurement of contamination in the workplace environment, such as those made with conventional occupational hygiene air sampling methods, and the actual quantity of a toxic material which may be present in the body.

The measurement made in biologic media may be for a particular chemical itself, or its metabolites. A reversible biologic change which is characteristically induced by

exposure to a chemical is another type of measurement used to evaluate workplace exposure. These measurements can be made in blood, urine, exhaled breath, or other media. Biologic monitoring methods are usually used to complement measurements of inhalation exposures, as they provide information on the total exposure from all sources (non-occupational and workplace), and by all routes, including skin and gastrointestinal absorption. The medium which is selected for sampling can be chosen to suit a particular purpose, as materials (e.g., organic solvents) may be eliminated by several pathways. In a study of workers exposed to n-hexane, for example, the solvent was rapidly cleared from the body in exhaled breath, with a biologic half-time of approximately 15 minutes. N-hexane vapor may be measured in exhaled air during the period of exposure, providing information about the level of exposure in the short time before sample collection. A n-hexane metabolite is also excreted in the urine, so end-of-shift urine samples could be collected from the same workers and analyzed for 2,6-hexanedione, providing a time integrated measure of daily exposure.

There are reference values for measurements made in biologic media.^{4,6} The ACGIH has prepared these values, known as biologic exposure indices (BEIs), with documentation for their measurement and interpretation of results, for approximately 40 chemicals. In most cases, these values are chosen to represent the level of a determinant (the parent chemical, a metabolite, or a characteristic reversible biologic change) in biologic medium that would be observed in a healthy worker exposed by inhalation to the parent chemical at the level of the TLV. As such, the BEIs are not clear boundaries between safe and dangerous exposures; rather they are intended to be indirect reflections of dose, to be used in conjunction with environmental exposure measures.

Interpreting exposure measurement information

Information on exposure in the work environment is collected for a number of purposes. Exposure measurements may be compliance driven, that is, the measurements are made to determine the levels of workplace contaminants with reference to an exposure limit or guideline. There are several sources of exposure limits, as discussed earlier. Whilst the exposure limit values vary between sources, virtually all these limits are specific to the air-borne concentration of a single chemical, and the vast majority set a level which is not to be exceeded as a time integrated average over an 8–10-hour work shift. Exposure measurements made to determine compliance with these exposure limits, therefore, are usually made in a manner which allows direct comparison between a worker's exposure level and the limit, as measures of a single contaminant averaged over the full workshift.

Although these data help determine compliance with a limit, they may not be useful as a predictor of health risk or the relationship between exposure and health effects. Several factors must be considered in interpreting exposure

information, including simultaneous exposure to mixtures of toxic agents, variability in the composition and levels of exposure over time, exposure by multiple routes, and unusual working conditions. In addition, a standard or limit may not be protective against a risk or health effect of interest. The interpretation of exposure measurements in comparison to a legally mandated exposure limit (such as the OSHA Permissible Exposure Limits) or a recommended value (such as the NIOSH Recommended Exposure Limits or the ACGIH Threshold Limit Values) must be done with caution. These limit values and exposure standards are not intended to be clear lines between safe and unsafe conditions, nor are they meant to be indices of relative toxicity between substances. The philosophy underlying these values is that they represent conditions under which it is believed that nearly all workers may be repeatedly exposed without adverse health effects. Variations in individual susceptibility, for example will result in some workers experiencing adverse health effects when exposed at or below the exposure limit value. It is not appropriate, therefore, to conclude that adverse health effects cannot be related to workplace exposures simply because exposure measurements do not exceed a limit value or exposure standard.

Evaluating mixed exposures

While most exposure limits are specific to a single agent, the work environment is likely to be composed of mixtures of potentially hazardous materials. Virtually all workers are exposed to environments containing more than one potentially hazardous agent, with work in agriculture, manufacturing, and construction commonly presenting combinations of chemical or physical agents. The evaluation of potential health risks posed by occupational exposures should also recognize the effects of non-work-related exposures, such as the consumption of alcohol, tobacco, or the use of insect repellants, cosmetics, or other chemicals that may act in concert with workplace exposures. The complexity of exposures and resulting biologic responses is illustrated by the synergistic effect of exposures to noise and the solvent toluene, which results in a 2–3-times higher risk of hearing loss than exposure to either component alone.

Another example is exposure to carbon monoxide and methylene chloride, which both produce elevated levels of carboxyhemoglobin, reducing the blood's ability to carry oxygen. The combined effects of materials which act upon the same organ system are recognized in the ACGIH TLVs.⁴ For example, an atmosphere containing a mixture of solvents, each of which may have neurotoxic effects, should be evaluated in consideration of the additive effect of the exposure. The TLVs provide guidelines for assessing the effect of exposures when the components of a mixture have similar toxicologic properties.

In epidemiologic investigations of exposure–response associations, the comprehensive assessment of exposure enhances the likelihood that a study will correctly identify and evaluate these relationships. Although these studies

usually are conducted with some prior specification of the exposure(s) of interest, comprehensive exposure assessment is necessary to deal with confounding or effect modification by exposures which may not have been anticipated. Studies of the respiratory effects of sulfur dioxide (SO₂), for example, demonstrate the potentiating effect of inert aerosols such as sodium chloride when the two materials are present as combined inhalation exposures. Exposure to atmospheres containing both SO₂ and an aerosol results in a much greater restriction in pulmonary flow than is observed for SO₂ alone, while inhalation of sodium chloride aerosol alone has no effect on pulmonary flow.

One common pitfall of exposure assessment in these studies is discounting the possible role of an exposure as a causal agent because the association is not thought to be biologically plausible. For example, the unexpected finding that carbon monoxide exposure (CO) potentiates noise-induced high frequency threshold shifts illustrates the importance of conducting comprehensive assessments of exposure, even in cases where a particular exposure is of primary interest.

Evaluating exposure variability

Exposure results from human contact with a contaminant in the environment. Regardless of the route (inhalation, dermal contact, or ingestion), exposure can be considered to be part of a pathway between the source of a contaminant in the environment, to a site in the body where it can cause molecular or cellular damage. Exposure is measured as a marker of human interaction with a contaminated environment. Since the nature of this interaction can vary, the characterization of exposure should consider exposure to be part of a dynamic process which changes through time, not as a fixed quantity.

The variability in exposure can be broken down into components. The characteristics (i.e., composition and intensity) of the contamination in the environment are described as the ambient concentration. The composition, e.g., the chemical makeup, or the distribution of particle sizes may change through time. The second characteristic is the intensity of exposure, expressed as its concentration, e.g., parts of benzene vapor per million parts of air, or number of asbestos fibers per cubic centimeter of air. In many occupational environments, these characteristics of exposure are highly variable over a workday, resulting in a constantly changing exposure. The third major component of exposure variability is introduced by the characteristics of the individuals in the exposure environment. Even among jobs at fixed workstations, where workers perform similar tasks, there can be substantial exposure differences between individuals because of personal work practices.

These sources of exposure variability should be considered in designing an exposure assessment strategy, and in the interpretation of exposure information. When exposure varies widely over time, the time course of exposure must be considered. Industrial hygiene sampling methods which collect air-borne contaminants for laboratory analy-

sis provide a measurement which is integrated over the time of sampling. The temporal component of exposure variability is lost in such a measurement. For example, the atmosphere in a work environment could contain a steady state concentration of 1 ppm of a solvent, so the exposure of a worker spending a full shift in this area would be measured as 1 ppm as an 8-hour time-weighted average exposure. Another worker could spend a full shift in an environment in which the level of exposure to the same solvent varied widely, from periods of no detectable exposure, to very high but short-term peaks of exposure. If this second worker experienced a single, high peak exposure level of 48 ppm of the solvent for only 10 minutes a day, then spent the remainder of the shift in an unexposed area, this worker's 8-hour time-weighted average exposure would also be 1 ppm. Interpreting these two exposures to be equivalent, in terms of their likelihood of causing a toxic effect, could result in an erroneous conclusion. Without any further information about the actual time course of the exposure, however, these two workers could be classified as equally exposed.

Exposure limits and guidelines are set in a manner which attempts to recognize that the risk of health effects resulting from extremes of exposure over time. For rapidly acting chemicals which are known to cause toxic effects from brief exposures, exposure limits can be designated as short-term exposure limits (STELs). These values are intended to be levels measured over a short averaging period (usually 15 minutes), which should not be exceeded during any period, even if the 8-hour time-weighted average does not exceed the exposure limit. These STELs are set to prevent irritation, chronic or irreversible tissue damage, narcosis, or other impairment which would result in material risk. For some acutely toxic chemicals, the exposure limit is designated as a ceiling limit, which is a level not to be exceeded at any time. In practical terms, the duration of a ceiling exposure limit is defined by the shortest time period over which an exposure measurement can be made. Depending on the chemical of interest, and the availability of methods for measuring its concentration in air, this may be a virtually instantaneous measurement, or the limitations of the measurement method may extend it to a period of approximately 15 minutes.

Tasks as the basis for exposure assessment

The overall variability in exposure levels within a population can be very substantial. In some cases where workers have been grouped for air sampling and analysis on the basis of their job title (assembler, or chemical operator for example), exposure levels between individuals in the group have been found to vary by factors as great as 15-fold.²⁸ Repeated measures of exposure on individual workers made from day to day have shown that the level of exposure for the same worker can also be highly variable. The overall variability in exposure for individual members of a group can be partitioned into between-worker (differences between individual workers) and within-worker (day

to day or variability over time for an individual worker) components. Environmental and production factors have been found to have a strong influence on the within-worker (day-to-day) variability, but not on the between-worker variability. Groups working outdoors and those working without local exhaust ventilation generally have greater day-to-day variability than groups working indoors and those working with local exhaust ventilation. Mobile workers, and workers involved in intermittent processes, also have great day-to-day variability in exposure.

The significance of this finding is that the title of a job may not be a good predictor of exposure, as workers with the same job title may have very different exposures. Sampling a subset of individuals in a group with the same job title, then applying these sampling results to the entire group, may severely misclassify individuals on the basis of their actual exposure. An alternative approach to exposure assessment is to use job task as the primary classifying variable, rather than job, group, or department title. The task-based approach identifies the characteristic work activities that influence exposure, then forms worker groups on the basis of similar activities.

A study of workers exposed to ethylene oxide in a hospital, for example, would seek to identify the primary work tasks and activities that may result in ethylene oxide exposure, then to characterize the exposure associated with each task. This exposure measurement approach has revealed that workers who load and unload the sterilizer, for example, have a very different level and pattern of ethylene oxide exposure than workers who sort the packages of sterilized materials for distribution throughout the hospital. While workers performing these different tasks may have the same department name (for example, Central Sterilization) and job title (for example, sterile area technician), those who load and unload the sterilizer may have much higher exposures than the other workers. Measuring the exposure associated with the work task therefore provides the information needed to correctly classify workers on the basis of exposure, and to target the workers at highest exposure risk and the specific work tasks that contribute to that risk. Tasks associated with high exposure can be prioritized for control measures.

When exposure is used as a risk factor in studies of exposure-response associations, unrecognized variability may occur, resulting in misclassification of exposure among the members of the study population, and obscuring actual exposure-response relationships.

In most studies, exposure is actually measured for a small sample of the population, and only for part of the period of interest. Based upon these measurements and other information which may influence exposure, such as production conditions, presence of ventilation, or use of protective devices, exposure values may be estimated and applied to entire groups of workers. The assumption underlying this approach is that it is possible to identify groups of similarly exposed workers to which a single exposure value may be correctly assigned. The extent to which this assumption can be validated should be considered in the interpretation of study results, particularly in studies which show no

apparent association between exposure and response. This problem is especially serious in retrospective studies of diseases with long latency, as there is usually very limited historical information available on actual exposures. The likelihood of exposure misclassification, which is likely to obscure associations, should be considered carefully in interpreting the results of these studies.

Evaluating exposure by multiple routes

Exposure assessments typically focus on exposure by inhalation of gases, vapors and aerosols, but absorption through the skin can be another important route of exposure. This fact has been recognized in the case of exposures to pesticides, and dermal exposure has recently received more attention as a potential route of exposure for other chemicals. The OSHA permissible exposure limits, the ACGIH threshold limit values, and most other exposure guidelines include notations indicating cases in which skin contact may be a significant route of exposure. In the case of the TLVs, this notation appears for approximately 10% of the chemicals listed. The likelihood of dermal contact with potentially hazardous materials is great in some occupations and industries.

For example, dermal exposure to polycyclic aromatic hydrocarbons (PAH) among coke oven workers has been found to be as important as inhalation as a contributor to total exposure and absorbed dose.²⁹ When these workers implemented hygienic measures to reduce dermal absorption (including laundered work clothes and gloves before each shift), the weekly average excretion of a PAH metabolite (1-hydroxypyrene) was reduced by more than a third. This illustrates the importance of dermal exposure route in the classification of exposure when cumulative or average exposures are calculated, and in the development of control strategies to reduce exposure.

The uptake of chemicals through the skin depends on the molecular weight, lipid solubility, polarity, and state of ionization. There has been considerable effort to develop quantitative measurement methods for dermal absorption of chemicals. Methods of assessing dermal exposure have been classified into three general types: surrogate skin techniques which rely on a collection medium placed against the subject's skin; removal techniques where substances deposited on the skin are removed, generally by washing or wiping; and fluorescent tracer techniques that rely on the measurement of UV fluorescence from materials deposited and retained on the skin. An example of a surrogate skin technique is the use of cloth patches placed on the outside of workers' clothing and removed for analysis of chemical contamination as an estimate of the exposure of unprotected skin.

A similar method has been used with patches placed under the workers' clothing, to measure the quantity of a contaminant which penetrates protective clothing. Exposure to the surface of the hands has been estimated by providing workers with thin cotton inspector's gloves which are worn during tasks of interest. Analysis of the glove material then provides an estimate of the exposure

of unprotected skin of the hands. This approach has also been used to evaluate the performance of protective gloves by wearing the cotton glove under the protective glove. The removal techniques include rinsing the hands, or both the inside surface of the protective gloves and the hands, after a worker has performed the task of interest. The volume of rinse solution is collected and analyzed for the contaminant.

The interpretation of information obtained by measuring dermal contact is complicated by the absence of guidelines or reference values. Measurement of skin contact does not necessarily provide a direct indication of the quantity of a chemical which may be absorbed, as the relationship between the material found on the skin and the absorbed amount depends on several factors. The physical and chemical properties of the material, the anatomical area of contact, the duration of contact, and the individual characteristics of the exposed individual can all influence the relationship between skin contact and dermal absorption. The importance of dermal exposure should not be underestimated, particularly in the case of pesticides that have been shown to enter the body primarily by dermal absorption.

Several techniques have been developed to measure contaminants on surfaces which may be sources of dermal exposure in the workplace. The measurement of surface contamination in a working environment can provide an indirect indication of dermal exposure. Techniques for wipe sampling have been developed to measure surface contamination. These methods have been widely used in industries where exposure may result from resuspension of settled aerosols. For example, surface sampling for lead in industries such as foundries and lead smelters have been extensively performed. In cases where exposure of interest is non-volatile, such as metals and polychlorinated biphenyls (PCBs), surface contamination is a useful measure of the risk of exposure from skin absorption, or ingestion resulting from eating or smoking with contaminated hands. There is a standardized surface wiping method specified by OSHA which describes techniques for collecting samples from contaminated surfaces (OSHA Technical Manual, Sampling for Surface Contamination).

Evaluating unusual working conditions

Information on exposure should be interpreted in view of the overall conditions in the working environment. Even the OSHA Permissible Exposure Limits, which are legally enforceable, are not intended to be used as specific lines to distinguish between safe and dangerous working conditions. When interpreting the results of exposure measurements, an environment should not be assumed to be free from risk when exposure levels do not exceed the limit value. In the case of individual workers in the environment, reported symptoms should not be dismissed as non-work-related because measured exposure levels are below a limit value. Any interpretation of exposure information should recognize that there is uncertainty associated with both measurement of exposure, as well as the limit value

to which it is compared. The extent of individual variability in response to workplace exposure may be considerable and a conservative approach to the interpretation of exposure is appropriate.

Among a number of factors which may influence the response to workplace exposures, the duration of exposure period is one which has been recognized in the OSHA permissible exposure limits. Exposure measurements are generally made with the expectation that the individuals are in the working environment for the 'normal' 8-hour day, and 40-hour work week. Many jobs, including a substantial portion of those in manufacturing, operate on a schedule which exceeds this. The potential effect of extended duration on occupational exposure may be recognized, but it is rarely quantified. Of the over 600 materials for which there are OSHA PELs, only the lead standard specifies that the maximum daily allowable exposure level be adjusted down in proportion to overtime activities exceeding 8 hours. Another factor which should be considered in the interpretation of exposure information is the time of day during which the exposure occurred. At least 20% of the workforce in manufacturing jobs work non-daytime shifts. Although limited information is currently available on the physical and psychological effects of shift work, overall job performance, as well as behavioral and psychological function, are diminished in night shift workers compared to day shift workers. The possibility of combined effects of exposure and the time of day during which it occurs should be considered in investigations where both could affect health outcomes.

Assessing previous work exposures

Many occupational and environmental exposures produce clinical disease years after the initial exposure. Past exposures are therefore important with regard to attribution of disease in an individual or establishing a causal association using epidemiologic data. In many instances, available data are sufficient for estimating past exposures only qualitatively; however, these estimates are often useful for establishing plausible ranges of exposure. Estimating past exposures requires a systematic approach to information gathering. First, an inventory of potentially toxic substances and exposures for various jobs, work locations, and work tasks must be developed. This effort requires detailed knowledge of industrial processes, work procedures, and materials, and familiarity with the toxic properties of the substances present in the workplace environment. In addition, the ever-changing character of work must be considered.

Use of past exposure measurement data

In ideal circumstances, quantified personal monitoring data, obtained from air sampling or other dosimetric methods (e.g., radiation film badges). However, in the more typical situation, quantified exposure data are sparse or non-existent. Even when data are available, they often represent special exposure situations that were measured in response to particular concerns about workers' health or because of

compliance enforcement requirements. Evaluations of sampling data are best determined when there is documentation of the circumstances under which exposure measurements were taken. Furthermore, occupational hygiene data tend to be most complete for recent years in which promulgated exposure guidelines and standards have required initial and periodic exposure monitoring.

For epidemiologic investigation, rather than for clinical evaluation, these limitations may be more significant. Industrial hygiene sampling data measuring individual exposures are by far the most useful for exposure classification. It is usually not feasible to measure all exposures for all individuals; therefore, samples are collected that are thought to be representative of employees doing the same or similar tasks. Typically in epidemiologic studies, attempts are made to assign workers to various exposure classifications, based on types of exposures and exposure levels. Occupational hygiene sampling data are useful for this purpose when sufficient descriptive data are recorded to allow identification of individual workers or specific jobs for which the exposure data pertain.

Because exposures can change qualitatively and quantitatively over time, it is important that these changes be taken into consideration. Changes in occupational hygiene and analytic laboratory techniques may diminish the validity of some past exposure monitoring data.

Special sampling studies are useful for correlating results from different measurement methods and for assessing the validity of the exposure rating scheme – at least in reference to current exposure levels. For example, exposure to asbestos containing dusts was formerly measured in units of millions of particles per cubic foot of air (all particles) using an impinger rather than fibers per cubic foot centimeter of air by the membrane filter method. Use of these old sampling data may require the investigator to estimate a conversion from the old impinger method to the membrane filter method. As no direct conversion is possible, statistical analyses of simultaneous sampling data using both methods can be used to arrive at an approximate conversion factor.

Estimates of exposure using surrogate data

In the absence of complete quantified exposure data, potential occupational exposures can be identified using an assessment of raw material, process, tasks, and control information. Jobs and work areas may be classified with respect to exposure levels and potential exposures. A 'job-exposure matrix' is frequently generated which links worker exposure histories with health outcomes for clinical and epidemiologic analysis.

The types of information that the occupational hygienist incorporates into the exposure rating scheme include data from the following: air sampling, physical agent exposures (e.g., noise dosimetry), biologic monitoring, materials usage records and purchase orders, plant production records, job and task descriptions, and documentation of engineering controls and use of protective equipment. Table 4.1.2 provides a summary of data useful for estimating exposures. The following are potential uses and limita-

Company records

Process, descriptions, flow charts and plant layouts
Job and task descriptions
Raw materials and intermediates, by industrial process
Plant production records
Engineering control records
Industrial hygiene sampling records
Physical and biological agent measurements
Personal protective equipment availability and use
Inspection and accident reports
Biological monitoring results
Environmental discharge and incident reports
Medical records
Injury reports or workers' compensation records

Labor union records

Records of work locations
Injury/illness records

Government records

OSHA or State program inspections
NIOSH studies/Health Hazard Evaluation Reports
State OSHA or consultation reports
Workmen's Compensation Records

Insurance company records

Plant inspection/reports
Industrial hygiene studies

Table 4.1.2 Sources and types of information useful for evaluating past exposures

tions of various data source with respect to estimation of past exposure.

1. *Process descriptions, flow charts and plant layout.* Changing plant process and raw materials may significantly affect actual or potential occupational exposures. Process changes often result in new raw materials or intermediates of potential occupational health significance. Proximity of plant operations to each other also may be important. Ideally, plant records should be maintained in sufficient detail to permit identification of dates of process changes or major changes in plant layout or equipment.

2. *Job and task descriptions.* The most commonly used method for assigning employees to exposure categories in epidemiologic studies is the classification of job titles. In studies where only a few significant exposures are present, job titles generally allow suitable stratification into exposed and non-exposed populations. Changes in job titles over time should be recognized. While job titles are useful for exposure classification, additional information – such as specific tasks performed and plant location – may be needed to appropriately classify exposures. Assessment of task-specific exposures is very important for exposures experienced by maintenance and craft workers.

3. *Raw materials and intermediates by process.* Raw materials and intermediates should be recorded in sufficient detail to allow identification of processes or plant areas where raw materials are used and changes in the use of these over time. Because it is usually not possible to measure all exposures in a given process or area, it is important that the materials list be as complete as possible so that multiple potentially hazardous exposures may be evaluated in epidemiologic studies. Purchase records can be a valuable source of information on the types and quantities of materials used. Such data are particularly valuable for case-control studies that may be necessitated at some future time.

4. *Plant production records.* In addition to raw materials, plant production or output rate may affect exposures. In many instances changes in measured exposures without other apparent plant changes can be attributed to increased or decreased processing of the materials in question. Annual production volume by product is useful as a measure of change in potential exposures.

5. *Engineering control records.* Engineering controls are the preferred method for controlling occupational exposures and, typically, change significantly over time. Engineering records should be maintained in sufficient detail to identify controls by process or equipment over time. Both control system design and operational parameters are important. Special studies evaluating effectiveness of engineering control measures are especially useful as these may suggest important changes in employee exposures. Photographs can be valuable supplements to such record systems.

6. *Physical and biologic agents.* Plant raw materials lists are usually helpful in identifying potential chemical exposures; however, additional records are often necessary to characterize exposures to physical and biologic agents. Physical agents include ionizing and non-ionizing radiations, noise, and vibration; biologic agents include viruses, bacteria, fungi and other microbial antigenic material. Exposures to physical and biologic agents often are generated within the workplace, rather than resulting from the intended use of defined raw materials. The presence or absence of such exposures should be recorded as well as associated levels of exposure.

7. *Personal protective equipment.* Personal protective equipment – such as respirators, gloves, protective clothing and hearing protection – may affect actual worker exposures significantly. In addition to recording protective equipment in use during industrial monitoring studies, documents detailing protective equipment policies and procedures should be maintained. Specific processes or procedures requiring protective equipment should be identified in these records.

8. *Inspection and accident reports.* Accidental spills or leaks may represent significant exposures that must be considered when drawing conclusions from epidemiologic studies. Spills or accidents can result in greater potential for atypical routes of exposure, such as clothing contamination and skin contact. Failure to account for such exposures can lead to incorrect conclusions concerning health effects of apparently low exposures. Incidents such as major spills or leaks should be documented in sufficient detail to allow for estimation of the potential severity of intermittent excessive exposures, as well as identifying workers potentially exposed.

9. *Biologic monitoring results.* Although results of blood, urine, breath and other types of biologic monitoring usually are maintained in medical departments, they also are frequently used by industrial hygienists for exposure monitoring. These data are especially valuable when there are multiple routes of exposure entry, such as inhalation and absorption. The collection of these data and their integration with the environmental data should be made with proper and mandated safeguards for confidentiality.

10. *Environmental discharge and incident reports.* Health effects among residents of neighborhoods in close proximity to industrial plants may be of concern. Federal regulations require annual reports of environmental discharges for specified pollutants for certain manufacturing facilities.

11. *Employee surveys/interviews.* Surveys of long-term employees, wherein workers are asked to rate jobs according to perceived relative exposure intensities, provide ancillary information. Questionnaire survey results are most reliable when the variations in exposure levels of the agent of concern are readily apparent (e.g., dust, malodorous fumes, irritating gases). Validation of reporting with objective information (e.g., measurements) is desirable when available.

Historical reconstruction of workplace exposures is essential to the validity of occupational epidemiology, and for establishing a causal relationship between exposures and disease. When sufficient data exist that permit a quantitative exposure rating scale, it is possible to estimate, within reasonable limits, true relative exposure intensities. Estimates of potential exposures using production-related data are also useful for epidemiologic research and for relating workers symptoms and disease with potential occupational exposures.

While occupational exposure data vary substantially in both quality and quantity within and across industries, there has been substantial progress toward a consensus set of standardized data elements to be captured with measurements and qualitative estimates of exposure to air-borne chemical hazards as well as noise. The Joint ACGIH/AIHA Task Group on Occupational Exposure Databases has developed consensus recommendations with the goal of harmonizing the collection of exposure data across different work sites, companies, agencies, and other institutions.³⁰ Occupational hygienists and other health professionals responsible for developing and maintaining exposure information should consult this document as well as similar guidelines developed in Europe, including the report of the Working Group on Exposure Registries in Europe and the information database (COLCHIC) developed by French insurance funds in collaboration with the French National Research and Safety Institute.³¹

Linkage of industrial hygiene and health outcome data

Strategies for evaluating occupational exposures may differ according to the population being studied and the available exposure data. Both quantitative and qualitative exposures are useful for purposes of disease surveillance as well as in etiologic research. For etiologic research, both the magnitude of the observed relative risk for disease in relation to exposure as well as trends in relative risks with increasing exposures are important considerations in establishing causal relationships. In industry-based studies, it is often possible to develop a more limited list of operations, jobs and tasks, and associated exposures. The process of retrospective exposure assessment is facilitated when at least some quantitative historical exposure data

are available, and the number of possible exposures of concern is limited. Prospective studies of exposures and health conditions have the advantage of measuring both health outcomes and exposures simultaneously, thus the investigator has more control over the quality of exposure data, as well as their analyses and interpretation.

The link between occupational hygiene data and health outcome data, available from sources such as medical surveys, cancer registries, and death certificates, may be accomplished using employer personnel records or other records which characterize the study population. From such records, work histories, indexed by time interval at various exposure levels, can be constructed. Techniques for and difficulties associated with linking information on industrial work conditions with health data have been discussed by investigators active in this area (see Chapter 6). Studies such as the assessment of lung cancer among welders, and radon-related lung cancers among miners, provide excellent examples of linkage methods as well as associated strengths and limitations of these methods.

Direct exposure measurements from monitoring surveys that are specific for individual workers offer the best exposure data. More commonly, occupational epidemiology studies rely on exposure estimation where jobs and tasks within the industry are assigned exposure intensity levels. Creation of a job-exposure matrix that is specific for jobs, tasks and calendar years, and can be linked with employee personnel records, has become standard procedure in many epidemiologic studies. This approach allows for aggregation of jobs and tasks according to either exposure levels or similarity of tasks and materials handled, depending on the extent of available information.

A job-exposure matrix (JEM) is often used to define the presence or absence of specific exposures within a given industry or job title. In general, a JEM can be organized as an array of information which relates industry and/or job titles with occupational exposures. Each cell entry in the array then contains a measure of exposure for the job title/chemical pair. Entries can be quantitative when sufficient exposure measurement data are available, semi-quantitative (e.g., categories of exposure), or qualitative (e.g., exposed or unexposed). If exposures vary with time period, a third dimension can be added to the JEM to account for temporal variations. More elaborate JEMs can sometimes be developed if jobs are analyzed at the task level. Any given job may be further characterized as a specific number of tasks, each with an associated exposure level.

JEMs have been used effectively to combine observational or direct exposure measurements with past work histories, to derive a measure of overall exposure for both surveillance and etiologic research. JEMs provide a global evaluation of a job category which can be used, through data linkages, to estimate exposures of anyone who worked in that job, or task, with their cumulative exposures based on length of employment in that job. Clearly there is some loss of precision compared to direct expert assessment and personal exposure measurements, but there can be very significant cost savings thus making it possible to study larger groups of workers than would be

possible if individual longitudinal exposure assessments were needed. In addition to their value for etiologic research, JEMs provide a useful tool for surveillance where potential exposures to many substances or work circumstances can be evaluated.

JEMs have been developed using many different techniques and in varying degrees of detail. Population-based JEMs may use broad definitions of exposures based on industry SIC codes and occupational codes. Industry-specific JEMs can often provide a much greater degree of detail and precision in defining exposures. While JEMs have largely been used for studies of chemical or physical hazards, more recent efforts have extended the JEM concept to include a wider spectrum of hazards including physical, chemical, biologic, ergonomic, and psychosocial factors. In addition to new dimensions of the matrix allowing for factors other than chemicals, the conceptual model includes more extensive documentation concerning exposure definitions and reference data sources.

The types of data which can be used to develop a JEM for linking industrial hygiene and health data include the following: occupational hygiene survey data, job classifications and descriptions, personnel employment records of workers, information on work location within a plant for specific jobs, and where available, medical records. Medical records, although most valuable as a source for case finding for injuries, accidents, dermatitis and other non-disabling conditions, sometimes contain results of biologic monitoring that can be an ancillary source of exposure classification.

Existing occupational hygiene or health physics sampling data, which are of obvious research value, may need to be augmented by currently obtained measurements in cases where many jobs cannot be classified into exposure level categories. When major changes in sampling and quantification technology have occurred over time, it may be inappropriate to add the newly obtained data to the historical data. Instead, the new data can be incorporated to generate ordinal exposure scales for the various jobs in the plant, or to confirm judgments that certain work locations and jobs probably entail no or minimal exposure level.

Resources seldom permit extensive occupational hygiene surveys; thus, a selective approach is recommended in which special groups of workers or job types are targeted for monitoring. These groups can be workers for whom data have never been collected, or workers in jobs where previous research has indicated important disease risks. Maintenance, crafts, quality control and laboratory workers are groups that frequently go unmonitored. Periodic monitoring surveys of these workers, especially maintenance workers who represent sizable proportions of the workforce in many industries, would serve to rectify the common problem of unknown exposure profiles. Almost invariably there will be some jobs that cannot be classified according to exposure level, either because there is inadequate job description (e.g., the laborer designation) or because sampling cannot be performed. This circumstance will necessitate the creation of an unknown exposure category for some workers in the study. The health experience of such workers should be evaluated in a similar manner as

that of workers with estimatable exposure profiles, although the results for the former will be less informative. Deletion of workers with unknown exposures would be wasteful of information and may introduce bias into the study.

The JEM that is generated should be documented carefully so as to indicate the basis for assignment of exposure levels. Thus, the occupational hygienist should maintain a file that indicates each job or task included in the analysis – the exposure value or rankings – by time period, and the data sources that were used to derive exposure estimates. The source information should indicate whether a given estimate was based on occupational hygiene sampling data, the nature of the sampling (e.g., area or personal, compliance or routine monitoring), the number of samples and the range of values, and whether the estimate was based on judgment. Documentation of sources of error and uncertainty as well as assumptions used in the exposure assessment process should be maintained.

PRINCIPLES AND LIMITATIONS OF CONTROLS

Hazard control in the working environment is one of the primary goals of occupational hygiene. The elimination, or reduction of hazards to the extent feasible is the primary means of prevention for occupational disease and injury. The strategy for effective hazard control is an ordered hierarchy, which NIOSH³² has described as including three elements, in order of effectiveness:

1. first, prevent or contain hazardous workplace emissions at their source;
2. next, remove the emissions from the pathway between the source and the worker;
3. last, control the exposure of the worker with barriers between the worker and the hazardous work environment.

This strategy mandates the use of engineering control methods on the environment as the primary means of exposure prevention. These controls may be implemented in several forms, or in combinations as part of an overall prevention strategy. The methods include substitution of materials for less hazardous substances, modification of the working environment to contain the source of the hazard, isolation of the worker from the hazardous environment, removal of the hazardous substance by ventilation, modification of work practices to reduce exposure, and use of personal protective equipment to reduce exposure. Use of this protective equipment, including respirators, is intentionally mentioned last. Respiratory protective equipment should be considered the least preferable means of hazard control, implemented only when other means of control are not feasible or effective.

This hierarchical approach to exposure control has been recommended practice, but it is now specified in the regulatory language of the OSHA respiratory protection standard. OSHA has stated that 'In the control of those occupational diseases caused by breathing air contaminated with harmful dusts, fogs, fumes, mists, gases, smokes,

sprays, or vapors, the primary objective shall be to prevent atmospheric contamination. This shall be accomplished as far as feasible by accepted engineering control measures (for example, enclosure or confinement of the operation, general and local ventilation, and substitution of less toxic materials). When effective engineering controls are not feasible, or while they are being instituted, appropriate respirators shall be used' (29 CFR 1910.134).

Material substitution

The preferred method of direct intervention to reduce workplace hazards is the removal of a toxic material and its replacement with a less toxic substitute. This practice is well established as a means of reducing risk in the workplace as well as in the general environment. Elimination or reduction of extremely toxic materials, such as asbestos as an insulating material, or benzene in solvents, adhesives, and gasoline illustrate the principle of substitution. These examples also demonstrate another factor which must be considered in substitution: the risk of replacing one hazard with another. Some of the materials used to replace asbestos as an insulating material, such as man-made mineral fibers and fibrous glass, may also have adverse respiratory effects, as more information is discovered about their toxicity. The replacement of benzene with another chemical with similar solvent properties, such as hexane, may reduce the risk of exposure to a carcinogen, but increase the hazard of exposure to a neurotoxin. Substitution is an important method of primary prevention of workplace exposures, but it should be practiced with a recognition of the effect the replacement material may have on the work environment. The result of substitution should not be the replacement of one hazard with another.

Process modification

The introduction of contaminants into the work environment may be prevented by changing the characteristics of the source. The application of engineering control technology in the design of industrial processes is a very effective method of intervention to reduce exposures. For example, the technology of spray painting has changed, substantially reducing solvent exposures by using airless atomization systems instead of compressed air spray guns. Many common industrial processes, such as material handling procedures can be redesigned to minimize the release of contaminants. At the design stage of a new industrial process, or in the modification of existing operations, exposure control should be included as a central design element. The anticipation and control of potential hazards at the design stage is more efficient than remediation of existing conditions.

Isolation

Isolation is an effective method of intervention to interrupt the pathway between the source of a hazard and the worker. The general approach of isolation can be implemented

in two ways: (1) by enclosure to isolate a source from the working environment, or (2) by isolating the workers from a contaminated environment. Although a comprehensive exposure control strategy may include both approaches, containment of the source is generally preferable.

A common example of containment as a means of hazard control is the glove box used in handling infectious materials, extremely toxic chemicals, or radioactive materials. This approach is particularly well suited to control individual point sources of contaminants, or physical hazards such as noise. By preventing the release of a hazardous agent into the work environment, exposure is controlled at the source.

In cases where contaminants are released from multiple sources dispersed through the work environment, isolation of the workers from the contaminated environment may be preferable. While this approach does not prevent the release of the hazard into the environment, it is possible to control exposure by protecting workers through isolation. The use of clean-air-supplied control rooms in chemical production facilities is an example of isolation of workers from general environmental contamination.

Administrative and work practice controls

Measures can be taken to limit or restrict the opportunity for exposure through changes in the manner in which work is performed. These controls are a hybrid, incorporating some features of source control and some modifications of work practices. Administrative controls may be implemented to prevent release or contain hazardous emissions at their source. In the healthcare setting, for example, administrative controls such as rapid identification, early treatment, and isolation of potential tuberculosis transmitters, limiting worker access to acid-fast bacilli (AFB) isolation rooms and other administrative procedures could be implemented to reduce risk of exposure. Modification of procedures such as using portable x-ray units in the room of a confirmed or potential tuberculosis transmitter, rather than moving the infectious person to the central x-ray department, is another example of the use of administrative control to reduce the chance of exposure.

Work practice modifications also can be implemented to reduce exposures. For example, methods used for clean up of lead-containing dust at weapon firing ranges makes a significant difference in the general level of contamination and personal exposure. Instead of using brooms to sweep up dry dust, which generates large amounts of lead-containing aerosols, vacuuming with equipment incorporating high-efficiency particulate (HEPA) filters keeps lead dust from being suspended, significantly reducing exposures. Analysis of individual work tasks also can identify practices that contribute to exposure. Painters using spray guns in ventilated booths, for example, may unnecessarily increase their exposure to solvent vapors by moving into the booth when they paint the back of a large part, rather than turning the part so they can always spray paint into the booth. Changing work practices such as these can reduce exposure significantly, and they are most likely to be effective when they are developed through on-site evaluation, with full participation to the workers who are actually performing the job.

Ventilation

In the working environment, ventilation is a central component of hazard control. There are two general types of ventilation: (1) dilution ventilation (also known as general or comfort ventilation), and (2) local exhaust ventilation. Virtually any indoor space has some amount of dilution ventilation, even if it is only the natural infiltration of outside air. The control of contaminant sources in the workplace frequently requires additional ventilation, in the form of local exhaust to capture contaminants at or near their source, and remove them from the work environment. These two types of ventilation are very different in design and performance, and are discussed separately.

Dilution ventilation

Dilution ventilation operates on the principle of replacement of contaminated air with fresh air. The simplest form is the natural entry of outdoor air through drafts around windows, doors and other openings. Most buildings used as places of employment have at least some means of providing mechanical air movement to supplement the natural airflow. Mechanical roof ventilators or wall fans are common in buildings used as workplaces. In office buildings where there are no industrial processes which release contaminants, the human occupants may be the primary source of indoor pollution. General building air provided by a heating, ventilation, and air conditioning (HVAC) system may be the only means of controlling the carbon dioxide, water vapor, particulate material, and biologic aerosols which are the result of human occupancy. Ventilation guidelines for general dilution are provided by the American Society of Heating, Refrigerating and Air-Conditioning Engineers (ASHRAE)³³ to specify minimum ventilation rates and indoor air quality which provide an acceptable work environment to building occupants, and the quantity of ventilation needed '...to minimize the potential for adverse health effects.'

For workplaces where there are sources of contamination in addition to human occupancy, dilution ventilation is generally not as effective a control method. It may be applicable in a limited number of situations, only when several criteria are met. Typically, dilution ventilation may be adequate in workplaces where small amounts of contaminants are released at uniform rates. In these cases, a reasonable amount of air added to the work space may be sufficient to dilute the contaminants to a level at which they do not pose a hazard. This approach is limited, therefore, to contaminants with low toxicity, and environments in which workers do not have contact with the contaminant until after it has been diluted. The volume of air which is needed to dilute contaminants to acceptable levels is usually large, requiring large and expensive air-handling systems to move the air, as well as to heat and cool it. The lack of positive control over the sources of contaminants, as well as the high airflow requirements and operating costs, usually limit the usefulness of dilution ventilation systems as exposure control methods in the workplace. These systems may reduce the amount of

contaminant present in the work environment, but they do not control its release.

Local exhaust ventilation

Local exhaust systems differ fundamentally from dilution systems. The operating principle of local exhaust ventilation is the capture of air contaminants at the source, preventing their dispersion in the environment. These local systems control emissions and prevent exposures, interrupting the pathway between the source of the contaminant and the worker. Local exhaust systems are usually tailored to the source they control. The components of the systems include the hood, which is the device to capture the air and facilitate its entry into the exhaust system; the fan which provides the force to move air into the system; and the duct work connecting the hood and the fan. Many systems also include an air cleaning device, such as a filter, to remove contaminants before the air is released to the environment. The hood, which is the collection point of the contaminated air, is typically designed in a manner which encloses the source to the extent possible. It may be designed to fit around the shape of existing machinery, or to receive material which is released from the source, such as the metal particles thrown from a grinding wheel, or the dust created by a circular saw (Fig. 4.1.7).

The design and testing of local exhaust systems is a specialized aspect of ventilation engineering. There are several sources of guidance which are very useful in the construction of systems which are effective in controlling exposures by local ventilation. These are included in the References, and should be consulted as sources of further information.

Personal protective equipment

A variety of devices are available to provide a barrier between a worker and a contaminated environment. These

Figure 4.1.7: An example of local exhaust ventilation, in this case used over a lathe-generated coolant mist and possible metal dusts.

include equipment to protect the eyes, such as safety glasses, goggles, and face shields. There are many types of skin protection, including gloves, aprons, and full body suits made of materials which are impervious to chemicals. The selection and use of these devices is largely driven by the particular application, and there is a large number of choices of protective equipment available.

The choice of chemical protective clothing for the skin usually centers on gloves, although the principles guiding the selection can apply to equipment that protects part or all of the body. The selection of chemical-protective gloves should include analysis of both the job task and the exposure against which protection is needed. The job task analysis should also include ergonomic factors, such as the manual dexterity, grip, and tactility required by the task. Guidance in the selection of gloves is available from the American National Standard for Hand Protection Selection Criteria.³⁴ This document establishes performance classes for various types of protective gloves, and it includes rating scales for the following factors: permeation, penetration, degradation, cut, puncture, flame, abrasion, heat and cold. This information, along with the analysis of the exposure the glove will protect against, will guide the selection of a suitable glove for the situation. The MSDS for the materials in use may also be a good source of information to guide the selection of gloves, and specific recommendations are often included on the MSDS. This guidance should not be a substitute for a thoughtful analysis of each job-task exposure situation, however. The demands of each work environment and characteristics of the individual worker must be considered in the selection process.

Information on the properties and characteristics of gloves is available from a number of sources, including the glove manufacturers. Publications that summarize available guidance on the selection of gloves and other protective equipment are included in the references.³⁵⁻³⁷

Respiratory protective devices

Respiratory protective devices are used to provide protection from exposure by inhalation. There are several factors which must be considered in the use of respiratory protection beyond the general considerations for other protective devices. OSHA has a specific regulation for respirator use (29 CFR 1910.134). In addition, some OSHA standards for specific air contaminants such as asbestos and lead include requirements for respiratory protection programs. These legal requirements, as well as the importance of matching the choice of respiratory protection with both the hazard and the individual respirator user, make respirator selection and use more complex than other protective equipment. The correct choice of a respirator depends upon the identity of the particular contaminant, as well as the concentrations at which the contaminant is present in the workplace environment. The ability of the individual worker to wear the respirator in a manner that provides adequate protection also must be determined as part of a respirator selection and use program. The degree of protection that a respirator provides in the working environment

varies widely between individual workers. Comprehensive respiratory protection programs must include respirator fit testing to ensure that each respirator performs effectively for the individual user.

NIOSH has exclusive authority over respirators, except for mine escape and rescue devices. Employers must select a respirator certified by NIOSH. There are two general types of respiratory protection. Respirators may remove contaminants from air by filtration, adsorption, or chemical reaction. Respirators which operate by this principle are described as air-purifying respirators. Respirators which supply air from a source other than the surrounding environment (such as from a cylinder of compressed air) are known as atmosphere-supplying respirators. Both types of respirators are tested and certified for use by NIOSH.

As a guide to the selection and use of respiratory protection, OSHA has prepared a respiratory protection advisor, which is based upon the requirements of the OSHA respiratory protection standard and the guidance of the NIOSH Respiratory Decision Logic. NIOSH has also incorporated information on respiratory protection in its Pocket Guide to Chemical Hazards. Both are sources of practical guidance on the selection of respiratory protection that is appropriate to the work situation for which respirator use is being considered. The OSHA advisor covers most elements of the respiratory protection program including selection criteria, medical evaluations, procedures for proper use, fit testing, and maintenance procedures. Proper selection and, if appropriate, fit testing of tight-fitting facepieces are necessary to assure that the respirator will provide adequate protection against the contaminants that affect use. Medical evaluations are necessary to determine whether the user is fit to wear a respirator without adverse health effects. Training on procedures for proper use and maintenance is needed so the wearer uses the respirator in a safe and healthful manner.

Some OSHA standards have specific respirator requirements when certain contaminants are present in the workplace, such as lead and asbestos. When these contaminants are present in the workplace, the substance-specific standard takes precedence over any recommendations provided by the respirator selection decision logic.

The OSHA respiratory protection advisor is designed to guide the user through the respirator selection process. The advisor asks if the atmosphere is oxygen deficient, that is if the oxygen content is less than 21%. For example, for work in an area with poor ventilation, or in a confined space, it is necessary to measure the oxygen level. If the atmosphere is oxygen deficient, then an atmosphere-supplying respirator is required. The user must be aware of the identity and approximate air-borne concentration of the contaminant the respirator will protect against. This requires an exposure assessment to determine the type and amount of hazardous exposure. The advisor asks the type of contaminant (particulate or gas) the respirator will protect against. It also asks whether the contaminant(s) is an eye irritant, or can cause eye damage at the exposure concentration. For gaseous contaminants, the maximum concentration of contaminants in the workplace must be known (in units of parts per

million or milligrams per cubic meter). For respirators to protect against particles, the user is asked if there is oil present in the workplace air, the filter efficiency that is desired, and whether the filter will be used for more than 8 hours. The advisor also asks about the existence of special working conditions, such as welding in confined spaces and abrasive blasting.

This guidance is based upon the NIOSH Respirator Decision Logic and the OSHA Respirator Standard (29 CFR191 0.134). The actual choice of the appropriate respirator is made with consideration of the assigned protection factor for the respirator and the expected concentration of the contaminant(s) that are present in the working environment. The assigned protection factor (APF), which is the ratio of the concentration of the contaminant outside the mask to the concentration inside the mask, is the key to evaluating the respirator's efficiency at removing air-borne contaminants. For example, a single-use disposable dust mask may have an APF of 5, meaning there is a five to one ratio between the concentration of the contaminant in air outside the respirator to the concentration inside the respirator. Put another way, such a respirator would allow 20% penetration of the contaminant it is designed to protect against. A full facepiece respirator with an HEPA filter would have an APF of 50, allowing only 2% of the contaminant to penetrate.

In practice, the APF guides the selection of the respirator to the one that provides sufficient protection. To choose a respirator for a particular exposure situation, the expected concentration of the contaminant (either an 8-hour TWA, or a short-term concentration) is divided by the exposure limit for the contaminant (the OSHA PEL, the NIOSH REL, or some other exposure limit). The result of this division is the minimum respirator protection factor required. For example, suppose respirators were being considered to protect workers in a factory where exposure control measures such as ventilation were either not feasible or were in the process of implementation to reduce exposure to Portland cement dust. The OSHA and NIOSH exposure limit for total Portland cement dust is 10 mg/m³. If the expected dust concentration in the workplace were approximately 20 mg/m³, then the minimum respirator protection factor required would be 20 divided by 10, or 2. Using the tables of APFs for the various types of particulate respirators, as described in the respirator decision logic, a properly fitted single-use respirator (which has an APF of 5) would be appropriate. If the exposure agent were a material of greater toxicity, such as the pesticide Endrin, which has OSHA and NIOSH exposure limit of 0.1 mg/m³, protection against an atmosphere containing 20 mg/m³ of the contaminant would require a respirator with a minimum protection factor of 200, which would indicate that a positive-pressure supplied-air respirator is needed.

Respirators can provide effective personal protection only when they are properly selected and when they are used in the context of a comprehensive respiratory protection program. OSHA has specified the minimum requirements for an acceptable program (29 CFR 1910.134). In order for respirators to provide adequate worker protec-

tion, both the proper selection and the correct use of respirators are essential. Despite the apparent simplicity of respirator use, respirators can be unreliable if not selected and used in a comprehensive protection program and are cumbersome and uncomfortable when used for extended periods of time. Respirators are the least preferred method of protection from respiratory hazards, and they should be used only when engineering controls are not technically feasible, while controls are being installed or repaired, or in emergency and other temporary situations.

Education and training

Worker education and training are key components of effective primary prevention programs for workplace injuries and illnesses. Workers must understand the physical and chemical hazards associated with their work as well as methods for controlling these hazards. Worker training is defined as instruction in recognizing hazards, and in using available methods of worker protection, whereas worker education is defined as instruction in analyzing and responding to new circumstances and conditions.

OSHA substance-specific regulations such as asbestos, lead, arsenic, and cotton dust require worker education and training, although these regulations often lack detailed training specifications. Training requirements also are contained in several OSHA process specific standards such as the respiratory protection standard, the blood-borne pathogens standard and the standard concerning process safety management for highly hazardous materials. In addition, the OSHA Hazard Communication Standard which was promulgated in 1985 establishes generic training requirements for hazardous substances.

The OSHA Hazard Communication Standard requires chemical manufacturers and importers to provide hazard information to users of their products. Information must be provided in the form of MSDS and product labels. The standard requires that employees be provided with information and training on hazardous chemicals in the workplace. Training must include the following.

- Information concerning requirements of the OSHA standard.
- Identification of hazardous materials in the work area.
- Information on the company's written hazard communication standard.
- Methods for detecting presence or release of hazardous chemicals in the work area.
- Specific hazards of chemicals in the workplace.
- Measures to protect workers from exposure to hazardous chemicals.
- Details concerning the employer's hazard labeling system for chemicals in the workplace.

Quality worker education and training must consider special needs of the worker and appropriate means of training delivery. While OSHA standards require training, little specification is provided concerning training content, delivery or quality assurance. The National Institute of Environmental Health Sciences (NIEHS) was given major

responsibility for initiating a training grants program under the Superfund Amendments and Reauthorization Act of 1986 (SARA). The primary objective of this program is to fund non-profit organizations, with a demonstrated track record of providing occupational safety and health education, to develop and deliver high-quality training to workers who are involved in handling hazardous waste or in responding to emergency releases of hazardous materials.

Since the initiation of the Hazardous Waste Worker Training Program in 1987, the NIEHS has developed a strong network of non-profit organizations that are committed to protecting workers and their communities by delivering high-quality, peer-reviewed safety and health curriculum to target populations of hazardous waste workers and emergency responders. A national clearinghouse for worker training has been established by NIEHS (<http://www.wetp.org/>). A consensus working group has developed minimum criteria recommendations for worker training quality assurance. The key components of these recommendations include: (1) experienced training program staff; (2) a well-defined training plan with tested curricula and materials; (3) students with prerequisite job skills; (4) adequate training facilities including provisions for hands-on training and demonstrations; and (5) quality control and evaluation plans including adequate peer review of the training program.

4.2 Occupational Health Surveillance

Edward L Baker, Thomas P Matte

GENERAL PRINCIPLES

Surveillance is the ongoing, systematic collection, analysis, and interpretation of health data essential to the planning, implementation, and evaluation of public health practice, which is closely integrated with the timely dissemination of these data to those who need to know.¹ To be effective, surveillance must be directly linked to preventive action.^{2,3} In the case of occupational health, the actions prompted by the surveillance system should be directed not only at the individual case or the affected group, but also at the responsible workplace factors.⁴ Surveillance programs (i.e., secondary prevention) should be designed to support programs intended to control workplace hazards (i.e., primary prevention). In occupational safety and health,^{5,6} surveillance programs should:

- identify cases of occupational illness or injury; and/or
- monitor trends of occupational illness or injury.

Identifying cases

The purpose of case identification is to target an intervention of direct value to the affected individual and to others at risk of developing the same disorder.⁷ Case identification is followed by attempts to identify other individuals at risk and to control environmental factors that are responsible for causing disease. Case identification is found in three types of surveillance programs:

- medical screening;
- healthcare provider reporting; and
- employer case reporting.

Monitoring trends

Surveillance programs in the workplace can also be used to monitor trends of illness, injury, or exposure to workplace hazards.⁸ In such activity, surveillance data are developed to assess variations in rates between (1) different industrial groups, (2) different geographic areas, and (3) different time periods. From such comparisons, health officials can identify target industries or geographic areas requiring further investigation or intervention.

In this way, surveillance of health or exposure trends is used to evaluate the efficacy of programs designed to control occupational hazards. Surveillance of occupational disease and injury can involve monitoring of either health effects among the workforce, or hazards present in the workplace.⁹ In many situations, surveillance of individual health effects or workplace hazards alone may be useful.¹⁰ Linkage of the data derived from health effects with hazard surveillance for the same population is even more desirable.¹¹

Health effects surveillance

In surveillance of health effects, a system may target the actual health event^{12,13} (i.e., the occurrence of an occupa-

tional injury or the diagnosis of a case of an occupational illness) or a change in a biologic function^{14,15} of an exposed individual (e.g., loss of pulmonary function or disruption of heme metabolism). For surveillance purposes, occupational illnesses can be divided into two groups:

- disorders caused primarily by a single occupational exposure or hazard (e.g., lead poisoning¹⁶ or silicosis); and
- disorders of multifactorial etiology for which occupational factors may serve as one of several causal factors (e.g., lung cancer¹⁷).

Further, occupational hazards may exacerbate a pre-existing health condition.

Surveillance of disorders caused by a single exposure or hazard can be accomplished by specifically identifying the condition and developing an approach to evaluate the health status of the worker and the worker's exposure history. Such diseases caused primarily by a single occupational exposure or hazard are termed occupational diseases by the World Health Organization (WHO). Surveillance of multifactorial diseases for which occupational factors may play a contributing role is seldom useful. Surveillance is made difficult by problems in diagnosis of the condition or in ascertainment of the relative importance of non-occupational factors in disease etiology. Control of such conditions is best accomplished by relying on primary control of the offending hazard through environmental measures and through the performance of hazard surveillance to monitor the effectiveness of such controls.

Hazard surveillance

Hazard surveillance consists of the periodic characterization of chemical or physical hazards in the workplace.¹¹ Such characterization can be accomplished by direct measurement of air-borne contaminants, using industrial hygiene procedures, or by indirect approaches for assessment of the degree of hazard present in the work environment. Because many chemical, physical, and biologic agents have been found to present a significant hazard to the health of workers, surveillance of the occurrences of hazards provides very useful information, even in the absence of simultaneous health status assessment. In many industries, certain types of hazard surveillance (i.e., direct measurement of levels of air-borne contaminants or noise level) are used to direct strategies for primary prevention.¹⁸

CONDUCT OF SURVEILLANCE

Use of medical screening data

Medical screening is the administration of a medical test for the purpose of detecting organ dysfunction or disease

before the person would normally seek medical care and at a time when intervention is beneficial.¹⁹ Screening tests may indicate the presence of a disease or merely a higher probability of disease and the need for additional, confirmatory testing.

If it is performed correctly, conduct of an occupational health-screening program is one of the most complex processes in medical practice. In designing the program, the practitioner must be familiar with clinical medicine and toxicology, and understand the importance of a standardized approach to data collection.²⁰⁻²² In analyzing and interpreting the data, the practitioner must be familiar with epidemiology and clinical decision analysis, and understand the applicability of industrial hygiene exposure measurements. Finally, in making recommendations based on these interpretations, the practitioner must be cognizant of existing laws and regulations and act ethically in situations in which conflicts of interest often exist.^{23,24}

Screening tests have certain operational characteristics that should be considered in designing and evaluating workplace medical programs.

- The *sensitivity* of a screening test is the probability that it will detect diseased individuals (i.e., recognize their disease).
- The *specificity* of a screening test is the probability that it will not label as diseased individuals who are free of the disease in question.
- The *predictive* value of a positive screening test (sometimes referred to as the positive predictive value) is the probability that a person with an abnormal test truly has the disease. Conversely, the predictive value of a negative screening test (sometimes referred to as the negative predictive value) is the probability that a person who has a normal test result is truly free of disease. The determination of 'true' disease status requires the administration of a definitive diagnostic test to a screened population. The predictive value depends not only on the sensitivity and specificity of the test used, but also on the proportion of truly diseased people in the population being screened.
- The *reliability* or *reproducibility* of a screening test is its ability to produce consistent test results on repeated administration to the same person (unless, of course, the person's disease status has changed).

Surveillance versus screening – terminology

As described in the definitions given earlier, the term surveillance encompasses a broad range of activities that includes monitoring the results of screening. The term medical surveillance in Occupational Safety and Health Administration (OSHA) Standards corresponds reasonably well in usage with the term screening.¹⁹ The process of medical surveillance, or screening, involves direct medical evaluations of individuals at risk for the development of certain disorders. 'Surveillance' describes any use of health or exposure data to identify cases or monitor trends; screening is one source of health data.

Purpose of medical screening and biologic monitoring

The main focus of workplace medical examination programs should be screening to benefit individual workers. In the context of the workplace, screening tests are used to identify toxic health effects at an earlier stage than they would be identified without screening. Target conditions should be those for which interventions, such as reducing worker exposure to the offending agent and/or medical treatment, are more beneficial when applied early in the disease process. Thus, the principal objective of workplace medical screening is secondary prevention of disease in the people who are screened. Screening can also be used to establish the work-relatedness of a previously diagnosed condition and to generate data for use in the surveillance of groups of workers.

Biologic monitoring

Biologic monitoring is the measurement and assessment of workplace agents or their metabolites in biologic specimens (e.g., blood and urine), to evaluate exposure and absorption by all routes (i.e., inhalation, percutaneous, or ingestion). Biologic monitoring results, collected as part of a screening program, can be used to supplement the results of exposure monitoring.¹⁹

A general approach to the performance of screening programs

Design and conduct of a screening program should follow 13 steps⁷ (Table 4.2.1). In addition to following these steps to screen individuals, the data collected can be aggregated for analysis of the health status of a group with similar risks.

Step 1: Hazard assessment

Exposure levels and routes of absorption of the substances in the work environment should be ascertained to assess individual worker risk. Situations in which exposure mixtures are seen and workload varies widely complicate the process of hazard assessment considerably.

1. Assessment of workplace hazards
2. Identification of target organ toxicities for each hazard
3. Selection of a test for each screenable health effect
4. Development of action criteria
5. Standardization of the testing process
6. Performance of testing
7. Interpretation of test results
8. Test confirmation
9. Determination of work status
10. Notification
11. Diagnostic evaluation
12. Evaluation and control of exposure
13. Record keeping

Table 4.2.1 Process of designing and implementing a screening program

Step 2: Identification of target organ toxicity

Potential toxicity for each significant workplace hazard can be identified in the toxicology, industrial hygiene, and medical literature.²⁵ Such information may be limited, particularly with respect to meaningful human dose-response data. Recommendations of the National Institute for Occupational Safety and Health (NIOSH) or regulations promulgated by OSHA are often based on data that are limited in this regard.

Step 3: Selection of tests

For a health effect to be identified through screening, a test must be available that can detect the toxic health effect before it would normally cause a worker to present for medical attention (i.e., during the preclinical phase), and at a time when intervention (reduction of exposure and/or medical treatment) is more beneficial than for more advanced disease. Generally, the preclinical phase of an effect must be of sufficient duration (at least weeks or months) to be detected by a screening test given at feasible intervals. Screening is of little help in preventing acute, severe health effects, such as cyanide poisoning, because the preclinical phase is too brief to be detected. Some acute, but intermittent, health effects, such as solvent intoxication,²⁶ may be amenable to screening by questionnaire, because workers may recall symptomatic episodes at screening examinations weeks or months after they occur. This information may be useful, because such episodes may precede the development of chronic central nervous system toxicity.

Test selection also should be governed by the considerations of sensitivity, specificity, predictive value, and reliability, as defined above.²⁷ Often, tests used in clinical practice are found to be inadequate if considered in this way.

Step 4: Development of action criteria

When medical evaluation of workers is undertaken, the health professional designing the program should have a plan for how medical data are to be interpreted and acted on.²⁸ This plan should include criteria to determine when action will be taken in response to medical test results. To assist in the interpretation of the results of some screening tests, guidelines have been developed by consensus groups. These guidelines exist primarily for biologic monitoring tests (e.g., the biologic exposure index [BEI] developed by the American Conference of Governmental Industrial Hygienists [ACGIH]). In certain OSHA Standards, guidelines are provided for the interpretation of such tests (e.g., blood lead levels). Guidance in the interpretation of the significance of other tests can also be found in selected OSHA Standards (e.g., pulmonary function testing in the Cotton Dust Standard). Unfortunately, guidance is limited and inconsistent. For this and other reasons, OSHA has proposed a generic approach to medical surveillance that would create a more comprehensive and uniform approach to this complex process.

Pending the development of more comprehensive guidance, practitioners should establish, for their programs, criteria for action that apply to each test. In developing these criteria, practitioners should evaluate testing data to

determine action levels that are statistically appropriate and biologically meaningful.

Step 5: Standardization of testing process

Staff should be trained in the proper performance of tests so that the results are interpretable. If adequate systems of quality control do not exist, data integrity over time cannot be ensured. Therefore, use of quality control systems and standardized tests is essential for optimum reliability and comparability.

Step 6: Test performance

Testing should be performed on a voluntary basis. Employees should be given information regarding the risks and benefits of testing and provide written evidence of informed consent to testing. Confidentiality of records should be protected through development of a record access control system, which ensures that only those who need to know the results will have access to them.

Step 7: Interpretation of test results

Tests conducted as part of a screening program should be interpreted in two different ways. First, results are compared against the predetermined action criteria to establish whether or not any *individual* action (e.g., removal from an exposure, referral for further tests) needs to be taken. At the same time, results of tests should be analyzed in the aggregate to determine whether or not there is any pattern indicating even subthreshold dysfunction, which would point to a potential workplace problem.²⁹ Is there any relation between the test results and a specific exposure? Do workers in one job category or area show altered (although possibly still normal) function relative to others? This aggregate interpretation may be as important or more important than the individual interpretation for determining what actions should be taken with the work environment itself.

Step 8: Test confirmation

Abnormal test results should be confirmed immediately, before further action is taken. At the discretion of the responsible person directing the program, the employee may be removed from exposure, pending results of confirmatory testing.

Step 9: Determination of work fitness

The proper use of medical testing in determining whether or not a worker should be removed from a hazardous job has received considerable attention and is subject to a proportional amount of controversy. If continued work exposure may further compromise the health of the worker, the worker should be removed from exposure, pending resolution of the health problem or abatement of the offending hazard. Because retention of salary and benefits may not be guaranteed following such 'medical removal', the physician should stress the importance of these protections to management if workers are expected to comply. In the US, OSHA has legislated these guarantees in some situations, such as in cases of overexposure to lead.

Step 10: Notification

Frequently, employees do not receive notification of the results of medical screening tests. Such notification should be prompt and informative, and strict confidentiality procedures should be followed. The implications of the test results should be explained by a qualified health professional in a manner that is clearly understood by the employee.

Step 11: Diagnostic evaluation

Screening tests rarely, if ever, provide a definitive diagnosis, and abnormal results should be evaluated according to good medical practice.³⁰ In some instances, further investigation may be limited to a more detailed medical history to clarify symptoms reported on a questionnaire. In other cases, referral to a specialist may be required.³¹ The action plan should include conditions under which such referrals are indicated.

Step 12: Evaluation and control of exposure

When a toxic effect is established or strongly suspected from medical test results, the most important action is to initiate a re-evaluation of the work environment of the affected employee and, if indicated, make modifications to reduce exposure to levels that are safe for the affected person.³² In such instances, notification of the employer is necessary. However, employers should only be provided with information that is relevant and necessary for evaluation and modification of the work environment, and every effort should be made to keep medical data confidential to the greatest extent feasible.

Once an employer has been notified of a screening result requiring evaluation of the work environment, a sequence of measures should be followed until the problem is resolved. This sequence should include measurement of air-borne levels, assessment of engineering controls (e.g., ventilation systems) and personal protective equipment, modifications in control measures as appropriate, and assessment of the effectiveness of modifications.

Once environmental modifications have been effected, it is again necessary to determine whether the worker can safely return to or remain in the exposed job. When an affected person is returned to an exposed job, frequent, ongoing medical evaluation may be recommended. Whenever an examining physician recommends that an employee be removed from an exposed job, the employee should be informed of the basis for the recommendation (i.e., the risk and severity of an adverse outcome if the employee remains in the exposed job).

Step 13: Record keeping

Medical records should include examination results, interpretations, and documentation of employee and employer notifications. In addition, employers should keep records of notifications they have received of the adverse effects detected by screening and of exposure evaluations and modifications they have carried out in response to such notifications.

Interpretation and action based on group test results

Results from individuals with similar exposure situations can be pooled to evaluate group health status. Such an evaluation is useful in evaluating the efficacy of control measures. At times, group analyses may reveal important information not provided by individual analyses alone. For example, although all measured levels of a test in an exposed group may be within normal limits, there may be a shift in the distribution, suggesting an early group effect. Practitioners have a responsibility to perform group analyses of screening data, because such analyses can identify potential breakdowns in hazard control programs before they would be evident from individual data. Unfortunately, such population surveillance is frequently not performed.

POLICY ISSUES³³

Responsibilities

Physician responsibilities

Screening programs should be designed by and administered under the direction of a licensed physician, preferably one with training in occupational medicine. The physician, or another appropriately licensed healthcare provider, has a responsibility both to the employee being screened and to the employer. If these responsibilities generate conflicting courses of action, the physician's responsibility to the employee takes precedence in determining the course of action.

Physicians should provide all medical test results to the employee, along with an interpretation of the abnormal tests. The physician also has a responsibility to ensure that appropriate medical follow-up of abnormal test results occurs. Further, the physician has a responsibility to the employee to ensure that if worksite exposures were responsible for abnormal test findings, these exposures are controlled to an acceptable level before the employee returns to work.

Finally, the physician should ascertain whether or not the employee's coworkers with similar exposures are at risk, and if so, the appropriate action that should be taken (e.g., screening). When a physician recommends an employee be removed from a particular job because of health risks from further exposure, he or she should inform the employee of the basis of the recommendation, including any uncertainty about the benefits of removal.

Physicians should only provide to the management of the company information that is needed to guide management actions. In situations in which the medical department is part of the company (i.e., in-house medical center), specific procedures should be developed to control access to medical information by personnel officers and by other company personnel. Medical results should be released by management if such knowledge would prompt action to protect the health of employees. In such

situations, the employee should be informed that disclosure will take place.

Employer responsibilities

In addition to providing unrestricted access to medical screening for employees at risk, employers should provide information to the responsible physician and should act on the results of tests when a workplace factor is implicated. Exposure information (e.g., job history and results of environmental sampling) should be provided to the physician. Information about applicable standards, material safety data sheets, and the extent of use of personal protective equipment should also be provided. Finally, the employer has the primary responsibility for maintaining a safe and healthful workplace.

Employee responsibilities

As in any medical evaluation, employees are responsible for providing accurate information (e.g., medical history) and for cooperating with medical testing procedures (e.g., providing full effort on pulmonary function testing). In those instances in which individual behavior, either job practices or personal habits, contributes to the development of a health problem, the individual should assume personal responsibility for changing the behavior to reduce the risk.

OSHA requirements

In the US, under existing OSHA Standards, employers are required to provide employees with access to medical screening examination when the employees are exposed to certain hazards (Table 4.2.2). Specific requirements for

2-Acetylaminofluorene
Acrylonitrile
4-Aminodiphenyl
Inorganic arsenic
Asbestos
Benzene
Benzidine
Bischloromethyl ether
Cadmium
Coal tar pitch volatiles
Coke oven emissions
Cotton dust
Dibromochloropropane
3,3'-Dichlorobenzidine
4-Dimethylaminoazobenzene
Ethylene oxide
Ethylenimine
Formaldehyde
Hazardous waste
Lead
Methylchloromethyl ether
Alpha-naphthylamine
Beta-naphthylamine
4-Nitrobiphenyl
Nitrosodimethylamine
Noise
Beta-propiolactone

Table 4.2.2 Hazards requiring medical surveillance by OSHA Standards

OSHA mandated surveillance is provided in Chapter 59. In a few instances, decision models are provided (e.g., Lead and Cotton Dust Standards) that guide physicians in their evaluation of results and in their recommendations for action. In most instances, little or no guidance is provided in the interpretation of results. OSHA requires that records be maintained for the duration of employment plus 30 years, and that access of the employee to his or her personal records be provided on request.

Healthcare provider case reporting

Regulations have been developed in many cities, states, and countries that instruct healthcare providers to report suspected cases of occupational illness or injury to an office of government. In some cases, consultation services are made available to assist in the investigation and remediation of the suspected causes of a case report. Requirements for reporting vary widely, and are not well publicized within the medical community. Further, healthcare providers often fail to report problems because, at times, no action is taken in following up the report.

To develop a systematic approach to the use of reports received from healthcare providers in the US, NIOSH developed the Sentinel Event Notification System for Occupational Risks (SENSOR).¹² The system consists of a network of sentinel healthcare providers who are linked to the state health department. In addition to developing a network of providers, the health department determines which conditions should be reported.

For each condition, reporting guidelines were developed to facilitate recognition of the case by the provider. Once reports are received and confirmed by the health department's surveillance centers, an active response occurs. Three possible actions may take place:

- management of the individual case;
- screening of coworkers with similar job exposures; and
- investigation of the worksite.

Monitoring injury, illness, and exposure trends

General considerations

Surveillance systems designed to monitor trends for occupational disorders or exposure usually rely on existing records collected for purposes other than surveillance. These records are coded or modified in some way to make them suitable for analysis. Each data source has certain limitations and advantages that must be considered in assessing the usefulness of the data for surveillance purposes.

Pre-existing healthcare and vital records

Many types of health records contain diagnostic information on conditions appropriate for surveillance. Death certificates^{34,35} (including those of fetal deaths), birth certificates, hospital discharge records, office records of healthcare providers, and insurance claim files represent potential data sources for surveillance activities. Limitations include:

- information on the occupation of the patient is often not in the record;
- physicians often fail to recognize disorders caused by occupational hazards;
- there may be misclassification or omission of conditions and occupations of interest.

Advantages include:

- records are available at modest cost;
- records are coded using generally accepted code schemes (e.g., International Classification of Diseases).

The process of using healthcare provider records in surveillance may serve to improve awareness among healthcare providers of the impact of work on health, particularly in light of the emergence of the electronic medical record.

In summary, healthcare records, if collected and coded, can be useful sources of surveillance data. Death certificates, which contain information on the occupation of the deceased person, may be particularly useful if the occupational disease leads to mortality, given the limitations noted above.

Employer case reporting

In the US, employers are required by OSHA to record occurrences of occupational illness and injury on a form maintained at the worksite (called the OSHA log). The responsibility for completing this record often falls to an individual who has had no medical training and guidance in determining what should be recorded. Studies have shown that many disorders, particularly occupational illness, are not reported in the OSHA log.

Each year, the Bureau of Labor Statistics of the US Department of Labor collects a sample of these records from a portion of employers; certain categories of the workforce are not included in the survey. This sample is used to generate national estimates for selected conditions.

Workers' compensation data

Each state in the US maintains a workers' compensation system that generates data that could be used in surveillance.³⁶ To be entered into the system, a worker must recognize his or her condition as work related and file a claim. To receive compensation, the worker must also satisfy state regulations for eligibility, and successfully win a decision by the workers' compensation board.

Limitations of workers' compensation data for surveillance follow.

- In view of reporting disincentives and inherent difficulties in recognizing occupational disorders, workers' compensation data consistently underestimate the true rate of occurrence of occupational disorders. Furthermore, the rate of underestimation varies among conditions, with greater under-reporting of diseases than for occupational injuries.
- Workers' compensation laws vary from state to state. Many workers' compensation systems have requirements that claims be filed within a brief time period (e.g., within 1 year) following the suspected exposure; this requirement may present substantial barriers to

filing claims for occupational diseases of long latency (e.g., cancer).

Nevertheless, significant advantages to the use of workers' compensation data include the following.

- All records in the data set relate to conditions of suspected occupational etiology.
- Information on the job and the industry for each claimant is contained in the record.
- The circumstances of the illness or injury are frequently described in a way that provides understanding of the cause of the condition.
- If case identification leads to improvement of workplace conditions, prevention of further claims should occur, thus benefiting both the employee and the employer.
- If these data are used for surveillance purposes, technical improvements in the data management system (e.g., better coding procedures or computer systems) could occur that would benefit the management of the workers' compensation insurance system itself.

In summary, workers' compensation data represent an important source of surveillance data that can be used to monitor trends in the occurrence of selected occupational disorders and to identify cases for follow-up action.¹⁶

Biologic monitoring data

In selected situations, employers and healthcare providers obtain samples for biologic monitoring (e.g., blood or urine) from workers exposed to toxic substances. Typically, analyses are performed by one or only a few laboratories in a state. Data from the laboratory can be collected by a government agency and analyzed to monitor trends in exposure to selected toxic substances. This approach has certain limitations.

- Biologic assays exist for only a few substances.
- Quality control programs for these analyses may be limited.
- Participation in biologic monitoring programs is often limited to larger workplaces in which hazards are well controlled.
- Within workplaces that participate in a biologic monitoring program, individual workers may choose not to be tested.

Nevertheless, there are advantages to this approach.

- Each test (e.g., blood lead concentration) is a specific index of exposure to the toxic substance of interest.
- In states where commercial laboratories are required to report results to the state agency, data can be obtained widely and at low additional cost.

In summary, for certain substances (blood lead testing is by far the best example), biologic monitoring test results can be a useful source of surveillance data.

National health surveys

Different countries maintain different health survey systems. Each year in the US, the National Center for Health Statistics (NCHS) performs surveys of statistical samples of the population. Within each sample, a subset of employed persons can be identified. In each survey, health status data and occupational listing information are

collected. The US Health Interview Survey (HIS) is a questionnaire survey that currently contacts 50,000 households, with 130,000 individuals. The National Health and Nutrition Examination Survey (NHANES) uses both a questionnaire and detailed medical tests to obtain health status information on 30,000 to 40,000 individuals. NIOSH collaborated with NCHS researchers to include tests in the NHANES III protocol which evaluate selected occupational disorders, such as lung disorders and neurotoxicity.

Exposure surveillance systems

Exposure surveillance can be performed using existing data or through the performance of worksite surveys.³⁷ Existing environmental data are most commonly developed as part of compliance inspections performed by the US Department of Labor (either OSHA or the Mine Safety and Health Administration, MSHA). Direct surveys have been performed by NIOSH: the National Occupational Hazard Survey, the National Occupational Exposure Survey, and the National Mining Survey. Each approach has important advantages in describing trends in exposure to hazards in the workplace.

Chapter 5

Toxicology

David L Eaton

INTRODUCTION

Toxicology has been defined as ‘the study of the adverse effects of chemicals on living organisms, and the assessment of the probability of their occurrence’ (Society of Toxicology). The discipline of toxicology has evolved over the past century from one that focused primarily on the acute adverse effects of therapeutic agents in patient populations (a subdiscipline within the field of pharmacology) to one that includes consideration of the adverse effects on both health and the environment of the much larger universe of industrial chemicals found in the occupational and general environment. There are a variety of identifiable subdisciplines within the field of toxicology, although there is extensive overlap and integration among these areas. For example, the subspecialty of environmental toxicology originally was developed to investigate the adverse effects of chemical pollutants in the environment on human health, but in the past decade it has been used frequently to describe environmental perturbations from chemicals in the environment (e.g., aquatic toxicology, wildlife toxicology, and ecosystems toxicology). Occupational toxicology (sometimes referred to as industrial toxicology) focuses principally on chemical hazards in the workplace and is closely aligned with the disciplines of industrial hygiene and occupational medicine. Many toxicologists employed in academia, industry, and government direct their research efforts on understanding the cellular, biochemical, and molecular mechanisms of the toxicity produced by chemicals.

The mechanistic information provided by research toxicologists often provides the scientific basis that supports many of the more applied areas of toxicology. Forensic toxicology is generally viewed as a subdiscipline of pathology that relates primarily to the resolution of medicolegal issues surrounding the causal connections between injury or death of an individual and specific chemical exposures. Forensic pathologists are generally physicians employed by medical examiner’s offices or large hospitals. Clinical toxicology focuses primarily on the biologic basis for chemical-induced injury, and implications for diagnosis and treatment; historically focusing on drugs and natural products (e.g., poisonous plants and animals). Clinical toxicologists are usually physicians, most often employed by hospitals, laboratories, and poison control centers. Regulatory toxicology is perhaps the newest subdiscipline of toxicology, and relates primarily to the use of toxicologic principles and data to establish regulatory standards aimed at reducing the adverse impacts of chemicals on human health or the environment. Although the background and

training of professionals involved in these subdisciplines of toxicology may vary widely, there is nonetheless a common body of knowledge shared by all, and integral to the practice of clinical occupational and environmental medicine, which will be the focus of the remainder of this chapter.

Historically, the heavy metals, most notably lead, mercury, and the metalloid arsenic, presaged the advent of occupational and environmental toxicology. Throughout recorded history outbreaks of poisonings were recorded based on interpretation of simple epidemiological observations. For example, the variety of symptoms attributable to lead were recognized and traced to such sources as plumbing systems, the glazing of pottery, and additives to wines to improve taste. With the advent of the industrial revolution, still other avenues for exposure to lead appeared, such as vaporization, with bioavailability to the respiratory tract during a variety of industrial operations. Mercury and arsenic have both plagued humankind as toxic substances, as well as being used in a variety of processes to improve our lifestyle. As an example, consider the remarkably widespread historic use of mercury in medicinal salves, ointments, oral diuretics, as well as in powders applied to the gums of infants to remedy the purported effects of teething. After the dire consequences of mercury were recognized in the middle of the 19th century, acrodynia, or pink disease, a unique hypersensitivity reaction to mercury in children, totally disappeared from clinical experience, only to re-emerge recently following exposure to mercury in latex paints.¹ Similarly, as these same metals were combined with organic chemicals, still new symptom complexes were recognized, such as the neurological toxicity of tetraethyl lead, and the teratologic consequences of exposure to methyl mercury. Although concerns about the toxic potential of modern organic pesticides may be justified, one need only remember that prior to the advent of synthetic organic pesticides, arsenic (often as lead arsenate) enjoyed widespread use in the world of agriculture, with significant detrimental effects on health.

By the turn of the century, with the emergence of the science of chemistry and its analytic techniques, a variety of new chemicals were synthesized and older forms and formulations were characterized. Much progress occurred in identifying ‘toxidromes’, combinations of clinical signs and symptoms that were associated with human and animal exposures. Initially, the focus was on acute exposure, but more than 100 years ago, the effects of chronic exposure to mercury in the felt-hat industry were delineated. Pressure to curtail mercury exposure culminated

in Lewis Carroll's famous classic *Alice in Wonderland*, and parliamentary action in Britain led to the elimination of mercury by the mid-1860s. Comparable public health measures were not adopted in the USA until shortly after the beginning of the Second World War, emphasizing the constant conflict between the risks and benefits of chemical use and associated health consequences.

In recent years the emphasis in toxicology has shifted to understanding the molecular basis by which chemicals induce adverse effects. The new field of 'toxicogenomics' has evolved through coupling of traditional toxicology with the recent advances in molecular biology and genomics. Toxicogenomics holds the promise of providing simple genetic tests that will identify individuals who are highly sensitive to workplace and environmental exposures to toxic substances. However, with such capabilities come many important ethical, social and legal issues, that themselves have spawned a new field of 'public health genetics'.²

DOSE-RESPONSE RELATIONSHIPS

The principal paradigm of toxicology was framed more than four centuries ago by Paracelsus (1493-1531), who stated that 'All substances are poisons; there is none which is not. Only the dose differentiates a poison from a remedy.' Regardless of the source - toxic plants, industrial pollution, or therapeutic drugs - the responses of biologic organisms to toxic substances often follow a similar pattern, commonly referred to as the dose-response relationship. This intuitively obvious concept, that the magnitude of response increases with the dose, can be graphically depicted, as shown in Figure 5.1. In a given individual chemical (known as an intrinsic toxin), there exists some dose below which there is no evidence of adverse effects. The body has a limited capacity to handle a certain amount of chemical insult before biologic function is compromised. The amount of this 'functional reserve capacity' can vary among individuals, and specific chemicals may readily exceed this capacity for specific organ systems at relatively small doses, whereas for other chemicals, a very large amount may be required before the 'threshold of safety' is exceeded.

For some substances, such as vitamins and minerals, which are essential for life, the dose-response curve takes on a biphasic shape. An inverse dose-response relationship is evident at 'low doses,' e.g., during vitamin or mineral deficiencies. Increasing the dose of these essential nutrients brings one into the region of homeostasis; however, toxicity can occur if the dose is too great and the threshold for toxicity is exceeded. This threshold may vary greatly among individuals in the population, and is influenced by many intrinsic factors, such as age, gender, weight, and genetic makeup, as well as extrinsic factors, such as exposure to other chemicals, diet, or personal habits, such as smoking or drinking. Because of such variation in response to chemicals, there are always individuals who respond at doses much lower than those of the average person, and others who are more resistant to toxicity with observable effects at

Figure 5.1: Individual dose-response relationship. dose-response curve for an individual exposed to either an essential substance or a non-nutritive substance. It is generally recognized that, for most intrinsic toxins, a threshold exists such that at doses below the threshold, no toxicity is evident. For essential substances, doses below the minimum daily requirement, as well as those above the threshold for safety, may be associated with toxic effects.

higher exposures. Today we recognize that many of such inter-individual differences are due to genetic factors.

The variation in population response to toxic chemicals often is presumed to follow a classic 'bell-shaped curve' (gaussian distribution, Fig. 5.2a), which is frequently depicted as a cumulative, quantal dose-response curve (Fig. 5.2b). These curves identify the response of a population to varying doses of a toxic chemical, with the midpoint of the curve representing the effective dose 50 or ED_{50} , that is, the dose at which 50% of the population responds. If the effect that is measured is death, then the ED_{50} is expressed as the lethal dose 50, or LD_{50} . For many years, the LD_{50} was used as the primary indicator of the relative toxicity of a chemical, and it can still be found as the principal measure of toxicity in many reference materials, such as material safety data sheets. It is important to recognize that the LD_{50} measures only the acute single-dose response to chemicals, and the only adverse response it reflects is mortality. It provides no meaningful insight into other types of non-lethal adverse responses, such as neurological effects, carcinogenic potential, teratogenic potential, reproductive effects, or other serious adverse effects that may occur at doses well below the LD_{50} . Furthermore, LD_{50} values are always based on laboratory animal data, and thus, they poorly reflect the diversity of human conditions and experiences that may drastically alter response to exposure. It is therefore never safe to assume that exposures far below the LD_{50} are harmless without much greater characterization of the types of effects a chemical may produce.

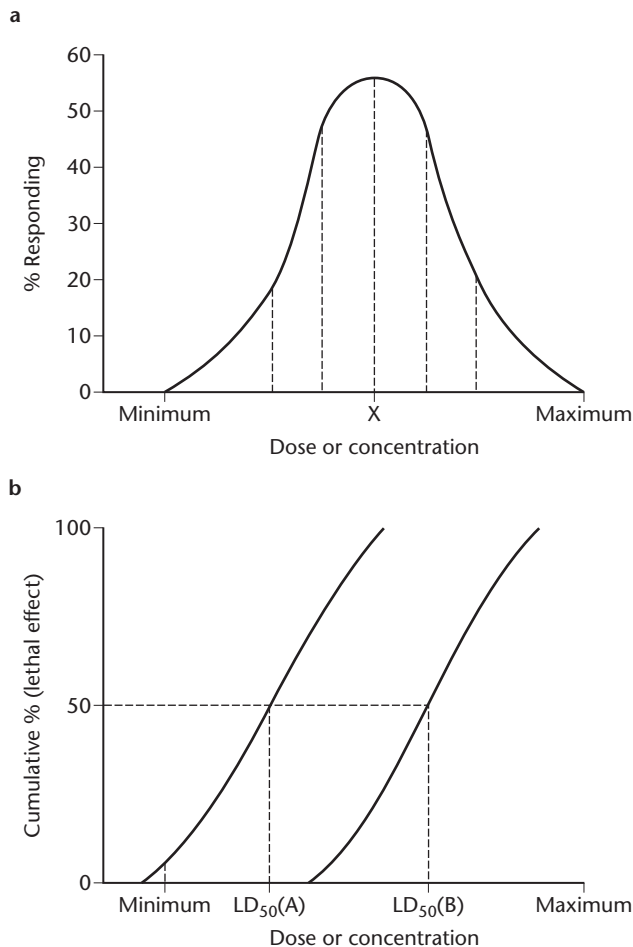

Figure 5.2: Frequency distribution and quantal dose-response relationship. Quantal dose-response curves for a population: a quantal (all or none) endpoint, such as death, is selected, and then the dose at which each individual in the population responds is determined. Curve (a) represents a frequency-response distribution curve for the quantal response of a 'normal,' or gaussian, distribution of responses among the population. Curve (b) plots the data for two different chemicals (A and B) as cumulative, quantal dose-response curves. The mid-point on the response curve represents the LD₅₀ if the quantal response is death. (Adapted from Loomis TA. *Essentials of toxicology*, 3rd edn. Philadelphia: Lea & Febiger, 1978. © 1978, the Williams & Wilkins Co., Baltimore.)

TYPES AND NATURE OF ADVERSE RESPONSES

Acute and chronic toxicity

Humans generally respond to toxic chemicals in a manner similar to that of laboratory animals and usually in doses that are relatively similar on a body-weight basis (or, more accurately, on a dose per unit surface area basis). The variation of effects (e.g., hepatic necrosis, central nervous system depression, and renal damage) between different individuals, and between humans and laboratory animals, is generally predictable for a given chemical agent, although the doses necessary to produce characteristic symptoms may vary substantially. However, there are often individuals within a population who have some genetic variation that

causes them to respond at a dose far below the anticipated dose. This type of hyper-responsiveness is often referred to as an idiosyncratic response, and it is usually seen only in a small percentage of the population who are genetically predisposed to toxicity. Most chemical idiosyncratic responses that have been identified have been associated with administration of therapeutic drugs. For example, 3-5% of the population expresses a variant form of the gene that encodes for the enzyme protein pseudocholinesterase, which apparently plays little or no role in normal metabolism. However, when such individuals are administered the muscle-paralyzing drug succinylcholine for surgical procedures, they remain paralyzed for much longer periods of time (many hours) than does the average individual with adequate pseudocholinesterase levels (several minutes). This adverse response occurs because the pseudocholinesterase enzyme is primarily responsible for metabolizing succinylcholine; the genetic basis for poor metabolism has recently been characterized.³

Other common genetically determined drug idiosyncratic reactions include significant differences in the rates of acetylation (and thus deactivation) of certain amines and amides, such as phenytoin, isoniazid, and hydralazine, as well as deficiencies in glucose-6-phosphate dehydrogenase, which can result in a severe hemolytic response following exposure to a variety of oxidizing pharmaceuticals and non-pharmaceutical chemicals. Numerous other examples of genetically determined hypersusceptibility to the adverse effects of drugs and non-drug chemicals have been described, and may be important in determining susceptibility to cancer and birth defects.⁴ Although such examples of idiosyncratic reactions are relatively rare for non-drug chemicals, it is certain that they do occur and one must always be alert to this possibility when a patient experiences symptoms of toxicity, even though others around him or her show no apparent effect.

Allergic reactions

In addition to the dose-related and idiosyncratic responses, some individuals may develop allergic reactions to chemicals. Although the incidence of this is usually small, for those substances capable of producing immunologic reactions, it can have important consequences. Unlike normal toxicologic responses, allergic reactions do not follow the classic population dose-response curve. In contrast, allergic individuals respond at doses far below those of non-allergic individuals; even within an allergic population, the magnitude of response is not always clearly dose-related. However, in a particular allergic individual, the development of an allergen response is usually related to the magnitude of exposure. In contrast to normal toxicological responses, individuals must first become sensitized, as the allergic response is dependent on the presence of specific antibodies that are directed against the chemical antigen (allergens). Many chemicals of environmental and occupational concern are not sufficiently large to stimulate the immune system directly, but must first combine with an endogenous protein. The chemical is then referred to as a

Classification	Examples	Mechanism
Type I anaphylaxis (immediate hypersensitivity)	Asthma, urticaria, rhinitis, atopic dermatitis	IgE bound to mast cell/basophil triggers release of soluble mediators (e.g., histamine)
Type II cytolytic	Hemolytic anemia, Goodpasture's syndrome	IgG and/or IgM binds to cells and results in destruction by complement, opsonization, or antibody-dependent cellular cytotoxicity
Type III Arthus	Systemic lupus erythematosus, glomerular nephritis, rheumatoid arthritis, serum sickness	Antigen-antibody complexes deposit in various tissues and may then fix complement
Type IV delayed-type hypersensitivity	Contact dermatitis, tuberculosis	Sensitized T lymphocytes induce a cell-mediated response
Adapted from Dean JH, Murray MJ. Toxic responses for the immune system. In Amdur MD, Doull J, Klaasen CD, eds. Casarett and Doull's Toxicology: the basic science of poisons, 4th edn. New York: Pergamon Press, 1991;282–333.		

Table 5.1 Gell and Coombs classification scheme of allergy

happen, and the chemical-protein complex becomes the antigen. After an antigen is formed, the production of antibodies requires several weeks following this first, or sensitizing, exposure. However, once antibodies have been formed, a subsequent exposure may result in a rapid and severe allergic response, involving one or more organ system's responses (Table 5.1).

A Type I, or immediate hypersensitivity, reaction is associated with the immunoglobulin (Ig)E-triggered release of endogenously active substances such as histamine from mast cells, most commonly presenting as rhinitis, asthma or atopic dermatitis. Far less commonly, it may result in angioedema or fatal anaphylactic shock. Occupational asthma from platinum salts and trimellitic anhydride are well-described Type I reactions but may also be associated with non-immunological responses. Other pulmonary irritants, such as formaldehyde, may produce asthmatic symptoms from a direct irritant effect on the airways, or non-IgE-related immune responses.⁵ Other antibodies, such as IgG and IgM, when activated by an antigen, may interact with tissues to generate cytolytic processes (Type II reactions).

The major targets of Type II reactions are circulating cells, such as erythrocytes and white blood cells, but type II reactions may also occur in other tissues, such as lung and kidney. For example, Goodpasture's syndrome results from the development of cytolytic antibodies directed against basement membrane proteins in the kidney, and is generally thought to be an autoimmune condition,⁶ although there is some suggestion that exposure to some solvents and other nephrotoxic agents can induce this response through cross-reactivity of the immune response with basement membranes.⁷ Type III, or Arthus, reactions, are mediated by IgG, with resultant antigen-antibody-complement complexes being contained in the circulation, rather than fixed to tissues. The circulating immune complex becomes deposited in the vascular endothelium, producing a destructive inflammatory response. This type of reaction is most commonly associated with autoimmune diseases, such as systemic lupus erythematosus and rheumatoid arthritis, and is presumed to stem from endogenous antigens. However, this response can also result from exposure to exogenous antigens, especially

exogenous proteins (e.g., serum sickness produced by horse antiserum). Type IV, or delayed-type hypersensitivity, reactions, which are cell-mediated reactions, are relatively common with exposure to environmental and industrial chemicals, and may manifest as contact dermatitis. Type IV allergic reactions to latex rubber have become one of the most common occupational health complaints in the healthcare industry.^{8,9}

Although allergic and idiosyncratic reactions occur in a relatively small percentage of the total population, they represent a significant portion of the adverse responses to chemicals found in selected workplaces with exposure to allergenic materials, as well as in workplaces with engineering controls limiting exposure to protect the majority of workers.

Carcinogenicity

The potential for the occupational environment to induce cancer has been recognized since Sir Percival Pott first identified scrotal cancer as an occupational disease among chimney sweeps in the 1700s. It was not until the early part of this century, however, that certain polyaromatic hydrocarbons (common chemical components of soots, tars, and oils) were identified as the probable carcinogenic agents in this industry. Since that time, there has been increasing concern regarding the potential carcinogenic effects of a variety of chemicals in the environment. The strong associations of asbestos with diffuse malignant mesothelioma and primary lung cancer, vinyl chloride with angiosarcoma of the liver, and certain aromatic amines with bladder cancer, stimulated the search for other possible associations between occupational and environmental chemical exposure and cancer.

There are numerous other chemicals for which substantial epidemiologic evidence exists to link occupational exposures with cancer. However, relative to the approximately 60,000 chemicals in commercial use in the United States, their number is currently small. The International Agency for Research on Cancer (IARC) has reviewed the literature on approximately 860 putative carcinogenic agents (chemicals, processes, infectious agents).¹⁰ IARC currently lists 89 different chemicals, mixtures or chemical

processes for which it judged there was adequate scientific evidence of carcinogenicity in humans (Group 1 carcinogens). Of these, 39 were occupationally related, 31 were pharmaceutical chemicals or radiation, 10 were infectious agents (e.g., hepatitis B, human papilloma virus), and nine were associated with diet or lifestyle (e.g., ethyl alcohol, aflatoxin and smoking). IARC identified another 64 chemicals for which the scientific data suggested probable, but not conclusive, evidence of carcinogenicity in humans (Group 2A), and another 236 chemicals that were possibly carcinogenic in humans, based primarily on laboratory animal studies (Group 2B). Nearly 500 chemicals or processes of industrial and pharmaceutical importance were identified by IARC for which there is some suspicion of carcinogenic potential, but for which the scientific evidence for carcinogenic potential remains inadequate (Group 3). Because exposure data are often inadequate, and limited to small numbers of cases (primarily because of the long latency period between exposure and development of cancers, requiring many years), it is extremely difficult to definitively characterize a specific chemical as a human carcinogen, against a high background incidence of cancer. Much of the data implicating chemicals as human carcinogens have been derived from laboratory animal studies, but some are a result of epidemiologic studies relating occupation to an increased risk of specific types of cancer. In some instances a process, rather than a specific chemical, has been linked to an increased incidence of cancer.

Although the precise biologic processes involved in the development of cancer are not fully understood, there is a consensus that chemical carcinogenesis is a multistep process.^{11,12} The first step, referred to as initiation, involves the binding of the chemical to DNA (Fig. 5.3). Most chemicals lack the reactivity necessary to covalently bind to DNA, but in the process of biotransformation, reactive electrophilic intermediates may be formed that bind avidly to nucleophilic sites in DNA. Genetic differences in the ability to activate or detoxify chemical carcinogens are often considered one of the most likely reasons for inter-individual and inter-species differences in susceptibility to chemical carcinogens.¹³ Most DNA damage is either inconsequential, lethal to the cell, or produces damage that is efficiently repaired by special DNA repair enzymes. However, some DNA adducts may escape repair, or be repaired incorrectly, and thus introduce a mutation into the cell. If this mutation is at a site important to the regulation of cellular replication, it may result in the loss of cellular growth regulation.

It is now recognized that there are certain genes present in all cells, called proto-oncogenes, which, when activated by mutation, transform a normal cell into a precancerous cell. Similarly, there are genes that act to suppress cell replication and, consequently, tumor growth, called tumor-suppressor genes. The mutation of tumor-suppressor genes appears to be a major factor in many types of malignancies. One particular gene, called p53, is mutated from the wild type in a high percentage of human malignancies.¹⁴ The product of this gene appears to function as a check-

point in the regulation of the cell cycle, ensuring adequate time for DNA damage to be repaired prior to cell division. In the absence of this regulation (e.g., mutated p53), cells can replicate before the DNA damage is repaired, passing on their mutations to daughter cells.

Precancerous, or latent, carcinoma cells may exist in a quiescent stage in tissues for many years. Many times, such transformed cells often express surface proteins that are recognized as abnormal to the immune system, and antibodies are generated that facilitate the destruction of these cells. However, if immune surveillance is ineffective or incomplete, these cells may begin to proliferate into tumors and eventually metastasize to distant sites. The multiple steps from initiation to early neoplastic foci and tumor development (promotion) to metastatic carcinomas (progression) are not well understood, although it is recognized that some chemicals can enhance the rate of these later processes. Chemicals that stimulate the development and growth of already initiated precancerous cells are often called promoters (Fig. 5.3). Promotion is often associated with stimuli that enhance the rate of cell division (e.g., mitogenic) and inflammatory responses. Thus, an increase in the rate of cell division and attendant DNA replication in a normally quiescent cell population greatly increases the chances of the fixation of mutations that arise continuously from natural processes and environmental mutagens. Therefore, drugs or other chemicals that enhance cell proliferation (the rate of cell division) may augment the expression of mutations accumulated over time, increasing the opportunity for mutated cells to expand in number and acquire additional mutations.¹⁵

Some chemicals may act as co-carcinogens, i.e., by themselves, they are incapable of inducing cancer but when given before or during exposure to initiators, they increase the potency or effectiveness of the carcinogen. Although promoters fit within this definition, the term co-carcinogen is usually reserved to describe chemicals that alter the effectiveness of protective pathways in the multistep process leading from initiation to tumor motion. For example, many chemicals can alter the relative fraction of procarcinogen that is activated to the ultimate carcinogenic form, by inducing competing inactivation pathways or inhibiting activation pathways. Likewise, chemicals that suppress immune function or alter the efficiency or accuracy of DNA repair processes, enhance the carcinogenic potency of other carcinogens and increase rate of tumor formation.

Chemicals that increase the incidence of cancer by promotional mechanisms are generally considered to respond in a threshold fashion; that is, they will not enhance tumor response at doses below that necessary to increase the rate of cell division. In contrast, chemicals that induce cancer through mutagenic processes (initiators) are often considered to act in a non-threshold fashion, that is, the incidence of cancer is directly proportional to the dose of carcinogen even at very low doses. Such a linear non-threshold model has important public health consequences, as there is theoretically no dose below which the probability of cancer becomes zero. The distinction

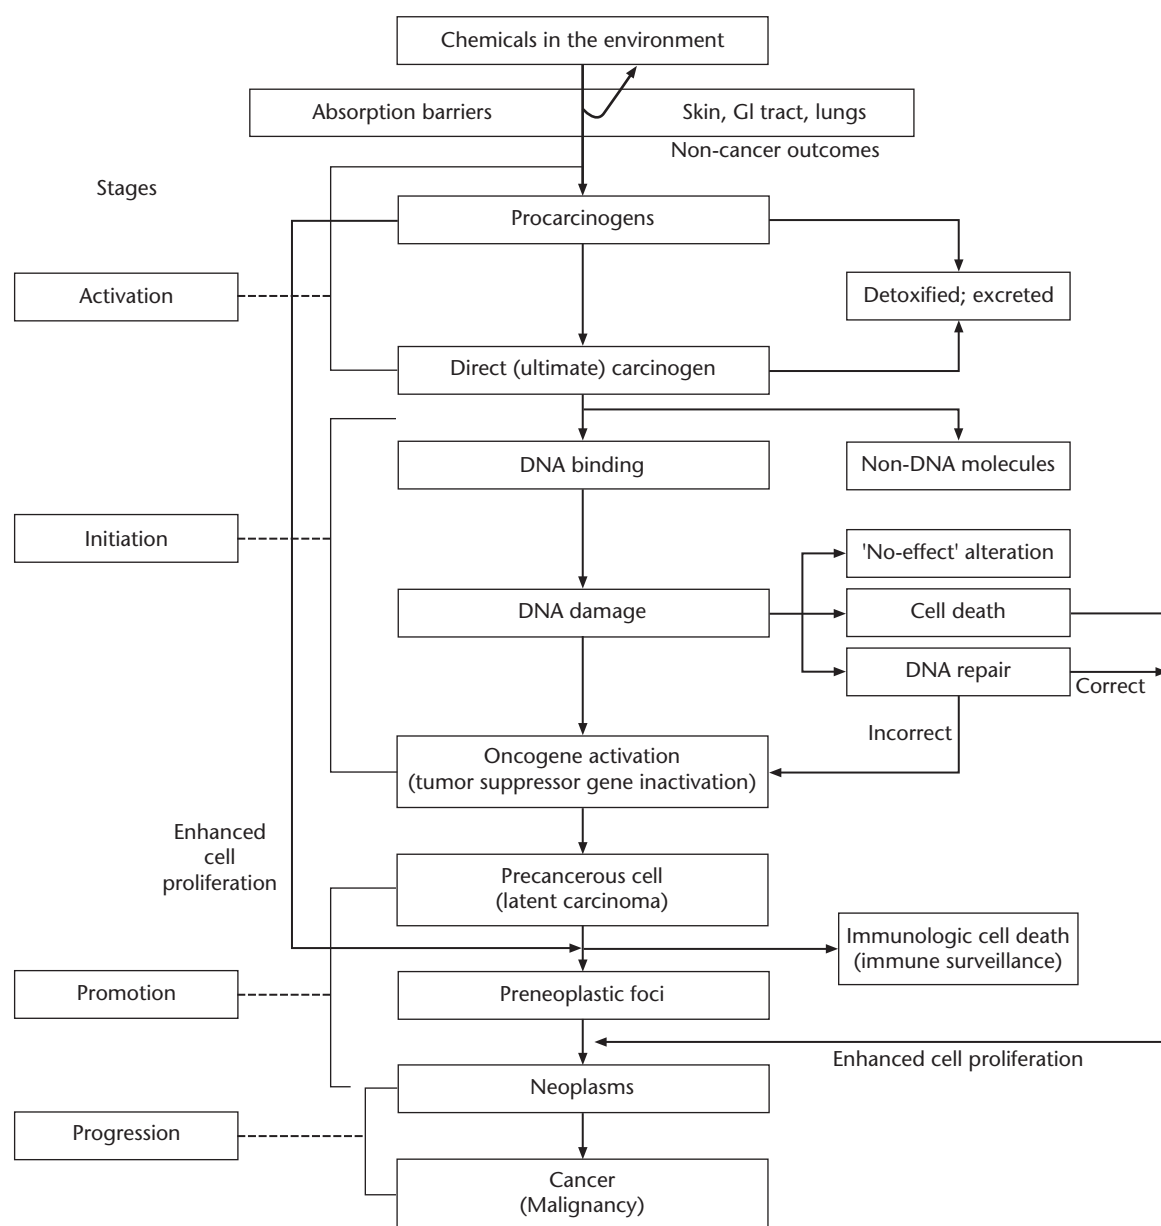

Figure 5.3: Process of chemical carcinogenesis. Carcinogenic chemicals must undergo a number of sequential events in order to produce tumors. Most chemicals require biotransformation to reactive intermediates (activation) before being able to induce somatic mutations. Mutation of a gene involved in cellular growth and differentiation (oncogene) often is referred to as initiation, whereas the stimulation of clonal expansion of the mutated cell to a colony of cells containing the mutated oncogene is referred to as promotion. Cells within this population may acquire additional mutations favoring growth, dedifferentiation, or both, ultimately leading to the development of cancers. This later stage is commonly referred to as tumor progression, and it may involve many successive changes in phenotype leading to increasing degrees of malignancy (e.g., benign to invasive to metastatic).

between chemicals that act by threshold processes (e.g., promoters) and chemicals that act through non-threshold mechanisms (e.g., initiators) also has potentially profound regulatory implications, as discussed later in this chapter.

Reproductive and developmental effects

With the increasing number of women of child-bearing age entering the industrial workforce, concern over the potential for occupational and/or environmental chemical exposures to produce reproductive disorders and birth

defects has heightened during the last few decades. Because the developing embryo is often exquisitely sensitive to toxic substances, it is necessary to consider women of child-bearing age as being at particularly high risk for toxic chemical exposures, and efforts must be made to make the workplace safe for this important sector of the workforce. Many causes of birth defects, such as maternal malnutrition, medications, alcohol, genetic factors, and infectious agents, have been identified, but the etiology of 65-70% of all human birth defects remains unknown (Table 5.2; see Chapter 27.2).

Known genetic transmission	20%
Chromosomal aberration	3–5%
Environmental causes	
Radiation	<1%
– Therapeutic	
– Nuclear	
Infections	2–3%
– Rubella virus	
– Cytomegalovirus	
– Herpesvirus hominis	
– Toxoplasma	
– Syphilis	
Maternal metabolic imbalance	1–2%
– Endemic cretinism	
– Diabetes	
– Phenylketonuria	
– Virilizing tumors	
Drugs and environmental chemicals	7–10%
– Ethanol	
– Androgenic hormone	
– Folic antagonists	
– Thalidomide	
– Organic mercury	
– Some hypoglycemics	
– Some anticonvulsants	
Potentiative interactions	Unknown
Unknown	60–65%

Table 5.2 Known causes of developmental defects in humans

Literally hundreds of chemicals have been identified as having the ability to cause birth defects, usually at high doses in laboratory animals, but the list of documented human teratogens remains surprisingly small, of the order of 10–20, with many of these subject to debate. The large inter-species differences in sensitivity to some teratogens is of critical importance; moreover, the timing of the exposure and stage of embryonic development has made reliable, quantitative extrapolation of animal data to humans challenging. For example, the drug thalidomide, which was used in Europe to ameliorate nausea and vomiting during the early stages of pregnancy, was found to produce an extraordinarily high incidence of a rare birth defect, phocomelia (failure of limbs to develop) among the offspring of women who took this drug during a specific period early in their pregnancies. Only later was it found that humans are about 700 times more sensitive to the teratogenic effects of thalidomide than is the hamster, and 100 times more sensitive than the rat. Recently, thalidomide has resurfaced as a potentially valuable drug in the treatment of a variety of infectious and malignant conditions (e.g., thyroid cancer), although obviously great care must be taken to prevent its use in pregnant women.¹⁶

Even though inter-species differences complicate the interpretation of laboratory animal studies to predict human risks, there are some basic concepts regarding the teratogenic response that appears to be true in all animals, including humans. First, the age of development of the embryo at the time of exposure to the teratogen is very important. The period of greatest sensitivity to chemical teratogens is during the first trimester of pregnancy (Fig. 5.4), a time of maximal cell differentiation.

In humans, this highly sensitive period for teratogenic effects extends generally from about 2 weeks through 12 weeks gestation. Exposures to many toxic substances during the first 2 weeks of embryonic development are likely to result in the death of the embryo, and it is probable that the woman would not even be aware that she was pregnant due to early miscarriage. Exposure to teratogens occurring beyond the tenth to twelfth week of pregnancy are far less likely to result in physical or morphologic abnormalities because major morphologic characteristics (extremities, palate, ribs, and organs) have been formed. However, other developmental problems, particularly relating to the nervous system, may result from exposure during the later stages of fetal development, because the brain is not fully differentiated and developed until after birth. Methyl mercury, lead, and alcohol are all examples of chemicals that can affect the developing nervous system in utero during the later stages of pregnancy.

The second important factor relating chemical exposure to teratogenic responses is the dose of the teratogen.¹⁷ Most, if not all, toxic substances can adversely affect the developing embryo and/or fetus, either directly, or indirectly if it produces a maternal toxic response. What generally defines whether a chemical is truly teratogenic is whether it affects embryonic and/or fetal development at a dose below that which produces maternal toxicity. As with other types of responses, teratogenicity follows the dose–response relationship for a population, although often the slope of this curve is exceedingly steep, e.g., the dose range is very small between no effect in the population and a very high percentage of the population responding. Although a steep dose–response curve argues for the concept of a threshold dose in experimental animals, it is very difficult to extrapolate such information to the human situation. Furthermore, because of the very wide genetic variability among individuals within the human population, relative to the highly inbred characteristics of laboratory animals, it is likely that the threshold for teratogenic response will

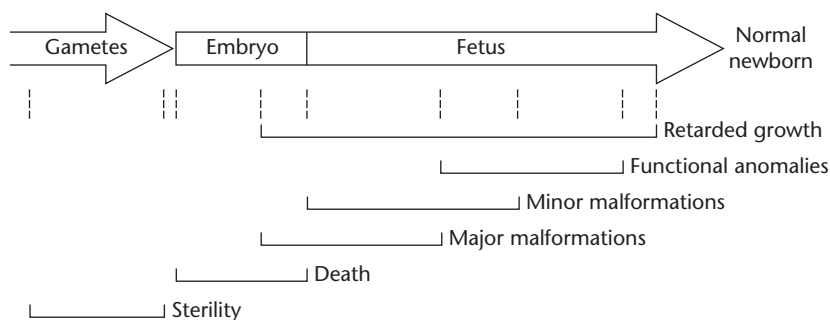

Figure 5.4: Sensitivity of the developing organism to birth defects. The period of development from fertilization to parturition is an important factor in reproductive toxicity. Damage to gametes usually results in infertility or early embryonic loss rather than frank birth defects. Exposure of the embryo during the early period of organogenesis may produce major malformations (teratogenic effects), whereas exposure during later periods of gestation more commonly produces functional anomalies and retarded growth.

vary more substantially among humans, making it more difficult to establish a safe level of exposure for everyone. Because of our relative ignorance about the causes of most birth defects and the likely high sensitivity of the developing fetus to some toxic chemicals, a high degree of caution in establishing so-called 'safe levels' of exposure for pregnant women is appropriate.

FACTORS THAT INFLUENCE TOXIC RESPONSES

Absorption

Although the terms exposure and dose are often used interchangeably, the two are substantially different. The term exposure has seldom been carefully defined, but generally, it connotes the amount or concentration of a pollutant present in air, water, soil, or other medium that potentially can be transferred to a subject. Dose, in contrast, generally refers to the quantity of material present in the medium of potential transfer that has actually passed from the medium into the organism. Different adjectives are sometimes provided to add more precision to these terms, such as exposed dose, administered dose, target dose, internal dose, and biologically available dose.¹⁸ A term frequently used in pharmacokinetics to describe the variation in the amount of exposed dose that is actually absorbed into the bloodstream (e.g., becomes systemically available) is referred to as its bioavailability. Conceptually, bioavailability is simply the fraction of the exposed dose that is absorbed. Thus, for example, ingestion of 100 mg (0.1 g) of soil containing 10 ppm of cadmium (10 micrograms of Cd per gram of soil) would result in an exposure (exposed dose or administered dose) of 1 microgram of Cd. Because the bioavailability of Cd through the gastrointestinal tract is only about 5-8%,¹⁹ the systemic or internal dose would only be 0.05-0.08 micrograms. The route of exposure (transdermal, gastrointestinal, or respiratory) is a critical determinant of the systemic dose, because some substances may be well absorbed by one route but poorly absorbed by another. For example, elemental mercury in its metallic form is extremely poorly absorbed following ingestion, yet inhalation of elemental mercury vapors results in rapid and nearly complete absorption by the respiratory tract.

There are several basic principles that dictate the extent of absorption of a substance at any given site of exposure. Because most toxic substances are absorbed by the process of simple diffusion, Fick's law of diffusion adequately describes the critical physicochemical parameters that influence absorption:

$$v_0 = dX/dt = \frac{PA}{d} (c_o c_i)$$

where v_0 = the rate of flux of compound across the membrane, P = the permeability coefficient, A = the surface area available for diffusion, d = the diffusion distance (thickness of the diffusion barrier), and $(c_o c_i)$ = the concentration gradient between the outside (c_o) and inside (c_i) of the compartment separated by the diffusion barrier.

Thus, for absorption of substances across the gastrointestinal, dermal, or pulmonary epithelium, where uptake occurs by simple diffusion, it is evident that the extent of absorption should be directly proportional to the surface area exposed, the concentration gradient, and the length of time over which exposure occurs, and inversely proportional to the thickness of the particular diffusion barrier. The permeability coefficient, P , is an arbitrary constant that is determined by both the physicochemical characteristics of the chemical and the particular diffusion barrier. Although small (molecular weight <100 Daltons) water-soluble molecules may pass with water directly through pores in biologic membranes, for the majority of toxic substances translocation across a biologic membrane occurs by diffusion through the lipid membrane. Because the diffusion barriers of skin, gastrointestinal, and pulmonary epithelium are principally lipid in nature, there tends to be a strong correlation between the permeability coefficient determined experimentally and the lipid solubility of the chemical. Lipid solubility, as determined by octanol/water partition coefficients (K_{ow} , unitless values that represent the ratio of a solute between two non-miscible solvents, octanol and water, at equilibrium), frequently is used as a crude predictor of bioavailability for chemicals about which little experimental data are available. Chemicals that are highly lipid soluble are in general well absorbed, whereas highly water-soluble substances are generally poorly absorbed. However, the relationship between the partition coefficient (K_{ow}) and the permeability coefficient is most appropriately described as hyperbolic (Fig. 5.5).²⁰

At low log K_{ow} values (e.g., low lipid solubility and high water solubility), chemicals cannot adequately diffuse through membranes. At log K_{ow} values between 1 and 10, substances are sufficiently water soluble to diffuse through the aqueous environment surrounding the cell barrier, yet

Figure 5.5: Relationship between partition coefficient (K_{ow}) and rate of absorption. Highly water-soluble chemicals (e.g., $K_{ow} < 0.01$) are generally poorly absorbed across the intact epidermis. Chemicals that exhibit characteristics of both water and lipid solubility (e.g., K_{ow} between 0.1 and 10) tend to have the highest transdermal absorption rates, whereas highly lipid-soluble chemicals (e.g., $K_{ow} > 100$) may partition into lipids in the epidermis and are only slowly absorbed into the systemic circulation.

they are also adequately lipid soluble to diffuse readily across the lipid membranes. Substances with very high log K_{ow} values may be unable to diffuse adequately through the aqueous unstirred layer that surrounds biologic membranes. Thus, organic chemicals that are highly lipid soluble but also sparingly soluble in water, such as some organophosphate insecticides, are generally well absorbed by either dermal or gastrointestinal routes and may have dermal LD₅₀ values that are close to those of the oral route.

Because the permeability coefficient is closely correlated with lipid solubility, the absorption of weak organic acids and bases is greatly influenced by the pH at the site of absorption. The extent of ionization of a weak acid or base is a function of both the pH and the pKa for the chemical, as described by the Henderson-Hasselbalch equation:

$$\text{For weak acids, } \text{pKa} - \text{pH} = \log \frac{[\text{non-ionized}]}{[\text{ionized}]}$$

$$\text{For weak bases, } \text{pKa} - \text{pH} = \log \frac{[\text{ionized}]}{[\text{non-ionized}]}$$

Thus, weak organic acids, which generally have pKa values between 3 and 4, exist predominantly in the lipid-soluble, non-ionized form at pH values less than 3, whereas weak organic bases (pKa values usually between 6 and 8) are in the ionized, water-soluble form at low pH. From this, one might assume that weak organic acids would be primarily absorbed in the stomach, with a pH of 2 to 3, relative to the intestine with a pH of 6 to 7. Although the rate of absorption is higher in the stomach, the extent of absorption is often greater in the small intestine because both the time of contact and the total surface area are much greater in the intestine than in the stomach.

Because there are specific features of each common route of exposure, and an understanding of these differences can have important practical clinical implications in both the preventive measures used to reduce absorbed dose and in the management of poisoning, each route is discussed separately.

Absorption by the gastrointestinal tract

The gastrointestinal tract functions physiologically as an organ of absorption; therefore, it is not surprising that many chemicals are well absorbed when ingested. In contrast to drug intoxications and attempted suicides by poisoning, however, gastrointestinal absorption is not the most common route of exposure in the occupational environment. Nevertheless, secondary ingestion of toxic substances by hand-to-mouth contact or mucociliary clearance of contaminants collected in the upper respiratory tract can be a major route of exposure in the occupational environment. Ingestion of contaminated food and water also is a common route of exposure to environmental pollutants.

As noted, although the stomach can serve as a site of absorption for most chemicals, especially weak acids, the majority of absorption occurs in the small intestine.^{21,22} In humans, the combined length of the duodenum, jejunum, and ileum is about 2.7 m. The inner surface of the intestine

Acid and other secretory products (e.g., proteolytic enzymes, mucus, and lipases)
Gastric and intestinal contents
Gastric and intestinal motility
Bile salts and other constituents of bile
Bacterial flora

Table 5.3 Factors that influence gastrointestinal bioavailability

contains numerous villi of about 0.5 to 1 mm in length and 0.1 mm in diameter. There are approximately 25 villi per square millimeter of surface, and the villi are covered with a simple columnar epithelium. These cells, called enterocytes, make up 90% of the surface area of the small intestine and contain a brush border membrane of microvilli. The total absorptive surface area (villi and microvilli) of the small intestine in humans is thus about 200 m². The colon also is a site of absorption in humans, principally of water, sodium, and other minerals. The length of the human colon is about 1.1 m, and it does not contain villi, although transverse folds enhance the total surface area.

In addition to the large surface area and relatively thin diffusion distance (one cell layer) of the gastrointestinal tract, blood flow to the small intestine is relatively high, receiving about 6-7% of the cardiac output in usual circumstances. This increases substantially after a meal, with the increase in blood flow specifically directed to the mucosal area. The high rate of blood flow through the intestine quickly removes absorbed substances such that the concentration gradient from the intestinal lumen to the circulation is nearly maximal, enhancing the rate and extent of absorption.

There are numerous factors that can influence the extent of absorption of toxic substances in the gastrointestinal tract (Table 5.3). An important consideration for the absorption, and even toxic characteristics, of some chemicals is the presence of a high concentration of anaerobic bacteria in the colon. These bacteria may themselves metabolically alter drugs and chemicals, with consequent changes in both bioavailability and toxicity. For example, the presence of β -glucuronidase-containing bacteria in the gut can result in the hydrolysis of highly polar glucuronide conjugates of toxic substances excreted in the bile. Hydrolysis of the glucuronide conjugate returns the chemical to a lipid-soluble, bioavailable form where it can be reabsorbed.²³

Early in life, the bacterial flora of the intestine is different in infants receiving only breast milk or formula, and is efficient at reducing inorganic nitrate to nitrite. In contrast, this bacteria-mediated reduction does not occur to any significant extent in adults. Thus, consumption of well water containing inorganic nitrate (e.g., 100 ppm) is of little consequence to the human adult but can result in serious or even fatal methemoglobinemia in infants.

Absorption of chemicals across the skin

In contrast to the gastrointestinal tract, the physiologic function of the skin is to act primarily as a barrier to the absorption of exogenous substances from the environment

Figure 5.6: Anatomy and function of healthy human skin. The skin is composed of several layers (epidermis, dermis, and hypodermis) and contains a variety of appendages. The major barrier to absorption lies in the outermost layer of keratinous cells in the epidermis (stratum corneum). (From Ritschel WA, Hussain AS. The principles of permeation of substances across the skin. *Methods Find Exp Clin Pharmacol* 1988; 10:39–56.)

and to prevent an excessive loss of water and electrolytes from the body.²⁴ The average adult has a skin surface area of approximately 1.8 m², which varies substantially among different anatomic areas in thickness and permeability to exogenous agents. The skin, as an organ, contains three anatomically distinct areas: the epidermis, the dermis, and the hypodermis (subcutaneous fat, Fig. 5.6). The protective function of the skin lies solely in the epidermis, which itself contains six identifiable layers (Fig. 5.7). The epidermis contains no blood vessels and varies in thickness from about 100 µm (eyelids and scrotum) to 800 µm (palms and soles). The outermost layer of the epidermis, the stratum corneum, consists of multiple layers of flattened, dead cells containing about 40% protein (primarily keratin), 40% water, and 15–20% lipids. This portion of the epidermis is between 10 and 50 µm in thickness, depending on the location and degree of hydration. The stratum corneum is continuously shed, with lost cells replaced by the migration of germinal cells toward the surface. The process of conversion of viable germinal cells to dead, keratin-filled cells in the outer layer of the stratum corneum takes approximately 5 days.

The dermis is about 20–30 µm in thickness and consists primarily of a gelatinous matrix of polysaccharides containing a fibrous protein structure of elastin, collagen, and reticulum. The dermis contains a rich blood supply,

which traverses into the innermost layers of the epidermis (stratum malpighii) containing the germinal cells of the stratum corneum. Thus, the actual site of absorption into the systemic circulation occurs at the dermoepidermal interface.

The hypodermis, or subcutaneous fat layer, serves as a heat insulator and shock absorber and a source of energy. It varies in thickness from practically non-existent (eyelids) to several millimeters or more. Because of the high lipid content of this layer, it can potentially serve as a significant reservoir for the accumulation of highly lipid-soluble chemicals following extensive dermal contact.

Skin appendages include hair follicles, sebaceous glands, eccrine sweat glands, and apocrine sweat glands. Although such appendages provide a means of bypassing the stratum corneum, the total surface area covered by all skin appendages is less than 0.1% in most anatomic regions, and their contribution to total percutaneous absorption is considered negligible.²⁵

The absorption of chemicals across the skin (percutaneous absorption) occurs exclusively by simple diffusion because no carrier-mediated transport systems or other means of translocation have been described. After a chemical has come into contact with the skin, it may enter the systemic circulation by either the transepidermal or transappendageal route (Fig. 5.8).²⁵

Figure 5.7: Anatomy of the human epidermis. The outermost layer of the epidermis, the stratum corneum, consists of multiple layers of dead, keratin-filled squamous cells, which serve as the principal barrier to dermal absorption of toxic substances. (From Ritschel WA, Hussain AS. The principles of permeation of substances across the skin. *Methods Find Exp Clin Pharmacol* 1988; **10**:39–56.)

As noted, the relative extent of absorption of chemicals across the skin that occurs by diffusion through the cells of the stratum corneum (intracellular) in contrast to between the cells (intercellular) has been the subject of debate. It has been postulated that the permeation of substances between cells may be a more important determinant of percutaneous absorption than either the thickness or number of cell layers. However, the diffusion distance postulated for intercellular absorption (359 μm) is nearly 15 times greater than the diffusion distance for intracellular absorption (25 μm), and the available surface area is 10 to 100 times less. Thus, the intercellular rate of diffusion would have to be several orders of magnitude greater than the intracellular rate if it were to contribute substantially to the total extent of percutaneous absorption. However, the dissolution of the extracellular lipids by repeated dermal contact with organic solvents, opening pores through the stratum corneum, may largely explain the large increase in percutaneous absorption that occurs following repeated dermal exposure to solvents.

The absorption of toxicants across the skin is a two-step process involving both (1) the diffusion of substances through the stratum corneum into the epidermis–dermis interface and (2) clearance of the diffused material from the dermis. Clearance depends on effective blood flow, interstitial fluid movement, and lymphatic vessels. Thus, depending on the relative rates of transepidermal diffusion and dermal blood flow, absorption may be either diffusion or flow limited. In places where the stratum corneum remains intact and blood flow is normal, diffusion is almost always the rate-limiting step. There is little question that the primary barrier to percutaneous absorption of chemicals is the stratum corneum. Removal of this horny layer of dead cells by repeated stripping with adhesive tape

resulted in more than a 100-fold increase in uptake of several corticosteroids, demonstrating the importance of this outermost layer of skin.²⁵ On penetration of the stratum corneum, diffusion through the inner layers of the skin is extremely rapid for most substances. For example, the rate of diffusion of octanol through the lower viable epidermal cellular layers and dermis was approximately 500 times faster than the rate of diffusion through the outer stratum corneum.

Factors that influence percutaneous absorption. There are numerous factors that can influence both the rate and extent of absorption of chemicals across the skin (Table 5.4).²⁴ The single most important consideration is the integrity of the stratum corneum. Physical damage to this barrier results in greatly enhanced penetration, as does

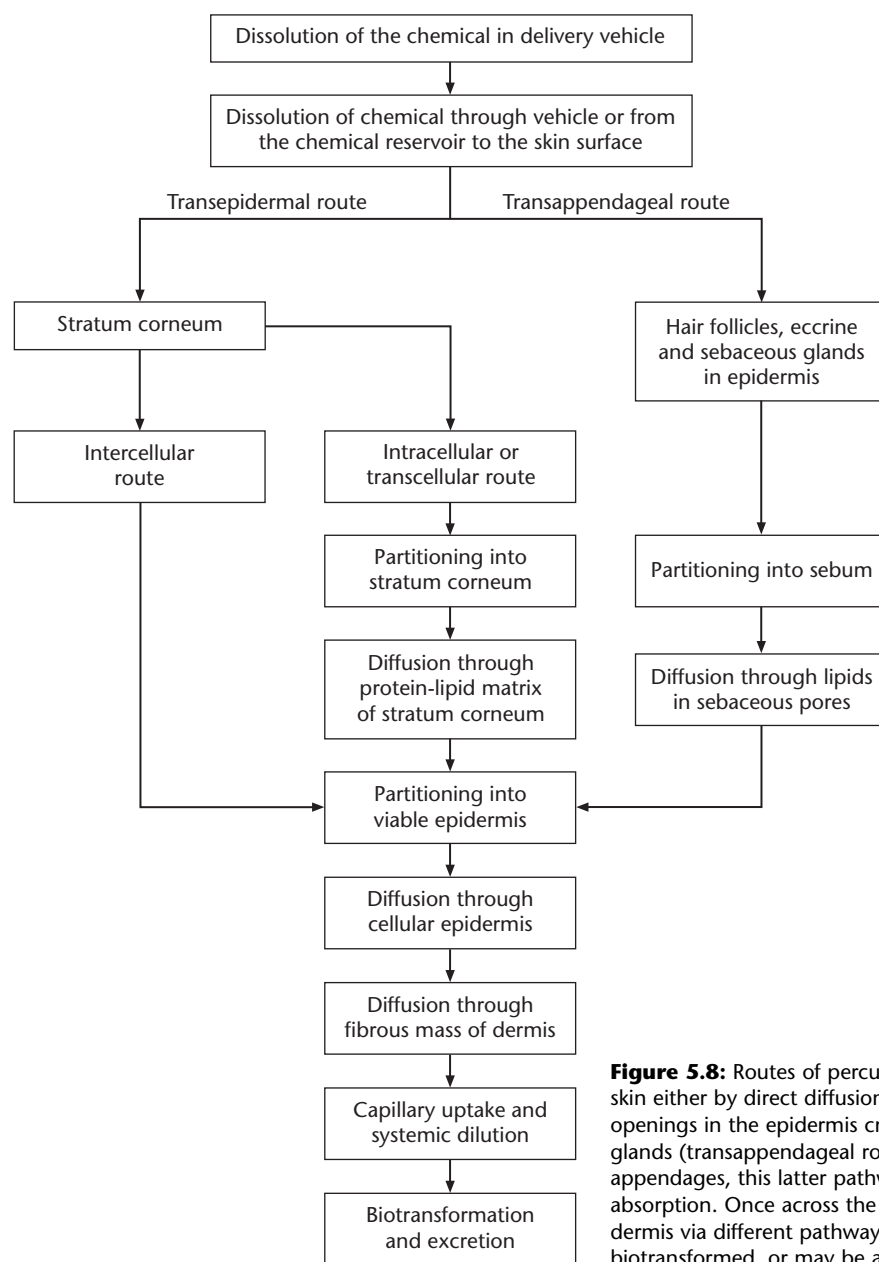

Figure 5.8: Routes of percutaneous absorption. Chemicals may pass through the skin either by direct diffusion through the epidermis (transepidermal route) or via openings in the epidermis created by hair follicles, sweat glands, or sebaceous glands (transappendageal route). Because of the small surface area of these appendages, this latter pathway generally contributes little to total dermal absorption. Once across the epidermal barrier, chemicals may diffuse through the dermis via different pathways, may partition into dermal lipids, may be biotransformed, or may be absorbed into the capillary circulation in the dermis.

irritation, inflammation, and other forms of injury. The age of the skin does appear to be important; children and elderly persons tend to have higher rates of percutaneous absorption than do young adults. The increased permeability of small children relative to adults may have to do with the increased degree of hydration, whereas the increase in percutaneous absorption in the elderly person is probably related to changes in skin structure caused by aging and cumulative solar damage. Skin diseases, such as eczema and psoriasis, also can alter the effectiveness of the stratum corneum barrier and increase the extent of blood flow to the dermis as a result of inflammatory processes. Enhanced blood flow facilitates the removal of diffused materials from the epidermal–dermal interface, which results in an enhanced concentration gradient from stratum corneum to dermis.

Regional differences in the absorption of chemicals across the skin have important implications for occupational and environmental exposures. There are relatively few studies that have carefully examined regional differences in absorption, and those that have are often contradictory. However, there is general agreement that the scrotum and posterior auricular skin are the sites of highest absorption, whereas plantar and palmar regions tend to be the least permeable. However, among different individuals, differences in the same region may be substantial. In general, the permeability across different areas of skin is inversely correlated with the thickness of stratum corneum. Penetration rates in cadaver skin increase in the following anatomic order: plantar, anterior forearm, instep, scalp and ventral thigh, scrotum and posterior auricular region.²⁴

There are also wide differences in percutaneous absorption among different species.^{20,24} The skin of rats, rabbits, and mice frequently have been used to examine the dermal bioavailability of drugs and chemicals, yet in the few studies in which comparisons have been made, the dermal permeability of most drugs and chemicals is greater in these animals compared with human skin. Although the relationship between species is not consistent for different substances, the permeability generally increases in the order monkey > dog > cat > rabbit > rat > guinea pig > mouse > forearm skin of humans.²⁰ The pig is often considered to be the best animal model for studies of transdermal penetration of drugs and chemicals.²⁶

Although skin is generally not considered a major site of biotransformation of chemicals, biotransformation of some substances in the skin may be of critical toxicologic significance. The activity of most drug-metabolizing enzymes in the skin is low relative to the liver, but even low rates of metabolism for chemicals that are slowly absorbed or accumulate in the epidermis can be important in the ultimate disposition. The skin has the ability to perform a variety of oxidative biotransformations, including the oxidation of hydrocortisone, testosterone, aliphatic hydrocarbons, alicyclic hydrocarbons, and polyaromatic hydrocarbons. Indeed, the cytochrome P450-mediated oxidation of benzo[a]pyrene to the vicinal diol epoxide in the skin is thought to be essential to the ability of this compound to induce papillomas and carcinomas following repeated dermal application. Although the activity of aryl hydrocarbon hydroxylase in skin is only about 2% that of the liver, it is highly inducible following repeated dermal applications of polyaromatic hydrocarbons. The ability of the skin to perform a variety of other biotransformation reactions, including reduction reactions, hydrolysis of ethers, and glucuronide and sulfate conjugation, has been reported. Evidence for cutaneous first-pass metabolism of chemicals following dermal application has been demonstrated.

Among the various physicochemical factors that can influence percutaneous absorption, the extent of hydration is one of the more important. The permeability of skin has been shown to increase as much as 4-5-fold following hydration. The increase in penetration after hydration may result from an increase in the size of the pores in the stratum corneum. However, at high water concentrations, there are changes in both the diffusion and activity coefficients of the penetrating agent, in addition to physical changes in the stratum corneum. Dehydration also may enhance absorption by causing damage to the integrity of the stratum corneum. At water concentrations below 10%, the stratum corneum becomes brittle and loses its functional integrity.²⁰

Occlusion of the skin is an especially effective means of enhancing percutaneous absorption; in one study, occlusion with an impermeable barrier resulted in a 50-fold increase in penetration compared with that of the same chemical in an identical formulation without occlusion. The significance of occlusion on skin permeability is especially noteworthy in the occupational setting. The use of

gloves that serve as an incomplete barrier to chemicals may actually enhance percutaneous absorption by (1) increasing permeability by increased skin hydration and elevated temperature and (2) increasing the contact time and epidermal concentration, especially for volatile chemicals that would otherwise evaporate from the surface of the skin. Thus, it is imperative that gloves worn to protect against skin contact from chemicals be truly impermeable to the chemical of concern.

Occupational and environmental exposure to chemicals often occur in mixed media. For example, many pesticides are formulated in organic solvents. The nature of the vehicle that contains the solute may be of prime importance in determining dermal bioavailability. The rate and extent of penetration of a chemical is dependent on the relative partitioning of the substance between the vehicle and the epidermis. The use of barrier creams may reduce dermal absorption by preventing contact of the material with the dermis or by providing a 'skin-vehicle' partition coefficient that highly favors partitioning of the chemical into the vehicle. Conversely, chemicals that are only sparingly soluble in a solvent but are readily soluble in the lipid matrix of the epidermis may penetrate the skin much more rapidly than if they were applied directly or in a vehicle in which they are highly soluble. For example, when pure alcohols are applied to the skin, their rates of penetration are much lower than their corresponding rates in aqueous solutions. Some substances, such as dimethyl sulfoxide, dimethylformamide, and propylene glycol, can act as 'sorption enhancers', greatly increasing the permeation of other substances through the skin.²⁷ Percutaneous absorption of some substances has been increased 1000-fold by sorption promoters. Detergents and other surfactants also can alter the percutaneous absorption of other substances. Among the various types of surface-active agents, anionic surfactants are the most effective at enhancing percutaneous absorption, followed by non-ionic and cationic agents.

Classification of chemicals in terms of risk from dermal exposure. The American Conference of Governmental Industrial Hygienists (ACGIH) and a variety of occupational health regulatory agencies worldwide have identified compounds that are regarded as especially hazardous following dermal contact by use of the 'skin' denotation. The ACGIH lists 179 different compounds regarded as skin hazards. Although there is a large degree of inconsistency among the different lists that have been compiled, with nearly 400 chemicals appearing on at least one list, there is a smaller group of chemicals that are commonly identified as skin hazards (Table 5.5). Although the limitations of such lists have been discussed, they do provide a useful and quick reference for chemicals that may be especially problematic if they do come into contact with human skin. However, as noted by Granjean,²⁸ '... the lack of skin denotation for a particular substance does not necessarily exclude that hazardous quantities can be absorbed, provided that, e.g., the vehicle is right or the skin is occluded or damaged'. Finally, the contributions of dermal

Acrylamide	Epichlorohydrin	Nicotine
Acrylonitrile	EPN	Nitrobenzene
Aldrin	Ethylene chlorohydrin	Nitroglycerin
Allyl alcohol	Ethylene glycol dinitrate	Nitrotoluene
Aniline	Ethylene glycol monobutylether	o-Methylcyclohexanone
Benzene	Ethylene glycol monoethyl ether acetate	p-Nitrochlorobenzene
Carbon disulfide	Ethylene glycol monomethyl ether	p-Dioxane
Carbon tetrachloride	Ethylene glycol monomethyl ether acetate	p-Nitroaniline
Cellosolve (glycol ether)	Ethyleneimine	p-Phenylenediamine
Chlordane	Furfural	Parathion
Chlorinated naphthalenes	Heptachlor	Pentachlorophenol
Chloroprene	Hydrazine	Phenol
Cresol	Hydrogen cyanide	Phenylhydrazine
Demeton-methyl	Lindane	Picric acid
Diazinon	Malathion	Polychlorinated biphenyls
1,2-Dibromoethane	Mercury	Propargyl alcohol
2,2'-Dichlorodiethyl ether	Methyl acrylate	Sodium fluoroacetate
Dichlorvos	Methyl alcohol	1,1,2,2-Tetrachloroethane
Dieldrin	Methyl bromide	Tetraethyl lead
Diethylaminoethanol	Methyl sulfate	Tetryl
Dimethylacetamide	Mevinphos	Thallium
Dimethylaniline	Morpholine	Toluidine
1,1-Dimethylhydrazine*	n-Butylamine	Trinitrotoluene
Dinitrobenzene	n-Methylaniline	Xylene
Dinitro-o-cresol	N,N-Dimethylformamide	Xylidine
Endrin		

* Only 1,1-dimethylhydrazine does not have a 'skin' denotation on the ACGIH list.

Table 5.5 Chemicals commonly identified as hazardous by dermal exposure

absorption to overall exposure to toxic substances is often underestimated, especially for volatile chemicals. For example, using an experimentally determined dermal permeability value for benzene, the amount of benzene absorbed through the hands during long-term exposure to solvents contaminated with 0.1% benzene could increase the theoretical risk estimate for leukemia by 42%.²⁹

Absorption of chemicals by inhalation exposure

The lung serves as an important site of contact with chemicals in the external environment. Such contact can result in direct damage to the respiratory epithelium or may lead to systemic toxicity following absorption into the blood stream. Like the gastrointestinal tract, the lung is designed for optimal absorption. It has a large total surface area (50-100 m²) and a high blood flow (4 to 5 L/min) that is in intimate contact with the respiratory epithelium, which itself is of minimal thickness (10 µm diffusion distance).

Absorption of chemicals from inspired air can occur regardless of the physical form. For gases and fine vapors, absorption occurs by direct diffusion from alveolar air spaces across the epithelial cells, whereas for aerosols and other types of particles, deposition occurs along various aspects of the tracheobronchial tree, with the specific location depending on the size and density (mass median diameter). (See Roth³⁰ for a comprehensive review of toxicology of the respiratory system.)

Absorption of gases and vapors. The rate of absorption of gases and vapors by the lung is largely a function of the

'blood-gas partition coefficient'. Applying the principles of Henry's law to blood and alveolar gas, the concentration of a gas in the blood as it leaves the lungs is dependent on the solubility of the gas in blood, which is defined as the ratio of the concentration of the dissolved gas in the blood to the concentration in the gas phase at equilibrium.³¹ Thus, chemicals with high blood-gas partition coefficients will have a high rate of uptake into the blood stream, relative to those chemicals with low blood-gas partition coefficients. For chemicals with a low solubility in blood, only a small fraction of the gas present in the alveolar space will be removed, and an increase in respiration will not enhance uptake. An increase in blood flow through the lung will greatly enhance uptake (perfusion limited). Conversely, an increase in respiration rate can significantly enhance the extent of absorption of gases that are readily soluble in blood because the delivery of gas to the blood, and not the dissolution into the blood, may be rate limiting in regard to uptake (ventilation limited). The solubility of a gas in the blood should not be equated to its solubility in water because components of blood other than water can greatly affect the solubility of some gases. For example, carbon monoxide, because of its high affinity for hemoglobin, has an extremely high apparent blood-gas partition coefficient even though it is only sparingly soluble in water.

The site of absorption of gases and vapors from the lungs is largely dependent on water solubility. Highly water-soluble gases present in low concentrations in inspired air, such as hydrochloric acid or sulfur dioxide, are usually removed in the upper respiratory tract, although higher concentrations and longer durations of exposure

Figure 5.9: Particle deposition by size distribution in various regions of the lung. Particles deposit in different regions of the lung, based largely on the size of the particle. (From Kennedy GL. Inhalation toxicology. In Hayes AW, ed. Principles and methods in toxicology, 2nd edn. New York: Raven Press, 1989.)

allow bioavailability to the alveolar regions of the lung where they may cause serious pulmonary damage. Gases that are less soluble in water, such as nitrogen oxides and ozone, are not efficiently removed by the upper respiratory tract and tend to reach alveolar regions at relatively low concentrations. For those gases and vapors that impart their toxic properties systemically, the site of absorption is of far less concern than the rate and extent of absorption.

Deposition and clearance of particles from the lung. In contrast to gases, for which contact with the pulmonary epithelium occurs exclusively by diffusion, particles (aerosols) deposit on the pulmonary epithelium primarily through physical forces dictated by the particle size, shape, and mass. Inhaled aerosols are heterogeneous in size, and the size distribution usually follows a log-normal pattern. The geometric mean and geometric standard deviation of the particle size distribution is commonly obtained by plotting the cumulative percentage of particles less than a stated size increment against the log of the stated size on log probability paper. The ‘mass median diameter’ is a common means of characterizing aerosol size distribution because it considers not only the physical diameter of the particles, but also their density. For particles that are not spheric (e.g., asbestos fibers), a consideration of aerodynamic drag becomes important, and the determination of ‘aerodynamic diameter’ is most useful. This term describes the settling behavior of a non-spheric particle, whatever its size, shape, and density, in terms of a unit density sphere having the same settling velocity as the particle under study. The aerodynamic diameter of particles is a primary determinant of the site of deposition within the respiratory tract. Figure 5.9 shows the influence of particle size distribution on the regional deposition of an inhaled

aerosol. It is evident that aerosols with aerodynamic diameters greater than 10 μm are not capable of passing beyond the nasopharyngeal area.³²

Particles may be deposited on the respiratory tract epithelium by three fundamental processes.

1. **Inertia.** Particles with sufficient mass will collide with the surface of the respiratory epithelium at points of branching and curvature. As the direction of air velocity changes, the inertial force of the particles will prevent them from changing directions at the same rate as that of the air flow. The greater the mass, the less the ability of the particles to change direction with air flow. Thus, deposition of particles occurs by impaction. For particles that are non-spheric (e.g., asbestos fibers), the term ‘interception’ is sometimes used to describe the deposition that results when an edge of the particle contacts the surface of the epithelium.
2. **Sedimentation.** Particles that are of sufficiently small size to escape deposition by inertia may deposit on the respiratory epithelium through sedimentation when the velocity of air flow becomes slow. Gravity is the predominant force behind sedimentation, and the rate of sedimentation is proportional to the density of the particle and the square of its diameter.
3. **Diffusion.** For extremely small particles, Brownian motion, in which suspended particles are bombarded by surrounding gaseous molecules, is the principal means of deposition. In contrast to both inertia and sedimentation, the rate of diffusion is not appreciably influenced by the particle density, but it is inversely proportional to the diameter.

Although particle size (i.e., aerodynamic diameter) is the principal determinant of deposition, other factors, such as

breathing pattern, airway diameter, and the anatomy of the nasal, oral, and pharyngeal areas, are also important. Thus, pathologic or irritant conditions that result in narrowing or obstruction of airways, excessive bronchial secretions, or other conditions that alter the size and shape of the respiratory tract can alter the extent and pattern of particle deposition.

Clearance of particles from the lungs. Particles may be removed from the lungs by several mechanisms. Particles deposited in the upper nasopharyngeal area are cleared primarily by entrapment in the mucous lining and removal by reflex responses, such as sneezing or coughing, or through the continuous movement of mucus up the mucociliary escalator, where the entrapped particles are either swallowed or expectorated. The former is an important toxicologic consideration because it can result in significant ingestion of toxic materials even though exposure occurred by inhalation of particles. The mucociliary escalator is the primary means of clearance of particles in the tracheobronchial tree and functions down to the level of the terminal bronchioles. The clearance half-time by this process is between 12 and 24 hours.

Phagocytosis of particles by pulmonary macrophages is the principal route of elimination of particles that deposit in the alveoli and terminal bronchioles. Macrophage-containing particles may migrate to the ciliated epithelium of the terminal bronchioles and move up the mucociliary escalator, or they may enter the lymphatic vessels. This process takes from 2 to 6 weeks for effective elimination of particles. Some particles may actually be solubilized by body fluids and the constituents absorbed into the blood stream or lymph.

Obviously, any toxicologic response that reduces or eliminates particle clearance can result in more extensive accumulation of particles and potentially enhance the toxicity of the particles themselves or of toxic constituents that are slowly dissolved from the surface of the particles. Cigarette smoking has been demonstrated to reduce significantly the rate and efficiency of the mucociliary escalator. The inefficient removal of particles in heavy smokers may contribute, at least in part, to the well-described synergistic interaction in the lung cancer risk between asbestos and smoking.

DISTRIBUTION OF CHEMICALS IN THE BODY

First-pass effect

Because the critical dose parameter for any toxic effect relates to the concentration of a chemical at the biologic receptor site, the extent and nature of distribution of the absorbed chemical in the body can have a significant impact on the toxicity of that chemical. After a substance has entered the systemic circulation, it is potentially available to all tissues in the body. However, biologic activity at or near the site of absorption may drastically reduce the availability of the original chemical to distant sites, even

though absorption into the circulation is complete. This phenomenon, referred to as the 'first-pass effect,' is most often described in association with absorption of substances following ingestion.³³ Generally, the first-pass effect after oral absorption is the result of efficient extraction and metabolism of a chemical by the liver. The blood perfusing the gastrointestinal tract is collected in the portal vein, and thus, all substances absorbed from the gastrointestinal tract must pass through the liver prior to distribution to other organs. The liver maintains a high capacity for both extraction and biotransformation of exogenous substances, and can effectively prevent some chemicals from ever reaching the rest of the body. Although hepatic extraction is generally recognized as the most important site of removal for chemicals demonstrating a first-pass effect following oral administration, extraction and biotransformation by the gastrointestinal epithelium may also contribute.³⁴ The skin is also capable of first-pass metabolism of chemicals following dermal exposure, although the extent of this effect is generally far less important than that for oral exposure.

Binding and storage

Binding of chemicals to proteins can also have a dramatic effect on the toxicologic response to a given absorbed dose. Many chemicals bind to plasma proteins, especially albumin and globulins. Because only the concentration of 'free' (unbound) chemical is available for interaction with biologic receptors, extensive protein binding can greatly reduce the toxicity of a compound. For chemicals that are highly bound to plasma proteins, even a small shift in protein binding can have a large effect on their pharmacologic functions. For example, if the equilibrium binding of an absorbed chemical to plasma proteins is 98%, a change in binding status from 98% to 96% would result in a doubling of the concentration of free chemical and an attendant increase in its toxicity. This is especially a problem when multiple exposures occur to substances that share the same binding site, and it is a common mechanism of drug-drug or drug-chemical interactions.

If protein binding of toxic substances to intracellular proteins occurs, the tissue may serve as a 'sink' for accumulation of a chemical, prolonging the biologic half-life of the chemical. For example, Cd is a highly toxic element that binds avidly to intracellular binding proteins called metallothioneins. These low molecular weight proteins, which are inducible (their quantity increases) on repeated exposure to Cd and certain other metals, are present in relatively high concentrations in the liver and kidney. Following oral exposure to a dose of Cd, the majority of the absorbed dose (usually only a small percent of the exposed dose) is concentrated in the liver and bound largely to metallothioneins.³⁵ In this instance, the preferential binding serves as a protective mechanism against Cd-induced liver damage by preventing Cd from binding to essential cellular proteins. However, the Cd-metallothionein complex is slowly transported out of the liver to the kidney, where the complex is

extracted by the proximal tubules. As the metallothioneins protein is degraded by normal catabolic processes, Cd is released and binds to either renal metallothioneins or other intracellular thiols, including critical proteins. The net effect of this is an extraordinarily long biologic half-life for Cd (up to 30 years), with the majority of the body burden eventually concentrated in the renal cortex. After the concentrations exceed the binding capacity of renal metallothionein, irreversible and potentially fatal kidney damage can result.

Lipid-soluble chemicals that are poorly metabolized will redistribute to poorly perfused fat depots following equilibration in the rapidly perfused tissues. Many lipid-soluble chemicals rapidly affect central nervous system function after exposure. A relatively high fraction of the absorbed dose enters the brain because of the high rate of perfusion of the brain and partitions into brain tissue because of the relatively high lipid content. The duration of action of this effect following an acute exposure is often short because the chemical quickly redistributes from the brain to the more slowly perfused peripheral fat stores, or to sites such as the liver where the chemical may be more rapidly metabolized to water-soluble forms and eliminated by urinary or biliary excretion.

Special barriers to distribution

The so-called 'blood-brain barrier' is an effective anatomic barrier to penetration of highly water-soluble chemicals into the brain.³⁶ This barrier is the result of several unusual anatomic characteristics, including the presence of tight junctions (desmosomes) between capillary endothelial cells, the presence of glial foot processes that effectively surround the capillary endothelium, a contiguous basement membrane, and a relatively low protein content in the interstitial fluid of the brain. The relative contribution of the last two elements to the barrier function is probably small compared with that of tight junctions and glial cells. Thus, in contrast to most other organ systems, where intercellular gaps in the capillary endothelium allow free access of chemical into parenchymal cells, in the brain a chemical must pass through several biologic membranes (capillary endothelial cells and glial cells) and interstitial fluid before coming into contact with neurons. This barrier is effective against most water-soluble chemicals, except very small substances that can diffuse with water through membrane pores, (e.g., lithium). However, it presents little impediment to the diffusion of lipid-soluble substances into the brain, and consequently, nearly all organic solvents can readily enter the brain and produce aberrant effects on central nervous system function.

A similar concept has been described for the testis. The 'blood-testis' barrier, like the blood-brain barrier, does limit the bioavailability of some water-soluble substances to germinal cells, but again, it provides little protection against lipid-soluble compounds.³⁷ Sertoli cells appear to be primarily responsible for the blood-testis barrier because adjacent Sertoli cells form occluding junctions between the germ cells in various stages of development.

The distribution of chemicals to different organs systems may also be affected by the presence of specific carrier-mediated transport processes. Such processes are most active in the liver, kidney, and intestine, although transport processes have been described in the choroid plexus and lung. The transport processes in the liver and kidney function primarily to aid in the uptake and elimination of foreign substances and metabolic byproducts from the blood, whereas those in the intestine function primarily to aid in the absorption of water-soluble nutrients that would otherwise not be absorbed. The physiologic functions of transport processes for organic substances identified in the lung are not known, but the presence of these transport systems can have important toxicologic consequences. For example, the herbicide paraquat is highly and specifically toxic to the lung, regardless of the route of administration, due in part to an active transport system that concentrates paraquat in type II pneumocytes.³⁸

Biotransformation of chemicals

For many chemicals, the toxic effects are highly dependent on the metabolic fate of the chemical in the body. Because few xenobiotics are actually fully metabolized to carbon dioxide and water, the metabolic processes that change the structure and characteristics of a chemical are appropriately referred to as 'biotransformation' reactions. There are a multitude of enzymatic pathways capable of such reactions, and the quantitative and qualitative differences in the ability of different organs to conduct such processes is often responsible for the 'organotropic' (i.e., organ-specific) effects of many chemicals. For example, the liver is the most common site of toxicity for chloroform and carbon tetrachloride, largely because of the ability of this organ to biotransform these compounds rapidly into reactive free radical intermediates.³⁹

Regardless of the specific pathways involved, conceptually the ultimate 'goal' of biotransformation reactions is to render potentially toxic chemicals less toxic. This is accomplished in two ways by: (1) the addition of polar groups to lipid-soluble chemicals, which decreases the ability of chemicals to penetrate cell membranes on the one hand and enhances the rate of elimination in urine or bile on the other, and (2) the alteration of chemical structure so that the chemical no longer 'fits' the specific biologic receptor (e.g., catalytic sites of enzymes or neurotransmitter receptors). However, it is now widely recognized that intermediates formed in the process may actually be of far greater toxicity than the 'parent' molecule, and thus, some biotransformation reactions may actually be deleterious 'activation reactions,' whereas others are considered 'detoxification' reactions.

Biotransformation reactions are commonly divided into two broad categories: phase I and phase II reactions.⁴⁰ Phase I reactions are so named because they are generally the first biotransformation step in what is often a multistep process leading to the eventual excretion of the biotransformed products. Phase II reactions are those enzymatic processes that use the products of phase I reactions to impart further

structural changes, usually greatly increasing the water solubility. However, this classification can be confusing because some biotransformation enzymes may act as either phase I or phase II enzymes, depending on the substrate. For example, the hydrolysis of epoxides by the enzyme epoxide hydrolase could be considered a phase I reaction if it were the first enzyme to metabolize an exogenous epoxide, such as trichloropropene oxide or heptachlor epoxide, whereas it would be considered a phase II reaction if it were acting on an epoxide generated endogenously by an oxidative pathway. However, with numerous notable exceptions, oxidation, reduction, and hydrolytic pathways are generally considered phase I reactions, whereas conjugation reactions are usually classified as phase II reactions. Virtually all biotransformation reactions of toxicologic significance can be identified as proceeding by one of the following four basic categories of pathways: oxidation, reduction, hydrolysis, and conjugation.

Oxidation reactions

The majority of oxidative biotransformation reactions are mediated by the cytochrome P450-containing mixed-function mono-oxygenase system. However, there are other important oxidative pathways, and thus, oxidation reactions are most conveniently divided into 'cytochrome P450-mediated' and 'non-cytochrome P450-mediated' pathways.

Cytochrome P450-mediated oxidation reactions

Cytochrome P450 is a heme-containing, membrane-bound complex located in the smooth endoplasmic reticulum. For experimental purposes, this enzyme system is most easily studied in crude subcellular fractions of homogenized tissues. The subcellular fraction containing the smooth

endoplasmic reticulum is referred to as the 'microsomal fraction,' and thus cytochrome P450-mediated reactions are often called microsomal oxidation reactions.⁴¹ Microsomes are readily prepared by differential centrifugation of homogenized tissues. The cell membranes, nuclei, mitochondria, ribosomes, and most other intracellular organelles are pelleted after centrifugation at 9000-15,000 *g*. Because the fragments of the smooth endoplasmic reticulum are less dense than these other organelles, they remain suspended in the supernatant (sometimes referred to as the S9 fraction). The microsomes can be separated from the soluble fraction of the cell homogenate by centrifugation for 1 hour at 100,000 *g*. The microsomal pellet obtained by this process can then be resuspended and used for in-vitro studies. The 100,000 *g* supernatant contains only soluble enzymes, and it can also be used for studies of soluble biotransformation enzymes. It is important to recognize that, in addition to the cytochrome P450 system, microsomes contain many other important biotransformation enzymes, and thus, microsomal metabolism is not completely synonymous with cytochrome P450-mediated reactions.

There are actually numerous forms of cytochrome P450 enzymes (more than 30 distinct enzymes have been identified in the human liver), and the genetics of these enzymes is becoming well understood. Although there is generally a broad overlap in substrate specificity between individual enzymes, specific P450 enzymes play a major role in the biotransformation of specific xenobiotics, and genetic differences in the expression and activity of specific P450 enzymes can be of substantial toxicologic and pharmacologic significance (Fig. 5.10). Genetic polymorphisms in xenobiotic metabolism are discussed in detail subsequently.

The number of chemicals that can undergo oxidation by the cytochrome P450 complex is large, as is the variety

Figure 5.10: Catalytic cycle of the cytochrome P450-dependent, mixed-function mono-oxygenase system. The cytochrome P450-dependent, mixed-function mono-oxygenase system catalyzes the addition of atomic oxygen to lipophilic substrates such as hydrocarbons. The iron in the heme portion of the molecule undergoes oxidation and reduction, transferring electrons from an electron donor (NAD[P]H) to molecular oxygen (O_2) and the substrate (S). The net result is the insertion of one atom of molecular oxygen into the substrate, and the second atom combines with hydrogen ions to form water.

Figure 5.11: Common oxidation reactions mediated via cytochromes P450. The cytochromes P450 system is capable of mediating the oxidation of a wide variety of drugs and other chemicals. See text for further discussion.

of biotransformed products that can result from a single substrate. However, it is possible to predict with some degree of confidence the possible array of metabolites that could result from cytochrome P450-mediated oxidation reactions by understanding the basic reactions that have been described. Cytochrome P450-oxidation reactions are commonly classified into ten different categories (Fig. 5.11).

The oxidation of aromatic and aliphatic hydrocarbons is one of the most common of the P450-mediated oxidations. The products of such reactions are generally hydroxylated metabolites. The hydroxyl group increases polarity

and also provides a molecular site for conjugation with highly polar groups, such as glucuronic acid or sulfate, by phase II biotransformation pathways. However, oxidation of hydrocarbons can also lead to the formation of highly electrophilic epoxides or other reactive intermediates, which may bind to nucleophilic sites within the cell, disrupting cellular function. Two common nucleophilic sites within the cell are reduced thiols in proteins and certain bases in DNA. The binding of electrophilic intermediates to thiols or other nucleophilic sites in essential proteins may result in cell injury or death, with a resultant loss in organ function. The formation of reactive epoxide

intermediates by cytochrome P450 oxidation is thought to be the initiating step in chemical carcinogenesis by a wide variety of chemicals, including polyaromatic hydrocarbons and the fungal toxin, aflatoxin B₁.

Oxidative dechlorination of carbon tetrachloride by cytochrome P450 is thought to be essential to the hepatotoxic effects of this chemical. Oxidative desulfuration by cytochrome P450 is essential to both the insecticidal activity and toxicity of many organophosphate insecticides because it is only the 'oxon' analogue that is capable of binding to and inhibiting acetylcholinesterase. Thus, although cytochrome P450-mediated oxidation reactions serve as a principal means of elimination of a wide variety of chemicals, this same pathway is also responsible for the activation of a variety of chemicals to more highly toxic and carcinogenic forms. Whether biotransformation through the P450 pathway results in net activation or detoxification is dependent on many other factors and is not always readily apparent. The kinetics of different cytochromes P450 enzymes toward the same substrate, relative to the kinetics of competing reactions, are critical to the ultimate outcome. For example, the widely used analgesic acetaminophen at normal therapeutic doses is largely metabolized by conjugation reactions (sulfation and glucuronidation), with only about 4% biotransformed by the cytochrome P450 system. Although one product of P450 biotransformation of acetaminophen is quite reactive, it is rapidly detoxified by intracellular reduced glutathione. However, at high doses, the ratio of biotransformation shifts more to the P450 system; with increasing doses, the tissue stores of glutathione become depleted, and the reactive intermediate then reacts with cellular thiols, binding to intracellular proteins and creating cellular damage, primarily in the liver where the majority of biotransformation of acetaminophen occurs.⁴²

Induction of cytochrome P450. An interesting and clinically relevant phenomenon of most cytochrome P450 enzymes (and many other biotransformation pathways) is their ability to increase activity after repeated exposure to certain exogenous agents. Enzyme induction occurs by gene activation in which the rate of messenger RNA synthesis increases, with a concomitant increase in enzyme production and activity. A wide variety of chemicals have been identified as 'microsomal enzyme inducers', but the specific pattern of enzyme induction differs. The two most widely studied enzyme inducers are phenobarbital and 3-methylcholanthrene (3-MC). Phenobarbital induces a broad spectrum of P450 enzymes (P4502B, 2C, 3A, and several other important biotransformation enzymes, including some glutathione S-transferases and glucuronyl transferases). 3-MC, other polyaromatic hydrocarbons, and the controversial and potent toxicant 2,3,7,8-tetrachlorodibenzo-p-dioxin (dioxin) induce a much narrower spectrum of biotransformation enzymes, most notably the cytochrome P4501A family, via the aryl hydrocarbon hydroxylase receptor (AHH) complex.

Although the spectrum of enzymes induced via the AHH receptor complex is more limited, the extent of

induction is often great, because constitutive (background) expression of the cytochrome P501A family of enzymes is very low. Thus, in the absence of exposure to AHH receptor agonists, enzyme activity is very low but increases dramatically on exposure. Because this enzyme system is principally responsible for the biotransformation of polyaromatic hydrocarbons, induction can be viewed as an attempt by the organism to respond to external stimuli by altering its capacity to deal with those stimuli. It is unclear whether induction of cytochrome P4501A enzymes is indeed beneficial to the organism because this enzyme system is responsible for the activation of polyaromatic hydrocarbons to carcinogenic intermediates, as well as formation of less toxic forms of the parent molecule.

Microsomal enzyme induction by phenobarbital-like inducers, which include many chemicals found in the workplace and general environment (e.g., some forms of polychlorinated biphenyls [PCBs] and organochlorine insecticides), can greatly accelerate the rate of biotransformation of numerous chemicals.⁴³ The significance of this effect is dependent on the relative toxicity of the products of biotransformation. Thus, induction with phenobarbital may decrease the toxicity of some compounds while enhancing the toxicity of others. Such chemical-chemical interactions are well described for therapeutic drugs, in which patients receiving chronic barbiturate therapy for epilepsy may require substantial dosage adjustment for other medications to be effective.

Non-cytochrome P450 oxidation reactions

Alcohol and aldehyde dehydrogenases. The pathways of oxidation of short-chain alcohols, such as methanol, ethanol, and isopropanol, are very important biotransformation routes because exposure to these substances is very common. Although cytochrome P450 2E1 enzymes are capable of oxidizing ethanol, the relative importance of this reaction to the overall metabolism of ethanol in humans is small. Primary oxidation of short-chain alcohols occurs by a two-step sequence involving alcohol dehydrogenase and aldehyde dehydrogenase.⁴⁴

The relative rates of metabolism of these two enzymes are important to the toxicologic effects of various alcohols. In the case of ethanol, the oxidation to acetaldehyde proceeds relatively slowly and in a zero-order kinetic fashion at doses capable of inducing even mild inebriation. That is, the quantity of ethanol metabolized is a fixed amount, rather than a fixed percentage, of the available dose. Thus, with repeated consumption of alcohol, the fraction of the dose metabolized becomes less as the dose increases. Aldehyde dehydrogenase functions relatively more efficiently than does alcohol dehydrogenase, preventing any significant accumulation of acetaldehyde under normal circumstances. Acetaldehyde is toxic and causes numerous adverse effects (headache, nausea, vomiting, hypotension, and flushing), and thus, chemicals that inhibit aldehyde dehydrogenase may produce these effects when combined with relatively low doses of alcohol. Several drugs and a few non-drug chemicals are capable of this effect. Disulfiram has been

used clinically for this purpose as a form of aversion therapy in the treatment of alcoholism.⁴⁵

Methanol metabolism proceeds by the same pathway as that for ethanol, but at a rate about seven times slower than that of ethanol. However, the consequences of formation of the two sequential metabolites, formaldehyde and formic acid, are much more severe. Virtually all of the severe and potentially irreversible effects of methanol can be attributed to these two metabolites. Retinal damage and blindness is thought to result from the localized production of formaldehyde in the retina. Life-threatening metabolic acidosis results from the formation of formic acid by aldehyde dehydrogenase. Because ethanol is preferentially metabolized by alcohol dehydrogenase and methanol will be eliminated largely unchanged in the urine if given adequate time, the inhibition of methanol biotransformation by intravenous infusion of ethanol or administration of fomepizole, an inhibitor of alcohol dehydrogenase, is standard therapy for methanol poisoning.⁴⁶ If the amount of methanol ingested is large, pharmacologic treatment may be combined with extracorporeal hemodialysis to aid in the elimination of unchanged methanol. Alcohol and aldehyde dehydrogenases are also important in the biotransformation of various other alcohols, aldehydes, glycols, and glycol ethers and in the reduction of ketones to alcohols.

Flavin-dependent mono-oxygenases (FMOs). Oxidation of certain secondary amines, tertiary amines, imines, arylamines, and hydrazines, and many sulfur-containing chemicals proceeds by microsomal mono-oxygenases that are distinct from the cytochrome P450 enzyme family. This family of flavin-dependent mono-oxygenases appears particularly active in the human liver and competes with the cytochrome P450 system for the oxidation of nucleophilic nitrogen and sulfur atoms.⁴⁷ The primary function of FMOs is in the detoxification of xenobiotics, and is likely the major route of oxidation of nucleophilic nitrogen, sulfur, phosphorus and other heteroatom-containing chemicals, including several important pesticides. Like the cytochromes P450, the FMOs are a multi-gene family of enzymes, with five different genes identified in humans to date. Interestingly, a genetic variant in one of these genes, FMO3, is associated with a malodorous syndrome known as 'fish odor disease'. Individuals who inherit the variant form of FMO3 are unable to metabolize trimethylamine, a highly malodorous component of fish oil.⁴⁸ Lack of metabolic elimination results in secretion of the compound in skin. Although not physiologically detrimental, this condition may be associated with psychosocial disorders.

Reduction reactions

Reduction reactions are relatively uncommon because cells function principally in an oxidizing environment. However, enzymatic reduction is important in the disposition of at least three general classes of chemicals: azo compounds, aromatic nitrates, and certain halogenated

hydrocarbons. Surprisingly, these reactions are also mediated by the cytochrome P450 system, but the substrate, rather than molecular oxygen, accepts the electrons and is reduced.

Reduction reactions occur commonly in the gut flora and can be quite important in the disposition and toxicity of substances. As noted, the formation of nitrite from nitrate is a reduction reaction that can occur in the gut flora of infants, resulting in potentially severe methemoglobinemia. The reduction of azo dyes by the gut flora may alter the absorption and toxicity of these compounds. Complex azo dyes such as Direct Black 38 or Direct Blue 6 may release carcinogenic products, such as benzidine, after azo reduction, whereas the reduction of single azo compounds usually is a detoxification step.

NAD(P)H:quinone oxidoreductase (NQO1) is widely distributed in mammalian species and tissues, and is involved in the reductive activation and detoxification of a variety of chemicals that contain, or can form, quinones or their derivatives. NQO1 is thought to play an important role in protection against oxygen radical formation that can occur from redox cycling of quinones.⁴⁹ It also is involved in the metabolic activation of several widely used antitumor agents, including mitomycin C and streptozin.

Hydrolytic reactions

The hydrolysis of esters, amides, and epoxides is important in the disposition of a wide variety of drugs and chemicals. The products of the hydrolysis of esters are an organic acid and alcohol, whereas the products of amide hydrolysis are an organic acid and a primary or secondary amine. The hydrolysis of epoxides results in a dihydrodiol.

There are a variety of different esterase and amidase enzymes with broad and somewhat overlapping substrate specificities.⁵⁰ Arylesterases are principally active on aromatic esters, whereas carboxylesterases are active on aliphatic esters. One form of arylesterase, called paraoxonase, is active in the hydrolysis of parathion and a few other organophosphate insecticides and has a demonstrated polymorphic distribution in the human population.⁵¹ Whether a genetic deficiency in paraoxonase activity places such individuals at increased risk for organophosphate insecticide poisoning is uncertain and the subject of current study. Genetic polymorphism in butyrylcholinesterase (pseudocholinesterase) is responsible for the prolonged muscular paralysis that occurs in 1-3% of the population following clinical use of succinylcholine. Cholinesterase is a more substrate-specific enzyme with important physiologic functions. A number of drugs and chemicals inhibit acetylcholinesterase activity, including all organophosphate insecticides. Esters may be hydrolyzed by plasma and hepatic esterases, whereas the metabolism of amides is more complicated, sometimes involving cytochrome P450-dependent N-dealkylation prior to amide hydrolysis. This is why amide-type local anesthetics (e.g., lidocaine) are generally longer acting than ester-type anesthetics (e.g., procaine).

The hydrolysis of epoxides by microsomal epoxide hydrolase is generally regarded as a detoxification pathway because the dihydrodiol product is far less reactive than the epoxides.⁵² However, in some circumstances, such as in the biotransformation of polycyclic aromatic hydrocarbons, the hydrolysis of the first arene epoxide generated by cytochrome P450 oxidation is required for formation of the ultimate carcinogenic form, the 'diol-epoxide,' and thus, epoxide hydrolysis is considered part of the activation process.

Conjugation (Phase II) biotransformation reactions

Glucuronide conjugation

UDP-glucuronosyl transferases are a multigene family of microsomal enzymes that function to add a residue of glucuronic acid to a variety of xenobiotics.⁵³ Because these enzymes are not capable of adding glucuronic acid directly to hydrocarbons, functional groups such as alcohols (COH), carboxylic acids (CCOOH), amines (CNH₂), thiols (CSH), or sulfonamides are necessary. If such groups are present on the parent compound, conjugation can occur directly. However, for hydrocarbons or other chemicals that lack these sites, prior biotransformation to generate or 'expose' such functional groups is required.

The addition of the glucuronic acid moiety to the xenobiotic imparts a substantial degree of water solubility and generates a bulky addition that would likely interfere with any structure-specific receptor interaction. Glucuronic acid per se is not used in the reaction; rather, an activated form (UDPGA), in which glucuronic acid is linked to the terminal phosphate residue of uridine diphosphate (UDP), serves as the co-factor for the reaction. Typically, glucuronidation reactions have been viewed primarily as 'detoxification' events, although some glucuronidation reactions are considered 'activation' reactions.⁵⁴ Glucuronide conjugates are generally endproducts of biotransformation and are commonly found in both the urine and bile. Because bacterial flora contain the enzyme β -glucuronidase, which is capable of hydrolyzing the β -glycosidic linkage to re-establish the less polar substrate, glucuronide conjugates excreted in the bile may undergo extensive enterohepatic circulation if the degluconated molecule is sufficiently lipid soluble to be reabsorbed through the intestinal epithelium. β -glucuronidase activity has also been identified in the bladder epithelium and is thought to contribute to the etiology of bladder cancer for certain aromatic amines, which are conjugated with glucuronic acid, concentrated in the bladder, and then subsequently hydrolyzed by this enzyme to release a reactive, mutagenic form of the chemical.

Sulfate conjugation

The arylsulfotransferases are a multi-gene family of soluble enzymes present in the liver, kidney, and intestine that function to add inorganic sulfate to phenols, aliphatic alcohols and hydroxylamines.⁵⁵

Sulfate is donated to the phenol or alcohol by 3'-phosphoadenosine-5'-phosphosulfate (PAPS), a molecule analogous to adenosine diphosphate, except that the terminal phosphate is a sulfate residue and the 3'-hydroxyl group is also phosphorylated. Because the products of this reaction are ionized regardless of pH, sulfate conjugates are rapidly excreted in urine. Although sulfate conjugation usually results in products that are less toxic than the substrate, sulfate conjugation of some hydroxylamines (R-NH-OH), such as the sulfate conjugate of N-hydroxy-2-acetylaminofluorene, can rearrange to form reactive electrophilic species capable of interacting with nucleophilic sites in DNA, and thus become potent mutagens and carcinogens.⁵⁶ The sulfate conjugation of phenol is a major metabolite of benzene, and the ratio of organic to inorganic sulfate in the urine was used at one time as a crude biologic indicator of benzene exposure in the occupational environment. However, much better biomarkers of benzene exposure are now available.⁵⁷

Glutathione conjugation

Glutathione (γ -glutamylcysteinylglycine) is an intracellular tripeptide that provides a number of critical physiologic functions and is the most important intracellular antioxidant. In addition to its important physiologic functions, it serves as the co-factor for a multigene family of cytosolic enzymes, the glutathione S-transferases, which catalyze the conjugation of a variety of exogenous substances to glutathione.⁵⁸ The best studied, and perhaps toxicologically most important, of these reactions is the conjugation of aliphatic and aromatic epoxides.

Glutathione S-transferases can also catalyze the addition of glutathione directly across certain unsaturated aliphatic sites, such as with diethylmaleate, and can also facilitate substitution reactions on certain halogenated organic compounds, with replacement of one halogen atom with glutathione. Like the cytochrome P450 family of enzymes, the glutathione S-transferases contain a relatively large number of different enzyme forms that are the products of separate genes. There are at least 13 different isoenzymes that have been characterized in humans, with some forms exhibiting tissue-specific expression. The different enzymes have broad and overlapping substrate affinities but are readily classified into one of six families: alpha (hGSTA), mu (hGSTM), pi (hGSTP), theta (hGSTT), zeta (hGSTZ) and omega (hGSTO).⁵⁸ Glutathione S-transferase P1 is highly expressed in many neoplastic tissues, and its expression is frequently used as an early marker of neoplastic change in experimental carcinogenesis. There is also a microsomal form of glutathione S-transferase, but its function in the biotransformation of xenobiotics appears limited, relative to the various cytosolic forms.⁵⁹ Several GSTs are polymorphic in the human population, and have been the subject of considerable investigation as possible 'environmental susceptibility genes' due to their involvement in a wide variety of detoxification reactions.⁶⁰

Glutathione conjugates are seldom excreted directly in the urine, although they may appear in the bile as intact glutathione conjugates. Most glutathione conjugates are

sequentially metabolized by (1) γ -glutamyltranspeptidase (GGT), which removes the N-terminal glutamic acid residue from cysteine; (2) non-specific peptidases, which cleave the peptide bond between cysteine and the C-terminal glycine to generate a cysteine conjugate; and (3) N-acetylation of the cysteine conjugate to form the N-acetyl cysteine (mercapturic acid) conjugate. Mercapturic acid conjugates are then readily excreted in the urine.

Although glutathione conjugation is an important detoxification pathway, recent studies have demonstrated that certain haloalkanes, such as ethylene dibromide, when conjugated to glutathione, can rearrange to form highly reactive episulfonium ions.⁶¹ Such glutathione metabolites may be at least partially responsible for the nephrotoxicity and carcinogenicity inherent in some of these compounds.

N-acetyl transferases (NATs)

Many aromatic amines are metabolized primarily by conjugation of the primary or secondary amine with an acetyl group.⁶² Two different genes for NAT are commonly expressed in human tissues, referred to as NAT1 and NAT2. Because most primary aromatic amines are in the positively charged state at physiologic pH, this conjugation can actually result in products that are not appreciably more water soluble and, in some instances, may be less water soluble than the parent compound. Nevertheless, this pathway is a major route of biotransformation of many aromatic amines, such as hydralazine, isonicotinic acid hydrazide, aniline, 2,6-dinitrotoluene, and some sulfonamide drugs. Both NAT1 and NAT2 are polymorphic in the human population, and have been the subject of considerable study as potential determinants of adverse drug reactions and as environmental susceptibility genes.⁶³

N-acetylation results in loss of pharmacologic activity of some widely used drugs and, as such, is a detoxification pathway. Occasionally, N-acetylated aromatic amines can undergo further metabolism by N-hydroxylation to yield the N-hydroxy-N-acetyl derivative. Both NAT1 and NAT2 are capable of catalyzing this 'activation' reaction. A different enzyme, called arylhydroxamic acid N,O-acyltransferase, catalyzes the transfer of the acetyl moiety from aromatic nitrogen to the hydroxyl group on the nitrogen, resulting in the formation of a highly unstable acyloxyarylamines that can react with DNA and proteins.⁶⁴ This complicated biotransformation pathway is implicated in the carcinogenesis of numerous aromatic amine compounds, including benzidine.⁶⁵

Methyl transferases

The methylation of xenobiotics is not a frequent route of elimination. In contrast to most other biotransformation pathways, products of methylation are almost always less polar than the substrate. Thus, methylation reactions do little to enhance the elimination of non-polar compounds from the body. Methylation of endogenous proteins, nucleic acids, and catecholamines occurs frequently, and is an important biochemical process for the regulation of many intracellular functions. The methylation of xenobi-

otics thus occurs primarily in circumstances in which the xenobiotic mimics some endogenous substrate. Examples where this occurs are the methylation of pyridine and catechols. The co-factor for methyltransferase reactions is S-adenosylmethionine. A few examples where methylation of xenobiotics is important include the methylation of dopamine and related catechol drugs by catechol-O-methyl transferase (COMT) and the methylation of the chemotherapeutic agent, 6-mercaptopurine by thiopurine methyltransferase (TPMT).⁶⁶ The presence of a single nucleotide polymorphism in TPMT is an important consideration in treatment of leukemia patients with TPMT because those who are homozygous for the variant allele may suffer serious toxicity at standard therapeutic doses. Conversely, for those who are homozygous for the high activity allele, a standard dose may not be efficacious because of rapid systemic clearance of the drug.⁶⁷

Amino acid conjugation

Organic cyclic carboxylic acids can undergo conjugation with several amino acids, including glycine, glutamine, and taurine.⁶⁸ For example, benzoic acid is rapidly conjugated with glycine to form hippuric acid. Because benzoic acid is the primary oxidative metabolite of toluene, hippuric acid is a primary urinary metabolite of toluene, and methylhippuric acids are primary urinary metabolites of xylenes. Both taurine and glycine are used biologically for the conjugation and biliary excretion of primary and secondary bile acids. Taurocholate, glycocholate, taurochenodeoxycholate, and glycochenodeoxycholate are the primary bile acids in human bile, and conjugation of newly synthesized bile acids in the liver is a prerequisite for biliary excretion.

Genetic polymorphisms in xenobiotic biotransformation

As noted throughout the previous discussion, several genetic polymorphisms in biotransformation pathways have been described. One of the best studied genetic polymorphisms is that associated with N-acetylation of various primary aromatic amines.⁶⁵ A bimodal distribution in N-acetylation activity has been described, with approximately 50-70% of caucasians having a slow acetylation phenotype, with only 10-15% of Japanese demonstrating this phenotype. The slow-acetylator phenotype has been associated with a high incidence of adverse drug reactions at normal therapeutic doses of isoniazid, hydralazine, procainamide, dapsone, and some sulfa drugs. In addition, a number of occupationally important arylamines, including naphthylamine, benzidine, 4-aminobiphenyl, and 4-nitrobiphenyl, are detoxified by N-acetylation. In occupations in which exposure to certain carcinogenic arylamines occurs (e.g., dyestuff workers), epidemiologic evidence has suggested that slow acetylators are at a slightly increased risk for bladder and perhaps a few other types of cancer.⁶⁹

Genetic polymorphisms in several P450 cytochromes have been described in humans, and may have implica-

tions for individualized drug therapy.⁷⁰ For example, the alicyclic hydroxylation of the antihypertensive drug debrisoquin is mediated via human CYP2D6, which is polymorphically distributed, with 7-10% of the population characterized as extremely poor metabolizers. The differences in activity between poor metabolizers and the rest of the population are remarkable, with an approximately 20,000-fold difference in debrisoquin hydroxylation. This is a single-gene polymorphism, but the enzyme has broad substrate specificity and is important in the oxidation of a variety of other drugs and chemicals. Although several studies have evaluated whether the CYP2D6 'slow metabolizer' phenotype/genotype is associated with increased risk for certain cancers, no clear association has been found.⁷¹ Thus, the importance of this genetic polymorphism in environmental and occupational toxicology remains to be established.

The cytochrome P450-mediated hydroxylation of polyaromatic hydrocarbons to mutagenic and carcinogenic intermediates is well established, although no clear polymorphic distribution in this activity has been identified in humans. However, some studies have suggested that high inducibility of aryl hydrocarbon hydroxylase activity may be associated with an increased risk of lung cancer in smokers.⁷²

A genetic polymorphism in the M1 form of glutathione S-transferase (hGSTM1) has been extensively studied in human populations as a possible risk factor for cancer and other environmentally related diseases. Approximately 50-60% of the population are genetically deficient in hGSTM1, and this deficiency has been associated with a modest increase in the risk of lung⁷³ and bladder⁷⁴ cancer in numerous studies.

Much remains to be learned about the biochemical and molecular mechanisms that underlie important inter-individual differences in susceptibility to environmental and occupational pollutants. The study of the relationship between genetic factors and individual susceptibility to drugs and chemicals is the basis for the rapidly emerging field of ecogenetics.⁷⁵ Recent advances in molecular biology now provide the experimental tools necessary to identify important genetic differences in individuals, and the identification of variant alleles in the human population has grown at a remarkable rate.⁷⁶ Application of these tools to toxicology, epidemiology and other areas of public health will be critical to the rational evaluation of individual risk from chemicals in the workplace and general environment, but will also raise important ethical, legal and social issues that must be addressed in lockstep with the science.⁷⁷

Excretory pathways

The ability of the body to rid itself of exogenous chemicals is largely dependent on the physicochemical characteristics of the chemical. Chemicals that have very low blood-gas partition coefficients (e.g., are poorly soluble in blood and have a high vapor pressure) may be effectively eliminated by exhalation, whereas chemicals that are highly water

soluble will generally be eliminated by excretion into the urine or bile. Because many chemicals of occupational and environmental concern lack either of these characteristics, accumulation in the body is likely to occur unless biotransformation processes alter the chemical to a more readily excretable form. Thus, elimination of a chemical from the body occurs by two processes, direct excretion of the unchanged substance or biotransformation to a different chemical form that may then be excreted as a metabolite.

Urinary excretion

The kidney is highly efficient at removing many foreign substances from the blood. However, the extent and rate of urinary excretion are highly dependent on the water solubility of the substance. Most chemicals in the blood are readily filtered by glomeruli; the only exceptions are those chemicals that bind avidly to high molecular weight plasma proteins. The rate at which plasma is filtered through the glomeruli (glomerular filtration rate or GFR) is approximately 125 mL/min in normal adults, and the rate of urine production is less than 1% of this volume. As the volume of glomerular filtrate is reduced by reabsorption of electrolytes, nutrients, and water in the nephron, the filtered xenobiotics are concentrated in the remaining tubular fluid, generating a large driving force for diffusion of the xenobiotics from the tubular lumen to the interstitial space and blood stream.

Thus, relatively lipid-soluble chemicals are not effectively eliminated in the urine following glomerular filtration because they readily diffuse back out of the tubular fluid into the blood. However, water-soluble chemicals are incapable of diffusing across the tubular membrane, can thus be concentrated to a very high degree in tubular fluid, and eventually are eliminated in the urine. For weak organic acids and bases, the extent of urinary excretion can be greatly influenced by the pH of the urine. In contrast to blood, where the pH must be maintained in a narrow range, urinary pH can readily vary between 5 and 8, resulting in large potential differences in the fraction of chemical in the ionized form. This knowledge has been put to practical therapeutic use in the treatment of poisoning with several weak organic acids or bases. The renal elimination of a weak organic acid with a pKa in the range of normal urinary pH can potentially be increased by 4-6-fold by simply alkalinizing the urine with an intravenous infusion of sodium bicarbonate. The renal elimination of salicylates and barbiturates has also been enhanced by alkalinization of the urine.

For some organic acids and bases, urinary excretion occurs in part by the presence of specific carrier-mediated transport processes in the proximal tubules.^{78,79} Such highly efficient active transport systems have been described for a number of weak organic acids and bases and are important in the elimination of certain drugs, such as penicillin, and a variety of glucuronide and sulfate conjugates. Because these carrier-mediated transport processes may be saturated at high doses or may be competitively inhibited by the presence of other substances, for the purposes of risk characterization, it is important to identify

whether such processes are functional in the elimination of chemicals. For example, phenoxy acids and several other weak organic acid herbicides appear to be relatively more toxic to dogs than most other species, apparently because the renal organic anion transport system is saturated at relatively low doses, resulting in decreased elimination and somewhat greater rate of accumulation in dogs compared with other species given the same dose.⁸⁰ In humans, renal elimination of these weak organic acids can be enhanced by alkaline diuresis and/or hemoperfusion.⁸¹

For chemicals that enter the tubular lumen exclusively by glomerular filtration and are not reabsorbed across it, the rate of renal elimination from the blood stream equals that of the GFR. For chemicals that are partially reabsorbed or are incompletely filtered because of protein binding, the renal clearance rate may be much less than the GFR. Because the rate of renal plasma flow is about five times higher than the GFR (e.g., only 20% of total renal plasma flow passes through the glomeruli), chemicals that are cleared from the blood by active transport processes can have renal clearance rates much higher than the GFR.

Biliary excretion

In contrast to urine, bile is not an ultrafiltrate of plasma, and the biliary tree has very little direct contact with the vascular compartment. Therefore, all substances that enter the bile from the plasma must do so by passing first across the hepatic sinusoidal membrane and then from the hepatocyte across the canalicular membrane to the bile.⁸² Bile flow is produced by the flux of water from the hepatocyte to the canalicular space in response to an osmotic gradient produced by active transport of bile acids and bicarbonate into the canalicular space. After chemicals enter the hepatocyte, they are generally biotransformed to polar metabolites, which may either re-enter the circulation for elimination in the urine or may be actively transported into the bile. As a general rule of thumb, polar chemicals with molecular weights in excess of about 325 to 350 Daltons will be secreted preferentially in the bile, whereas chemicals of lower molecular weights will be excreted primarily in the urine. The liver possesses several distinct active transport systems for endogenous and exogenous hydrophilic compounds. For example, biliary elimination of anionic compounds, including glutathione S-conjugates, is mediated by a transport protein known as MRP2, whereas bile salts are excreted by a bile salt export pump (BSEP); class I-P-glycoprotein (P-gp) is involved in the secretion of amphiphilic cationic drugs, whereas class II-P-gp is a phospholipid transporter.⁸³

A widely used liver function test, based on the rate of plasma clearance of the blue dye sulfobromophthalein (BSP) or indocyanine green, is in fact a measure of the functional integrity of a hepatic organic anion transport system distinct from that which transports bile acids. Because the removal of these dyes from plasma occurs almost exclusively by hepatobiliary elimination, a decline in the rate of plasma clearance is a useful indicator of hepatic dysfunction. Bilirubin is also excreted in the bile (primarily as the diglucuronide conjugate), by active transport processes,

and a dysfunction in this system will result in elevated plasma bilirubin levels (jaundice; see Chapter 26.1). Indeed, genetic defects in biliary transport processes have led to new insights into how hepatobiliary transport processes function in humans.⁸⁴ Mutations in specific bile acid or lipid transporters have been identified within specific cholestatic disorders, and genetic polymorphisms have been established for specific diseases.⁸⁵

Some metals are eliminated in the bile, albeit slowly, and this can be an important route of elimination. For example, methyl mercury is secreted in the bile, but it is largely reabsorbed in the intestinal tract. Interruption of this 'enterohepatic recirculation' by the administration of thiol-binding resins greatly reduces the half-life of methyl mercury and is a useful therapeutic approach to the treatment of methyl mercury poisoning.⁸⁶

Some relatively non-polar compounds can also be excreted in the bile, probably by dissolution in biliary micelles. These are formed by the aggregation of bile acids and phospholipids, and are an important means of solubilizing the large quantity of cholesterol that is normally secreted in the bile. Too high a ratio of cholesterol to bile acids and phospholipids results in the precipitation of cholesterol as gallstones.⁸⁷ Because micelles are extremely effective at dissolving non-polar compounds, lipid-soluble xenobiotics can partition into the micelles from the hepatocyte. However, after biliary micelles reach the intestinal tract, the non-polar xenobiotics will be rapidly absorbed. Interruption of the enterohepatic circulation with the non-absorbable anion-exchange resin cholestyramine (used clinically to lower blood lipids) has been used successfully in humans to reduce the half-life and toxicity of the highly lipid-soluble pesticide kepone following very high occupational exposures.⁸⁸

Hepatic dysfunction from disease or chemical toxicity can alter the kinetics of elimination and, thus, the toxicity of a wide variety of chemicals.⁸⁹ For example, the adverse effects of some digitalis glycosides can be enhanced in the presence of hepatic disease because hepatobiliary clearance is decreased, although this is a less common cause of digitalis sensitivity than other factors such as poor renal function, hypokalemia or hypothyroidism.⁹⁰ Some drugs that induce microsomal enzymes also enhance bile flow and may increase biliary excretion of other xenobiotics. Phenobarbital treatment increases bile flow and enhances the biliary elimination of methyl mercury. The potassium-sparing diuretic, spironolactone, has been shown experimentally to decrease the toxicity of several chemicals, including mercury and cardiac glycosides, by enhancing biliary excretion.

TOXICOKINETICS

The absorption, distribution, biotransformation, and excretion of xenobiotics in the body is a dynamic process. The concentration of toxicant at its receptor site is thus dependent on the various rates of reactions that affect absorption, distribution, biotransformation, and excretion. The field of pharmacokinetics developed largely out of a need to under-

a One-compartment open model

b Two-compartment open model

Figure 5.12: One- and two-compartment pharmacokinetic models. A one-compartment model (a) represents the simplest approach to understanding the distribution of chemicals in the body and assumes that the chemical is instantaneously distributed throughout the compartment (body) and that elimination from the compartment occurs by a first-order process (a constant per cent of remaining compound is eliminated per unit time). A two-compartment model (b) takes into account a slower, distribution phase between the central compartment (blood) and peripheral compartments (tissues). Elimination proceeds only from the central compartment, which is in dynamic equilibrium with the peripheral compartments. Absorption rate constants (k_{ab}), equilibrium rate constants (k_1 , k_{-1}), and elimination rate constants (k_{el}) can be determined, which describe these processes under conditions of first-order kinetics.

stand the factors that dictate the determination of efficacious and non-toxic doses of pharmaceuticals. Essentially the same biologic factors also determine the biologic fate of non-drug chemicals in the body; therefore, toxicokinetics and pharmacokinetics are nearly identical disciplines, and toxicologists frequently use the terms interchangeably.

The mathematic modeling of the fate of chemicals in biologic systems commonly uses compartmental models and rate constants to reflect various physiologic functions.⁹¹ A 'one-compartment open model' assumes that a chemical is instantaneously distributed equally throughout the body, and uses the concentration of a chemical in plasma as representative of the concentration throughout the compartment (Fig. 5.12a). For chemicals that more slowly redistribute from the vascular compartment to tissues, a two-compartment model is used (Fig. 5.12b). The central compartment conceptually represents the vascular space and rapidly perfused tissues, whereas the rest of the body represents the peripheral compartment. There is a rate constant for exchange between the two compartments, a rate constant for influx to the central compartment (where absorptive processes are involved), and a rate constant of elimination (k_{el}) from the central compartment. For chemicals that slowly redistribute to 'deep' compartments, such as fat and bone, a three-compartment model, with different rate constants between the central compartment and the two peripheral compartments, is sometimes used to explain the very long terminal half-life of some chemicals.

The volume in which a chemical is dispersed, of course, varies greatly, depending on its solubility in water and fat, whether it binds to proteins in the plasma, or whether it binds to intracellular sites. This so-called apparent volume of distribution is an important pharmacokinetic parameter and is essentially a constant that relates the concentration of a chemical in the plasma to the total amount of chemical in the body. Thus, for chemicals that are tightly bound to plasma proteins, the majority of the chemical is confined to the plasma (central compartment), and the apparent volume of distribution (V_d) is relatively small, perhaps on the order of 5-10 liters. In contrast, for chemicals that are highly lipid soluble or are sequestered in intracellular sites, the V_d may be very large, exceeding the 'true' volume of the body by many fold.

The apparent V_d is a necessary factor to estimate the 'body burden' or total amount of chemical in the body, at any point in time. Thus, the body burden is equal to the concentration of the chemical in the plasma times the V_d . 'Clearance' is a term that refers to the ability of the body to 'clear' a chemical from the blood and has units of flow rate (e.g., milliliters per minute). Thus, a chemical with a clearance of 50 mL/min is eliminated from 50 mL of blood in 1 minute. Clearance is thus a measure of the overall efficiency of the removal of a chemical from the body. Total body clearance (Cl_T) can be proportioned to specific pathways of elimination, such as the liver and kidney, such that:

$$Cl_T = Cl_H + Cl_R + \dots,$$

where Cl_H and Cl_R represent the rate of hepatic and renal removal, respectively. Clearance is thus related to the apparent V_d and a first-order elimination rate constant, k_{el} , according to the simple equation:

$$Cl_T = V_d \cdot k_{el}$$

Elimination of a chemical from the central compartment usually occurs exponentially by a first-order rate process, in which the fraction of chemical removed per unit time remains constant (a constant per cent of chemical is eliminated per unit time, e.g., 10% per minute). A plot of the log of the plasma concentration versus time will result in a straight line (Fig. 5.13). For first-order elimination rates, the plasma half-life (time required for the concentration of a chemical in plasma to decrease by 50%) is proportional to the elimination rate constant, k_{el} , by the following equation:

$$T_{1/2} = \frac{0.693}{k_{el}}$$

If elimination occurs by a process that is saturable (e.g., enzymatic metabolism or carrier-mediated transport), the rate of elimination will follow zero-order kinetics (a constant amount of chemical is eliminated per unit time, e.g., 10 mg/min), regardless of the concentration. The importance of enzyme saturation at high doses to toxicity is illustrated by the hypothetical situation shown in Figure 5.13b. This figure illustrates the hypothetical one-compartment elimination kinetics of two individuals given the same dose of a chemical, in which the elimination pathway in subject A is saturated at plasma concentrations above about 50 $\mu\text{g/mL}$, but saturation of the elimination pathway in subject B does not occur within the dose range shown. If toxic effects were evident at plasma concentrations above 10 $\mu\text{g/mL}$ in both subjects, the period of time necessary for subject A to reduce the plasma concentrations to below the toxic level is over twice as long as that for subject B. The upper panel shows the plasma concentration versus time curve for the two subjects; the lower panel plots these same data as the log plasma concentration versus time. The linear response for subject B is typical of a first-order rate of elimination from a one-compartment model, with a half-life of 1 hour. The convex shape of the log-plasma concentration versus time curve in subject A is indicative of saturable metabolism or zero-order kinetics.

Toxicokinetic modeling of repeated exposure to chemicals in the workplace and/or environment requires the important additional consideration of the period between exposures, or the 'dosing interval'. If the dosing interval is longer than the elimination half-life, then accumulation of the chemical in the body will occur. Assuming a first-order rate of elimination at all concentrations, the amount eliminated between doses will eventually become equal to the amount taken in, and no further accumulation will occur. The point in time at which the amount of chemical eliminated equals the amount taken in during a dosing

Figure 5.13 First-order and zero-order kinetics of elimination. When the plasma concentration of a chemical is plotted directly with time (a), a straight line is achieved only when elimination processes are saturated (A), and elimination from the plasma occurs via zero-order kinetics (a constant amount of chemical is removed per minute). However, elimination of most toxic substances occurs via first-order kinetics, in which a constant per cent (or fraction) of the dose is eliminated per unit time. When the log of the plasma concentrations is plotted against time (b), a straight line results when elimination is first order (B). Note how much longer chemical A remains in the region of toxic plasma concentration compared with chemical B, even though both have the same first-order elimination rates.

interval is called the 'steady state'. The average amount of chemical in the body (body burden) at the steady state is described by the following equation:

$$X_{ss} = \frac{(1.44)t_{1/2}D}{\tau}$$

where X_{ss} = the body burden at steady state, $t_{1/2}$ equals the elimination half-life, D = the amount of the dose at each dosing interval, and τ = the dosing interval (in the same time units as the $t_{1/2}$).

If the apparent V_d for the chemical is known, then the average plasma concentration at steady state can be

obtained by simply dividing the body burden at steady state (X_{ss}) by V_d . From this relationship, it is evident that repeated daily exposure to a chemical with a half-life of 1 day would result in an accumulation of chemical in the body to an amount about 1.5 times greater than the amount of the daily exposure. For chemicals with very long half-lives, such as many chlorinated polyaromatic compounds (e.g., PCBs, DDT, and dioxins, which may have half-lives greater than several years) and some metals (e.g., Cd), accumulation may occur throughout a lifetime, potentially reaching toxic levels many years after the initial exposure. The relationship between toxicity and body burden is not always straightforward because accumulation may occur in body 'compartments', such as adipose tissue or bone, which may not be target organs for the toxicity of the chemical. As long as the chemical remains highly partitioned in non-target organ compartments, its presence may be of little toxicologic consequence. However, if for some reason this site of storage becomes mobilized (e.g., fasting in the case of fat storage of chlorinated hydrocarbons or osteolysis in the case of bone storage of lead), the subsequent release of stored chemical to the circulation and, thus, its redistribution to target organs could result in toxicity many years following the exposure.

Chemical-chemical interactions

The evaluation of toxicity for drugs and chemicals often assumes that the exposure to the suspect drug or chemical is isolated. However, this is seldom the case because simultaneous or sequential exposures to multiple drugs and chemicals are commonplace in our society. Interactions of prescription, over-the-counter, and/or recreational drugs with other such drugs, drugs with chemicals in the home or workplace, or with dietary factors can and do occur. There are many well-known adverse interactions, such as the interaction between monoamine oxidase inhibitors prescribed as antidepressants with other pressor drugs (sympathomimetics) and/or with tyramine, which occurs naturally in some foods (e.g., some types of wine and cheese). However, the number of chemicals for which specific interactions have been documented is likely to be only a small fraction of what really occurs. Of course, beneficial chemical-chemical interactions are the basis of antidotal therapy.

The number of potential drug-chemical combinations is, by definition, nearly infinite, and it would be impossible to study all such combinations systematically. Nevertheless, clinicians familiar with the basic mechanisms of action of drugs and chemicals can reasonably identify many potential interactions. Particularly because analytic techniques have emerged over the past few decades, the clinical problems seen as a consequence of such interactions have been recognized. Moreover, certain principles have been developed to estimate the likelihood of such problems, often in advance of their actual occurrence. These can be summarized as follows.

1. Interactions between two compounds prior to actual exposure by the host. For example, an acidic drug, when combined with an alkaline compound, may become insoluble and precipitate out of solution, thus becoming unavailable for absorption. Other examples include the high binding affinity of some drugs, such as cholestyramine, for other drugs, thus reducing their bioavailability.
2. Interactions that occur after ingestion but have an impact on the rate or the degree of absorption. Classic examples include antibiotics, such as penicillin, tetracyclines, many barbiturates, dicumarol, and a variety of hydroxide compounds. In these instances, multiple mechanisms may be involved so that the physician managing a given case will do well to consult the listing of such interactions. As a generalization, these types of interactions may serve to minimize therapeutic efficacy but seldom contribute to the enhancement of poisoning.
3. Drug interactions resulting from alterations in metabolism and/or disposition may lead to clinical problems.⁹² For drugs that are largely bound to proteins, the displacement of as little as 1% or 2% from protein can greatly increase the biologically active compound. An example of this would be the interactions between various cardiac glycosides and dicumarol. Moreover, such displacement also alters the biologic half-life of the displaced drug. In other instances, concomitant administration of drugs, such as phenobarbital, with a wide variety of other drugs produces induction of enzyme systems (e.g., the cytochrome P450 series), with the result that the second drug will have enhanced elimination. In other instances, such as adding erythromycin to the regimen of a patient already taking theophylline, metabolism will be impaired such that the theophylline concentration may reach harmful levels.
4. 'Competition at the receptor site', the locus of pharmacologic activity, can occur. Classically, naloxone's ability to displace a variety of opioid entities is well known; other drugs, such as phenothiazines, tricyclic antidepressants, and antihistamines, exert comparable alterations at other receptor sites within the nervous system. With increasingly sophisticated analytic techniques, still more unanticipated interactions are being uncovered, although many have little or no clinical significance.
5. Alteration of pH of some body fluid and modifying the pharmacologic activity of a second compound. One example is the administration of sodium bicarbonate to treat an overdose of salicylate; the resultant alkalization of the renal tubular fluid enhances the ionization of filtered salicylate, precludes its resorption, and significantly increases its excretion.

TOXICITY TESTING AND PREDICTIVE TOXICOLOGY

Although epidemiology can be an effective tool to identify and characterize chemical risks to humans, a major limitation of human epidemiologic studies is that the damage has been done by the time it is identified. Furthermore, the utility of epidemiology for purposes of 'predictive' toxicology is limited by a number of factors, including: (1) the presence of confounding, (2) difficulties in dose and exposure assessment, (3) difficulty in identifying suitable exposed populations, and (4) limited statistical power associated with many environmental and occupational epidemiologic studies.

Increased public awareness of chemical hazards, coupled with a few notable and highly publicized and potentially preventable chemical disasters, has stimulated the search for biologically meaningful and relevant tests to predict hazards from chemicals before human exposures occur. Most predictive toxicity tests rely on the use of common laboratory animals, such as rats, mice, and guinea pigs, although bacterial tests systems and cell and tissue cultures have gained widespread use in some types of toxicity testing, most notably mutagenicity. It is beyond the scope of this chapter to describe in detail the design and conduct of the multitude of toxicity tests that are currently available. However, a summary review of the nature and approaches used in toxicity assessment is given. (For a detailed description of these approaches and techniques, the reader is referred to the excellent reference text on this topic by Hayes.⁹³)

The fundamental principle that dictates the utility of animal models for predicting human response is that the adverse effects of a chemical on a test organism, when properly qualified, are applicable to humans; that is, laboratory animals are useful biologic surrogates for the human response to toxic substances. This premise underlies all experimental biology and medicine and is not unique to toxicology. The basic premise that laboratory animals are useful surrogates for human responses to toxic substances is well supported by a wealth of scientific data.⁹⁴ However, there are many circumstances in which the data obtained from animal models may differ from those in humans substantially, both quantitatively and qualitatively, because of mechanistic, pharmacokinetic, and/or pharmacodynamic properties. Thus, basic research into the biochemical and molecular modes of action and the biologic fate of chemicals in experimental animal and human tissues is a critical component of predictive toxicology.

Toxicity testing is generally divided into several major categories, based on the duration of exposure and/or the specific endpoint to be measured.

Acute toxicity testing

Acute toxicity studies involve the administration of a single dose of chemical to test animals. Acute toxicity tests can be conducted by a variety of routes of administration, including oral, dermal (percutaneous), inhalation, or

parenteral (intravenous, intraperitoneal, or subcutaneous). A common measure of acute toxicity is the LD₅₀, although much additional useful information is generally obtained from acute toxicity studies. In addition to identifying the lethal and sublethal doses, acute toxicity tests provide information on target organs, mode of action, duration, and the reversibility of the non-lethal effects. In product safety evaluations, the acute toxicity test is used primarily to establish appropriate doses for subacute or subchronic studies, where repeated dosing occurs.

Subacute toxicity testing

For chemicals that are expected to accumulate in target organs or produce irreversible effects from individual doses, repeated administration of an agent over a period of 2-4 weeks is sometimes used to provide additional dose range information for the design of longer term studies. Additional information on target organs, pharmacokinetics, pharmacodynamics, and the mechanism of action is generated from such studies but does not generally fulfill regulatory requirements for the product safety evaluation of pesticides, food additives, and other chemicals for which routine exposures are likely to occur.

Subchronic toxicity testing

Routine toxicologic evaluation of a chemical for potential human health risks almost always requires the inclusion of studies in which the test chemical is administered daily for a period of 90 days.⁹⁵ Usually four to five doses are selected, the highest dose of which produces overt toxicity and limited mortality at the end of 90 days of dosing and the lowest dose selected approximates the maximum dose that would produce no observable adverse effects (NOAEL) even with 90 days of repeated dosing. For regulatory purposes, the objective of a subchronic bioassay is to identify the NOAEL. Because estimates of acceptable human doses are frequently derived from the animal NOAEL, the care and thoroughness of such studies can have a major impact on the regulatory standards for the workplace and environment. In general, most regulatory agencies establish acceptable levels of exposure by identifying the animal NOAEL (in units of milligrams of chemical per kilogram animal body weight per day), then dividing that value by an arbitrary 'safety' or uncertainty factor. Frequently a value of 100 or 1000 is used, depending on the degree of confidence the regulator has in the quality and relevance of the animal data to humans.

This approach assumes that a threshold exists in the dose-response relationship; that is, there is some dose below which no response will occur, regardless of the size of the population exposed. The animal NOAEL is an experimental estimate of the threshold dose in that strain of animal, and the safety factor is used to account for possible differences in species sensitivity, differences in response among various human individuals, and for 'scaling factor' differences (on a body weight basis, small animals generally require relatively larger doses than large

animals to elicit the same response; the use of body surface area, rather than body weight, is often a better scaling factor). Because dose–response relationships for many toxic effects are steep, a 100-fold uncertainty factor in most circumstances may afford a large degree of protection. However, where there are significant differences in the mechanism of action, pharmacokinetics, or pharmacodynamics between the animal species used for estimation of the NOAEL and humans, the use of a 100-fold uncertainty factor may be significantly underprotective or overprotective. Thus, the establishment of relevant exposure standards for humans depends on a good understanding of the many factors that influence toxic responses, and how these factors may be similar or different between test animals and humans.

Chronic toxicity testing and carcinogenicity evaluation

In circumstances in which a chemical has a very long half-life, it causes irreversible effects at doses well below the lethal dose, and/or it is suspected of being potentially carcinogenic, a chronic bioassay may be warranted. These studies generally involve the administration of the test substance to animals for an entire lifetime, which for rodents is about 2 years. Generally, the route of administration is the one that is most relevant to human exposures. Administration of the test substance in the diet or drinking water is most common, although chronic bioassays using inhalation exposure are occasionally conducted. The latter are very expensive and, technically, much more difficult to conduct.

Although chronic bioassays may occasionally be conducted to assess endpoints other than cancer, by far the most frequent purpose for such studies is the assessment of oncogenic (carcinogenic) potential. Most chronic bioassays utilize both sexes of two species (almost always rats and mice), at least two exposure doses, and one unexposed control group, with approximately 40–50 animals per group. Dose selection is a major consideration in the design and conduct of a chronic bioassay, especially if the study is intended to evaluate the oncogenic potential of the chemical.⁹⁶

For the purposes of quantitative cancer risk assessment, most regulatory agencies assume that all chemicals that increase tumor incidence do so in a non-threshold manner. Although studies in experimental animals have demonstrated that the extent of DNA damage is often proportional to dose at relatively low concentrations, experiments have not been, nor could they be, conducted at the very low lifetime doses that would be associated with cancer risks of less than about 0.1% (1 in 1000). The statistical power of studies that use even maximum experimentally manageable sample sizes (e.g., 50 animals per dose) is extremely limited. For example, consider a study that exposed 50 animals for a lifetime at dose x , with no tumors found in either the control or dose x group (Fig. 5.14). The most that could be said about such a negative experiment is that we would be 95% confident that, if a

Figure 5.14: Statistical power of animal tests - power versus number. The statistical power of an animal test to determine a small positive response is highly dependent on the sample size. This curve tells us that we can be 95% confident that a chemical that tested negative in 100 animals will not produce more than about 4% incidence of tumors in a larger population. Thus, a negative test, even using 100 animals in a single dose, cannot be used to prove that a chemical is not capable of causing a significant incidence of cancer in a larger population exposed to the same dose.

human population equal in sensitivity to the test animals were exposed at dose x for a lifetime, the true incidence of cancer would not be greater than about 8%.

Obviously, it is experimentally impossible to demonstrate that a chemical poses no significant cancer risk using doses in the range of human exposures. For example, to detect a statistically significant ($P = 0.05$) tumor incidence of 1 in 1000 (0.1%), it would require the use of 460,000 animals in *each* dose group, plus control, assuming that the background incidence of tumors was near zero.⁹⁷ Thus, the only reasonable alternative is to assume that there is some describable dose–response relationship, test animals at doses high enough to give statistically measurable response levels (tumor incidence above about 5% to 10% in most instances), and then extrapolate the dose–response data down to the doses encountered by humans. Based on this logic, current carcinogenicity testing guidelines require that animal studies used for the quantitative risk assessment of potentially carcinogenic chemicals utilize the maximum tolerated dose (MTD) and some fraction (usually one half or one fourth) of the MTD to characterize tumor dose–response relationships and then extrapolate the dose–response data to the very low doses associated with ‘acceptable’ lifetime cancer incidence (e.g., one additional lifetime cancer per million exposed individuals). Thus, it is not uncommon to find that cancer risk estimates are based on extrapolation from animal studies with dose–response curves containing only two or three high-dose data points to doses four to six orders of magnitude below those in the measured response range. Figure 5.15 shows the process of extrapolation of observed animal data to the very low doses generally deemed necessary to

Figure 5.15: dose-response extrapolation to low doses. The upper panel represents the log-dose-response curve for four different chemical carcinogens. The lower panel represents the same data plotted on a log-log scale to demonstrate the extent of extrapolation typical of most quantitative risk assessments. The dose data for each carcinogen have been normalized by setting the lowest dose of each carcinogen that gave a positive result to 1, and subsequent doses as a multiplier of that dose. Actual dose ranges and routes of exposure for the four carcinogens were vinyl chloride, 50-6000 ppm (inhalation); aflatoxin, 1-100 ppb (diet); nitroacetic acid, 7500-20,000 ppm (diet); dimethylnitrosamine, 5-20 ppm (diet). (From Amdur MO, Doull J, Klaassen CD. *Casarett and Doull's Toxicology: the basic science of poisons*, 4th edn. New York: Pergamon Press, 1991.)

protect public health. Regulatory agencies frequently use additional lifetime risk of 10^{-4} – 10^{-6} (1 in 10,000 to 1 in million) as the level of socially acceptable risk.

Because of the uncertainty in the actual shape of the dose-response curve at very low doses, a great deal of potential error is introduced in modeling and extrapolation from the high-dose animal data to the low doses of environmental concern. This uncertainty is aggravated by the realization that high doses may produce tissue toxicity that does not occur at low doses, and that this toxicity in itself may produce a strong promotional effect by stimulating tissue repair and cell division.

The selection of a mathematic model to extrapolate the observed animal dose-response data to the very low dose levels encountered by humans can have a large effect on the projected acceptable risk level. Although numerous mathematic models have been proposed, there are few scientific data that would allow one to support the use of one model over another.

In addition to model selection, there are many other areas of uncertainty in the quantitative risk assessment process, such as the selection of animal data studies when more than one is available, the type of tumor responses to be used (e.g., total tumors or malignant tumors only), exposure assumptions, and human dose estimations. The current practice of making conservative assumptions (e.g., assumptions that tend to overestimate risk) when uncertainties exist is often justified as necessary to ensure that risks are not underestimated. Although the accuracy of risk projections based on these methods has limitations, and may overestimate risk, the process provides a useful means of comparing the relative magnitude of potential cancer risks posed by different chemicals, and is a useful addition to other scientific information necessary for the establishment of regulatory guidelines that are adequately protective of public health.

There is currently much controversy over the use of high-dose animal testing in cancer risk assessment. There is little question that the quantitative interpretation of the apparent magnitude of risk can be significantly altered by relatively small changes in the slope of the dose-response curve in the measured region, which can result from tissue damage and/or saturation of biotransformation pathways likely to occur at doses near the MTD. Consideration of the differences in pharmacokinetics and pharmacodynamics at high doses versus low doses will substantially enhance the reliability of predictive toxicology tests and represents a very active area of research in toxicology.⁹⁸

Mutagenicity testing

There are numerous different tests commonly used to assess the mutagenic ability of chemicals.⁹⁹ There are two fundamentally important types of mutations, i.e., mutations in somatic cells and mutations in germinal cells. Mutations in somatic cells are not passed from generation to generation but may be associated with the development of cancer in the mutated somatic tissue. In contrast, germinal mutations may not express themselves as overt toxicity in the host but can be passed on to offspring in the form of a heritable genetic alteration.

Most chemicals encountered in the workplace and general environment are not sufficiently chemically reactive to interact directly with DNA, but they may be oxidized by enzymes in the liver and other tissues to highly electrophilic intermediates that covalently bind with nucleophilic sites in DNA. Because the interaction of electrophilic chemicals with nucleophilic sites in DNA is largely independent of the source and type of DNA, simple organisms such as bacteria, coupled with mammalian tissue fractions containing the enzymes necessary for activation,

are commonly used. Thus, in contrast to most other predictive toxicity tests, mutagenicity assays most frequently utilize responses to bacteria or cells in culture.

The most widely used method for determining the mutagenic potential of a chemical is the Ames Salmonella mutagenicity assay. This test employs cultures of *S. typhimurium* bacteria that have been genetically altered from the wild type. These bacteria have a mutation in the gene that normally functions to synthesize the essential amino acid histidine. Because this gene is defective, the bacteria are unable to synthesize their own histidine (termed His⁻), and thus, they cannot grow in a histidine-deficient medium. However, the genetic alteration responsible for the histidine deficiency is readily altered back to the wild type (a 'reverse' mutation) in the presence of genotoxic chemicals. In addition to the His⁻ mutation, these strains of bacteria have additional mutations that enhance their responsiveness to mutagenic chemicals, such as genetic alterations that reduce the efficiency of DNA repair and increase the cell coat permeability to exogenous chemicals. Thus, one can plate millions of bacteria on a medium deficient in histidine, add a potentially mutagenic test chemical and the mammalian enzymes necessary for metabolic activation to the culture plates, and culture the bacteria for 48 hours. Readily visible bacterial colonies will form on the plate only where individual bacteria have been mutated back to the wild type.

The number of 'revertant' colonies formed per unit of mutagenic chemical is thus an index of the mutagenicity of the chemical. Generally, the 9000 g supernatant fraction (S9 fraction) of a rat liver homogenate is added to the culture plates as the source of the biotransformation enzymes. Because millions of bacteria can be used in a single plate, only a very small fraction of bacteria actually have to be mutated at the His⁻ locus to produce a readily measurable response. This simple and relatively inexpensive test has been used to screen thousands of different chemicals for mutagenic potential.

There are many other assays that employ other types of bacteria, yeast, and mammalian cells in culture to identify the mutagenic potential of chemicals.⁹⁹ The Ames test and other similar bacterial assays generally identify point mutations or 'microlesions', e.g., single base-pair substitutions or frame-shift mutations (deletions or additions).

There are also a number of in-vitro and in-vivo tests that have been developed to assess major alterations in DNA, sometimes referred to as 'macrolesions'. For example, incorporation of radiolabeled thymidine into high molecular weight DNA (unscheduled DNA synthesis) can be readily determined as a measure of DNA damage following exposure of normally quiescent mammalian cells in culture to a mutagenic chemical. Because the extent of DNA damage is reflected by the rate of DNA repair and thymidine incorporation, this test can be used to assess widespread but non-specific damage to DNA. Mammalian cells in culture are frequently used to identify chromosomal aberrations such as 'sister chromatid exchanges', chromosomal rearrangements or deletions, and micronuclei formation.⁹⁹ Increases in chromosomal aberrations in

circulating mononuclear leukocytes from occupationally exposed populations have been used as an in-vivo indicator of human exposure to mutagenic chemicals.¹⁰⁰ However, one should always insist on the use of appropriate controls because the association between exposure and effect can only be made when an appropriate non-exposed population is used for comparison.

Although short-term mutagenicity assays are extremely valuable in assessing the potential mutagenic activity of a chemical, the quantitative interpretation of such assays to human health risks has limitations. Generally, a chemical is tested in a variety of different mutagenicity test systems before qualitative judgments about the potential genotoxicity to humans are made. Chemicals that test positively in multiple different test systems are likely to be mutagenic and, thus, potentially carcinogenic in humans, whereas the mutagenicity of chemicals that test positively in only one or two assays but test negatively in several other tests may be of questionable relevance to humans.

Short-term mutagenicity assays are frequently used to assess carcinogenic risk. Although the qualitative relationship between mutagenicity and carcinogenicity is significant, it is not absolute. There are chemicals that may test positively in short-term mutagenicity assays that do not present a significant carcinogenic risk to humans (false-positive result relative to cancer risk) because of pharmacokinetic and/or pharmacodynamic factors. Similarly, there are chemicals that may pose a carcinogenic threat to humans that test negatively in short-term mutagenicity assays (false-negative result). For example, several inorganic substances, such as arsenic, chromium, and asbestos, test negative in the majority of mutagenicity assays, yet they are known human carcinogens. In general, all chemicals that modify the carcinogenic response by epigenetic mechanisms (e.g., promoters, co-carcinogens, and immune suppressants) may be important human carcinogens, even though they are not mutagenic. Conversely, the identification of chemicals that are mutagenic provides supportive, but not confirmatory, evidence of potential human carcinogenicity.

Reproductive and developmental toxicity tests

Well-defined experimental protocols have been developed for the assessment of the reproductive and developmental effects of chemicals in both male¹⁰¹ and female¹⁰² test animals. These tests often involve the exposure of laboratory animals throughout gestation, weaning, and early reproductive life. For example, a typical three-generation study (Fig. 5.16) to determine the effects of chemicals on reproductive capacity involves continuous exposure of both male and female animals (F₀, or Parental), generally by the diet or drinking water route, after weaning. Males are generally exposed for 8-11 weeks, and females for 2 weeks, prior to mating. The animals are then mated, reproductive success is evaluated, and the offspring (F₁A generation) are examined by autopsy at weaning for malformations. The parental generation (F₀) continues to

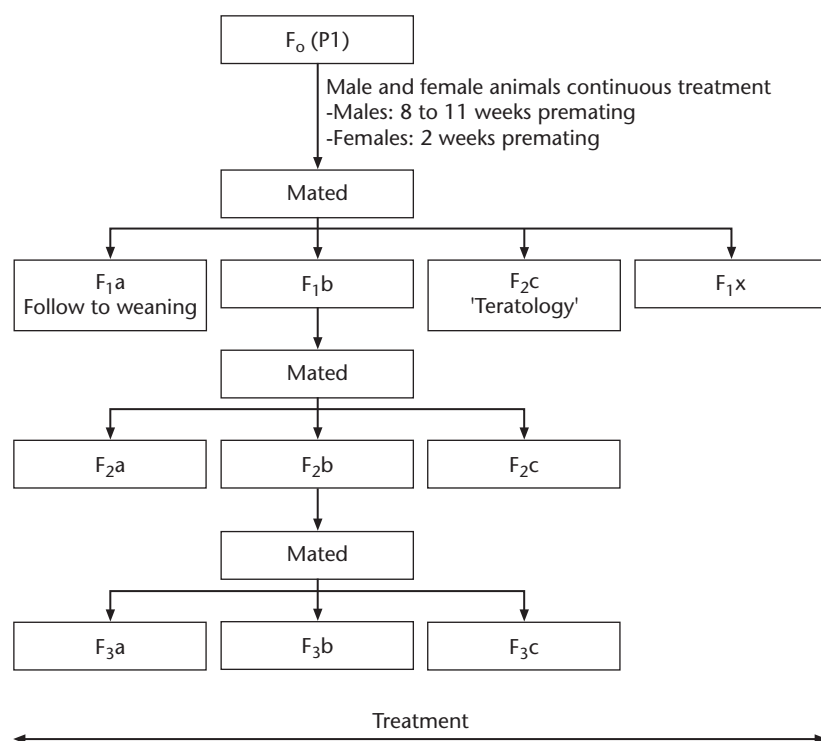

Figure 5.16: Three-generation reproduction study. Generations and time intervals involved in a three-generation study of effects on the reproduction process in rats. Adapted from Christian MS. Test methods for assessing female reproductive and developmental toxicology. In: Hayes AW, ed. Principles and methods of toxicology, 4th edn. Philadelphia: Taylor & Francis, 2001;1301–80.

be exposed and mated a second time after 1 to 2 weeks to produce the F₁B generation. These offspring are then continued on the study, receiving potential exposure by lactation from the exposed dams, and then are switched to the exposure diet at weaning.

Selected parents from this generation (F₁) are continued on the study and mated twice in the same manner, and the offspring (F₂A and F₂B) are treated as described previously, such that the cycle is repeated to a third generation (F₃A, F₃B). At one or more of the mating points in the three-generation study, one half of the pregnant female animals are killed and evaluated for the number and distribution of embryos, early implantation sites, and resorptions. These comprehensive studies provide useful information about the potential effects of the test chemical on male and female reproductive capacity and teratogenic effects. If abnormal responses are obtained in either category, more specialized tests can be performed to evaluate male and female reproductive effects individually and/or evaluate the teratogenic effects by limiting the exposure to specified portions of gestation at doses that are not associated with maternal toxicity.

Interpretation of reproductive and developmental tests must include an assessment of O relationships, the presence or absence of frank histopathologic damage to the reproductive organs, and evidence of maternal toxicity in which teratogenic effects have been identified. Because of the well-known occurrence of significant species differences in response to teratogenic agents, information on the mechanism of action, pharmacokinetics, and pharmacodynamics are again critical to the rational extrapolation of laboratory animal data to human health risks.

Specialized tests to assess other forms of toxicity

In addition to the basic toxicity testing discussed, numerous other special tests have been developed to assess ocular toxicity,¹⁰³ dermal toxicity,¹⁰⁴ neurobehavioral effects,¹⁰⁵ and immunologic alterations.¹⁰⁶ Ocular and dermal toxicity have classically been determined by direct application of the materials to the cornea or skin, usually using rabbits or guinea pigs as test animals. The 'Draize' test was originally developed in 1944 to identify human eye irritants using rabbits. Although this test is sometimes a regulatory requirement prior to manufacture of products that might result in eye contact, concerns over animal welfare have stimulated the search for better ways to assess the eye irritation potential of chemicals. Modifications of the procedure in recent years have reduced both the number of animals necessary and the level of discomfort, and new in-vitro procedures using corneal cells in culture and other similar approaches are now being used to screen for ocular irritancy potential.

The shaved surface of the guinea pig is frequently used to assess dermal irritation. A variety of protocols and methods of interpretation are available that attempt to quantify dermal irritation, delayed hypersensitivity, and other types of dermatotoxicity. These tests generally involve the direct application of material to the shaved surface of the animal, followed by occlusion of the site with an impervious material for a defined period. A scoring system for erythema, eschar formation, and edema is then used to provide an overall score of dermal irritation. The assessment of allergic reactions, such as delayed hypersensitivity, usually involves the application of the test

Carcinogen	One-hit		Linearized multistage		Weibull		Multihit	
Vinyl chloride	1	(0.03)	1	(0.03)	1×10^{-7}	(0.56)	2×10^{-8}	(0.32)
Aflatoxin	1	(0.07)	20	(0.49)	1000	(0.64)	8000	(0.54)
Dimethylnitrosamine	1	(0.04)	600	(0.57)	600	(0.63)	200	(0.72)
Nitrotriactic acid	1	(<0.001)	10	(0.09)	30,000	(0.48)	40,000	(0.48)

* The numbers shown represent the difference in VSD estimates compared with those obtained from the one-hit model.

The values in parentheses represent the P value for goodness-of-fit of the data to the model.

Table 5.7 Methods for behavioral toxicity assessment

material and an adjuvant to facilitate the expression of dermal sensitization.

Experimental methods for the neurobehavioral assessment of chemicals have been developed and are finding increasing use in routine toxicity assessment.¹⁰⁵ Common tests in adult animals include the assessment of sensory and motor performance, sensorimotor integration, and the assessment of higher cognitive functions, such as learning, memory, and social, emotional, and reproductive behavior (Table 5.7).

In contrast to many other areas of predictive toxicology, routine protocols for neurobehavioral assessment have not been widely adopted by regulatory agencies, yet in recent years there has been increasing concern about the neurobehavioral toxicity that may result from environmental and occupational exposures. The standardization and widespread use of such tests are made difficult by the qualitative nature of the observations. Nevertheless, neurobehavioral assessment using experimental animals is an important area of toxicologic investigation, and refinements and broader applications of current methods should greatly enhance our abilities to identify, prior to distribution and widespread use, chemicals that may produce serious adverse neurobehavioral effects in humans.

Chapter 6

Epidemiology

Harvey Checkoway, Ellen A Eisen

Epidemiology is the systematic method of identifying occupational health hazards and quantifying the magnitude of risks. There is a long history of epidemiologic recognition of work-related risks, much of which was stimulated by clinical observations of seemingly unusual or unanticipated illnesses in workers. Respiratory diseases among underground metals miners in 16th century Germany and Czechoslovakia and scrotal cancer among London chimney sweeps in the 18th century are two prominent examples. Epidemiology has made significant contributions to occupational and environmental medicine, especially during the past 100 years. These contributions are directly related to advances in epidemiologic methods and to a growing appreciation by clinicians of the role of epidemiology in occupational and environmental hazard identification.

Although many important epidemiologic leads originate from clinical observations made on individual patients or small case series, the goal of formal epidemiologic research is to permit inferences about risks from exposures to populations. The at-risk populations typically studied initially are workers exposed to known or suspected toxic agents, and secondarily are community residents or consumers of industrial products exposed environmentally to the same agents. Ultimately, the findings from worker population studies can be used to evaluate risks to individual workers and other members of the population, thus contributing to the scientific bases of exposure guidelines for workplace and ambient exposures.

This chapter summarizes commonly used epidemiologic approaches to the study of occupational and environmental hazards. The intention is to provide an overview of study designs, including the relative advantages and limitations of each, a review of potential sources of bias that may undermine research findings, and a discussion of how clinicians and the public-at-large can interpret and make use of epidemiologic data. Most attention is focused on occupational exposures because risk factor identification is often more clearly derived from worker health studies due to generally higher and better assessed exposures in the workplace. Examples illustrating various research methods are drawn from the published occupational and environmental health literature. Readers seeking more in-depth treatment of epidemiologic methods are referred to texts devoted to this topic (see Further reading).

EPIDEMIOLOGY STUDY DESIGNS

Various approaches can be adopted for investigating relations between occupational or environmental exposures

and disease risks. To a great extent, the design of a given study is governed by the types of exposures of concern, anticipated health outcomes, and feasibility. Epidemiologic investigations can range from case series reports of illness or injury to long-term follow-up studies of large occupational cohorts with well-characterized exposures. Typically, epidemiologists prefer relatively large studies of occupational populations, although size is by no means the sole determinant of the public health and scientific importance of a study. Other factors, especially the clarity of the research objectives, validity of exposure and health data, and the appropriateness of study design, are the distinguishing features of valuable epidemiologic research.

Case series and cluster investigations

As mentioned previously, case series reports provide insights into past or emerging occupational and environmental health problems. The recognition of cases of hepatic angiosarcoma at a polyvinylchloride manufacturing plant, and impaired fertility among male workers exposed to the pesticide dibromochloropropane (DBCP), are vivid occupational examples. Examples of adverse effects from secondary (indirect) exposures to workplace toxicants are reports of malignant mesothelioma, berylliosis, and lead poisoning among family members of workers exposed to the causative agents. In such instances, where the disease is rare and there are few if any other known causes, a case series is sufficient to trigger efforts to eliminate exposure.

More typical, however, are situations where there are reports of acute diseases or injuries among segments of a workforce or among individual workers from multiple workplaces with similar exposures. Case reports suggestive of environmental hazards also arise from the community-at-large. Noteworthy examples are reports of adverse reproductive outcomes and other morbidity among persons living near hazardous waste disposal sites or in communities exposed to polluted ambient air or water sources contaminated by industrial discharges. An epidemiologic study in many such situations may be unnecessary if the cause(s) can be determined (e.g., poor ventilation, contaminated water) and rectified.

Profound episodes of environmental pollution and subsequent illness can lead to epidemiologic follow-up studies of affected populations, particularly when the pollution source is readily identifiable and sequelae are severe. Two episodes of illness resulting from environmental water pollution in Japan, namely neurologic impairment in

residents of Minimata Bay exposed to industrial mercury discharges, and bone and kidney disease ('itai-itai' disease) among Toyama Bay residents exposed to cadmium effluents from a mine, are well-known examples. In both instances, clinical recognition of unusual disease patterns prompted investigations into environmental causes and follow-up of cohorts of exposed populations for subsequent disease occurrence.

As with case series reports arising from the workplace, causal links with exposures in community case series are most convincing when the disease in question is either very rare or specific for the putative etiologic exposure. This was certainly true in the mercury and cadmium poisoning episodes in Japan. More generally, however, the consequences of environmental exposures are not clear-cut, as evidenced by findings from follow-up investigations of populations exposed to dioxins from a trichlorophenol factory explosion near Seveso, Italy, in 1976 and nuclear fallout from the 1986 Chernobyl disaster.

There are, however, numerous episodes of illness for which there are no obvious etiologic factors. The term 'disease cluster' has been used to describe such occurrences. Apparent clusters may simply be due to an especially intensive medical evaluation of workers or community residents in which previously unnoticed morbidity is reported. Alternatively, some clusters have been ascribed to heightened awareness or concern for potential health risks among workers or community residents. While such clusters may not represent exposure-related health effects, as a general rule, dismissing disease clusters as necessarily spurious without conducting some form of medical or epidemiologic inquiry, either by review of past data or by conducting a focused study of the problem, is unjustified both scientifically and from the perspective of protecting public health. Of course, the availability of resources to conduct an epidemiologic study will dictate its scope.

Case series reports or disease clusters should be appreciated for what they are: evidence of potential risks from exposure. There is no consensus among epidemiologists as to how one should address a disease cluster or what inferences can be drawn from case series reports. Initially, one would like to confirm that the cluster truly represents an excess. Data on disease incidence in relation to the timing of exposure is valuable in this regard. For example, either an increased incidence following the introduction of exposure or a decreased incidence after exposure reduction or removal would support a cause and effect association. Unfortunately, such unambiguous data are not readily available in many instances.

A second consideration in deciding whether a cluster warrants concern is the specificity of the reported health outcome. Case reports of homogeneous clinical entities, rather than a wide spectrum of adverse health outcomes, improves confidence that there has been an environmental factor contributing to risk. For example, a cluster of urinary bladder cancer cases in a workplace, as has been seen on numerous occasions among workers exposed to benzidine-based dyes, is more persuasive evidence of an occupational etiology than a cluster consisting of a mixture

of various site-specific cancers. Also, conditions with relatively short latencies between exposure and case diagnosis or symptom reporting (e.g., reactive airway symptoms) are more readily assessed than conditions that typically have long induction and latency times (e.g., chronic bronchitis).

A reasonable approach for investigating a disease cluster might involve the following strategy. First and foremost, the priority assigned to investigating a cluster has to be determined by the medical significance of the problem. Importance of the problem to workers and management, in terms of psychological well being and workplace relationships, also deserves considerable weight. Next, the available resources to conduct a formal study need to be inventoried. For example, one case of acute myeloid leukemia in a small shop where solvents are used is a cause for genuine concern. However, if there were only a small number of exposed workers and no past exposure monitoring data, then a meaningful epidemiologic study would be unlikely. In such an instance, causality for the individual worker or recommendations for exposure control may have to be based on data from prior epidemiologic research.

Some have argued that, if an epidemiologic study is undertaken pursuant to a cluster, then one should delete the 'cluster cases' because their inclusion would bias the ultimate study findings. However, epidemiologic principles dictate that all relevant findings should be presented in a balanced manner. This means that the so-called 'cluster cases' are as valid as any other cases that might be detected on further inquiry. On the other hand, exclusion of some of the cluster cases would be justified when there is convincing evidence that case diagnoses or reports are biased, as might occur when aggressive case-finding efforts are made preferentially among persons exposed to presumed causal factors. A valid epidemiologic assessment requires that efforts should be made to expand the scope of the study to include events before and subsequent to the cluster occurrences, and that case identification should be performed in a uniform and unbiased manner.

Some researchers hold the opinion that cluster detection and follow-up are poor uses of resources; instead one should devote more attention to an understanding of basic disease mechanisms. This viewpoint certainly has some academic merit, but offers little guidance to practicing clinicians and epidemiologists. Epidemiologists generally prefer to conduct studies that examine well-formulated prior hypotheses, although there are situations where cluster recognition can offer valuable preliminary insights. Reaching conclusions about disease causation from cluster reports can be a vexing problem when they are the only available evidence. Statistical significance can be misleading because populations at risk and expected disease frequencies are seldom known when clusters are reported. Also, it should be appreciated that diseases in populations do not occur uniformly in time or place. Thus, some apparent clusters of disease are to be expected. (By analogy, inspection of a table of random digits will reveal clusters of repeated numbers in various places.) In general, the best evidence is obtained from formal epidemiologic studies. Determining whether an epidemiologic study should be

mounted will always require clinical and epidemiologic judgment.

Cohort studies

Cohort studies involve the identification of an exposed worker population (cohort), follow-up over time, and determination of disease frequency in relation to exposure type and level. Among epidemiologic study designs, cohort studies are by far the best understood and recognized as scientifically valid because they mimic, at least in structure, an experimental approach. However, it should be appreciated that other designs, in particular case-control and cross-sectional, can also provide valid data, and are, in fact, more suitable than cohort studies in certain situations.

There are numerous types of cohorts that can be defined for study. The most typical is a population of workers from a single plant or industry. Other cohort definitions are workers from a trade or professional association, preferably with similar exposures, or persons with previously diagnosed occupational diseases, such as registered cases of pneumoconiosis. The choice of cohort depends on the goal of the study and availability of data necessary for cohort enumeration. If the research objective is to survey the exposure and health experience of workers in a particular industry, then a cohort defined as workers from plants in that industry will be most appropriate.

Trade union or professional association members might constitute the study population if plant- or industry-specific cohorts cannot be defined readily from existing data (e.g., construction painters), or if access to personnel and exposure records is denied. A cohort consisting of cases with certified or registered diseases customarily is followed to evaluate adverse sequelae related to those diseases, and for situations such as the pneumoconiosis or pesticide poisoning, to study workers assumed to have experienced the heaviest exposures to the causative agents.

Follow-up in a cohort study can be either prospective or historical. A prospective cohort study begins with a population of current workers and follows them into the future. Prospective cohort studies of diseases with long induction and latency intervals, such as most malignancies, are uncommon but not unprecedented in occupational epidemiology. The most efficient applications of the prospective cohort design are studies of common illnesses, injuries, or physiologic states that are observable within reasonably short time periods. Data from a prospective cohort study of longitudinal pulmonary function changes in cotton and silk textile workers in Shanghai¹ are shown

in Table 6.1. This study has features of both a short-term and longer-term prospective cohort study in that cross-shift FEV₁ measurements obtained at the baseline survey represent a follow-up of a single day, and the repeated FEV₁ measurement 5 years later is the longer-term component. In this study, although the differences between the cotton and silk workers, who were the non-exposed comparison (referent) group, were small, there was a detectable association of accelerated lung function decline among cotton textile workers who experienced the largest baseline cross-shift changes.

Historical cohort studies offer a more convenient and time-efficient method than prospective cohort studies for investigating chronic diseases. The principal limiting factors of most historical cohort studies are the availability of past data on employment, typically obtained from personnel records, and exposure, obtained from environmental monitoring data. The design and analysis of historical and prospective cohort studies are identical. The only distinction is the timing of when the studies are conducted relative to when exposures and disease have occurred. Thus, for example, a cohort may be followed from 1970 to 1999 for disease incidence. The study would be prospective if the investigators had enumerated the cohort in 1970 and followed it throughout the study interval. In contrast, the study would be historical if cohort enumeration and follow-up were conducted retrospectively after 1999.

As mentioned earlier, the identification of a case series of cancer among chimney sweeps was an important discovery in occupational medicine. A more modern investigation of this issue was addressed in a historical cohort study of Swedish chimney sweeps followed for 40 years² and is shown in Table 6.2. The cohort included 5542 chimney sweeps registered in a trade union that had been employed between 1918 and 1980. The cohort was traced for mortality outcomes during 1951–1990, and cause-specific mortality rates were compared with prevailing rates in Sweden. The chimney sweeps experienced mortality excesses for all causes combined, circulatory diseases, respiratory diseases, and various cancers. The two-fold elevated lung cancer risk was especially noteworthy because it was based on a reasonably large number of deaths and was consistent with the prior hypothesis regarding carcinogenic effects of inhaled soot particles. Additionally, data on cancer incidence were available from the Swedish National Cancer Registry for the years 1958–1987, and permitted contrasts with national rates for cancers with low mortality rates, such as bladder cancer. Analyses of cancer incidence according to duration employed as a chimney sweep revealed a trend indicative of a dose–response relation for lung cancer, although no such gradients were observed for cancer of the stomach and bladder (Table 6.3). The absence of gradients with duration for the latter cancers may reflect truly absent dose–response associations, although it is equally plausible that either employment duration is a poor surrogate for dose or that the actual dose–response relations are not continuously increasing.

Some special cohorts can be defined as workers who have experienced unusual exposure circumstances, such as

Cross-shift drop in FEV ₁ at baseline	Annual change in FEV ₁ (mL)	
	Cotton workers*	Silk workers*
<5%	–35 (236)	–34 (243)
≥5%	–57 (73)	–36 (37)

* Number of workers in parentheses

Table 6.1 Five-year mean annual change in forced expiratory volume in 1 second (FEV₁) among Shanghai cotton and silk textile workers in relation to cross-shift change at baseline

Cause of death	Observed	Expected*	Relative risk	(95% CI) ⁺
All causes	919	680	1.35	(1.27–1.44)
Circulatory diseases	354	276	1.28	(1.15–1.42)
Respiratory diseases	44	27.8	1.59	(1.15–2.13)
Digestive diseases	39	20.1	1.30	(0.92–1.77)
All cancers	216	148	1.46	(1.27–1.67)
Esophageal cancer	12	3.1	3.86	(2.00–6.75)
Stomach cancer	20	16.6	1.21	(0.74–1.87)
Colon cancer	8	10.5	0.76	(0.33–1.50)
Liver cancer	11	3.3	3.31	(1.65–5.93)
Pancreatic cancer	10	10.0	1.00	(0.48–1.85)
Lung cancer	53	25.8	2.06	(1.54–2.69)

Table 6.4 Mortality experience, 1953–1992, of 243 German workers exposed to dioxin (2,3,7,8-TCDD) following an industrial accident at a trichlorophenol plant

a chemical spill or explosion. An example is a 40-year mortality follow-up of 243 workers who were exposed to 2,3,7,8-tetrachlordibenzo-p-dioxin (TCDD) consequent to an accident at a trichlorophenol manufacturing plant.³ Blood concentrations of TCDD measured periodically after the accident were incorporated into pharmacokinetic models to estimate cumulative dioxin doses, and permitted dose-response analyses (Table 6.4). Increasing gradients of relative risk for all cancers combined and for respiratory cancer, small numbers notwithstanding, support a carcinogenic potential for TCDD.

Special cohorts can be formed from workers with diagnosed disease. An example is a mortality follow-up study of a cohort of roughly 1500 workers, from numerous industries in Hong Kong, who were included in a silicosis

registry organized largely for compensation purposes.⁴ Compared to Hong Kong males, the cohort experienced a nearly two-fold increased risk of lung cancer, with a particularly accentuated risk gradient associated with the extent of large radiographic opacities (Table 6.5).

Studies in which workers are selected on the basis of health status frequently include cohorts whose source populations are less well characterized than conventional cohort studies of workers from particular plants or industries. The advantage of restricting cohorts in this manner is that this approach is efficient for estimating risks theoretically related to high dose levels. However, subtle selection biases may create confounded results. For example, if smoking-related morbidity increases the probability that a pneumoconiosis case will seek medical attention, and hence be more likely to

receive a definitive diagnosis and be awarded compensation, then a cohort study of subsequent lung cancer risk among compensated pneumoconiosis cases may overstate the effect of dust exposure. This problem may be overcome by including in the cohort exposed workers with and without the index condition. The data in Table 6.6 from a study of silica-exposed workers in the diatomaceous earth industry⁵ illustrate this approach. An exposure–response lung cancer trend was evident among persons without radiographic evidence of silicosis (ILO category <1/0), suggesting that silica was an important contributor to risk that was independent of the presence of silicosis. Disentangling the carcinogenic effects to the lung of occupational dust exposures per se from effects secondary to fibrosis, which may be an intervening pathogenetic step, is a challenging epidemiologic problem with no simple solution.

There is a logical sequence to analyzing data from a cohort study. The first step is to examine the cohort's overall pattern of mortality and morbidity. This analysis identifies diseases that are occurring more or less commonly in the cohort than would be expected, based on rates in a reference population assumed not to be exposed to the agents of interest. The most commonly used measure of association in mortality studies is the standardized mortality ratio (SMR), which is the observed number of deaths from a particular disease divided by the number of deaths expected for that disease, based on reference rates, usually derived from the source national or regional population.

The standardized incidence ratio (SIR) is the analogue of the SMR in situations where comparative rates for disease

Occupational group	No. cases	Relative risk

>0–<40	11	1.9
40–99	8	3.1
≥100	19	2.7

Table 6.8 Leukemia incidence according to cumulative exposure to benzene among Chinese workers

incidence are available. The SMR (or SIR) provides an estimate of the relative risk among the cohort compared to expected in a non-exposed population, as was done in the study of Swedish chimney sweeps² (Table 6.2). Next, when there are sufficient job history or environmental data to classify workers according to exposure type or level, an analysis can be performed for subsets, or subcohorts, of the cohort. This approach is illustrated with data from study of leukemia incidence among Chinese workers from numerous factories exposed to benzene.⁶ Workers from the same factories, but not exposed to benzene, provided the comparison group. Leukemia excesses were identified for exposed workers in all industries, with the largest excess seen in chemical manufacturing plants (Table 6.7).

The informativeness of an epidemiologic study is greatly enhanced when exposure data can be linked to employment for dose-response estimation. It was possible to reconstruct historical exposures to benzene in the study of Chinese workers⁶ and to estimate a dose–response trend for leukemia with cumulative exposure (expressed in parts per million benzene × years, ppm-yrs) (Table 6.8). Unfortunately, quantitative data on exposure levels are often not available in historical cohort studies, or available data are incomplete. The reason is that, traditionally, exposure monitoring has not been performed for epidemiologic or medical surveillance research purposes, but rather to assess levels in relation to exposure standards, i.e., compliance testing. In the absence of representative and reliable quantitative exposure data, investigators are forced to rely on surrogates of dose, such as employment duration in various jobs ranked according to cumulative exposure level. This was the case in the Swedish chimney sweep study² where employment duration was the dose surrogate in the dose–response trends analyses (Table 6.3).

Many occupational cohort studies focus on fatal diseases because of their importance, and because of the relative ease of obtaining mortality data. Studies of cancer incidence also receive considerable attention, but require linkage to cancer diagnosis and reporting registration

systems. Cancer incidence studies are facilitated when cohorts are located in population centers with cancer registries, such as the Surveillance, Epidemiology, and End Results (SEER) registries in the US, or the national population-based cancer registries maintained in some of the Scandinavian countries. The lack of national disease incidence registries in most countries (including the US) limits the ability to determine risks for workers who relocate after leaving employment. Some companies maintain their own disease registries as part of health surveillance programs, but this is not a widespread practice. Currently, most small industries are not likely to have adequate resources to maintain disease registries.

Cohort studies of health endpoints other than mortality or cancer incidence often require intensive questionnaire or clinical surveys of the workplace. An example is a historical cohort study of spontaneous abortion history among semiconductor fabrication workers.⁷ In this study, self-reported reproductive histories were obtained from 506 active and 385 former workers who had been pregnant during 1986–1989. The cohort was identified from company records for more than 6000 women workers at 14 companies. Women were classified according to exposures to various chemicals that occurred at the estimated times of conception. As shown in Table 6.9, there were relatively strong associations for highest exposures to ethylene glycol ethers, xylene, and fluoride.

At times, the only available data for a worker cohort may be information on disease occurrence, generally death certificates. This situation occurs when the data necessary to assemble a cohort do not exist or cannot be obtained feasibly. Studies of union memberships sometimes

encounter this problem when the membership represents workers from a large number of geographically scattered plants and companies. Data on disease frequency can be used to a limited extent by adopting a design known as a proportionate mortality or morbidity ratio (PMR) analysis. In a PMR study, the distribution of various diseases in the exposed group is compared with an expected distribution derived from the experience of a reference population. Thus, for example, if leukemia accounts for 10% of deaths for a group of workers exposed to solvents, but only 2% of deaths in the national population, then an estimate of the relative risk would be 5. Alternatively, one might compare the observed and expected proportions of death from a given cause in relation to a more specific encompassing category of diseases than all causes combined. Comparing observed and expected distributions of site-specific cancers as proportions of all cancers, rather than all deaths, is the most common application of this approach. For example, data from a proportionate mortality study of cancers among garment workers exposed to formaldehyde⁸ suggest a relative excess of buccal cavity cancer, but not lung cancer (Table 6.10).

The main advantage of PMR studies is the relative speed with which they can be conducted, provided that a roster of deaths in the population of interest is available. A potential drawback of the PMR approach is that, without having followed a defined cohort, there is often no way of knowing whether the available deaths or cases constitute a biased sample, e.g., death certificates for cancer deaths may have been archived more completely than death certificates for other diseases. Another potential disadvantage is that, in a PMR analysis, excesses of certain diseases

Table 6.10 Proportionate mortality of garment industry workers exposed to formaldehyde

necessarily will be counterbalanced by deficits of the residual diseases. This occurs because the total number of deaths available for the study is fixed. Consequently, the investigator may not be able to determine which of the disease excesses and deficits are more valid findings. As a general rule, PMR studies serve best to give a general picture of disease experience, whereas follow-up studies of well-defined cohorts yield more complete and valid data.

One important aspect of cohort studies is that they are designed to assess multiple health outcomes, even in instances where a specific agent/disease association triggers the investigation. As a result, previously unanticipated associations may emerge and stimulate further research or interventions. As discussed earlier, prospective cohort studies of chronic diseases are seldom practical. Historical cohort studies are a convenient alternative, although a thorough analysis of disease risk in relation to complete occupational history can require several years of effort, even for relatively small cohorts. An alternative, more cost-efficient design is the case-control study which is considered next.

Case-control studies

In a case-control study, past exposure histories are compared between cases of index diseases and controls free of these conditions at the times when the cases are identified. Case-control studies were originally devised in the 1950s as a practical alternative to cohort studies. Some of the original case-control studies explored associations of lung cancer with cigarette smoking and cervical cancer with sexual history. Most of these studies were conducted in hospital settings. Early critics of the case-control design argued that an approach that begins with the outcome and works backward to its causes is inherently inferior to a cohort design that has the reverse, more intuitive, temporal sequence. This viewpoint, while not fully discarded, has in large measure been discounted following numerous theoretical and empirical demonstrations that, when conducted validly, cohort and case-control studies of the same research questions yield similar results. This has been amply demonstrated with smoking and lung cancer, for example.

There are two general types of case-control studies. The first are 'nested' case-control studies in which the cases and controls are both selected from within a defined occupational cohort. The other type are community-based case control studies in which study subjects typically are identified from hospitals, disease registries, or other sources of population-based data, rather than from enumerated industrial cohorts. The two types of case-control studies are considered in turn.

Nested case-control studies

Comparisons of disease rates can be made between subcohorts that comprise a defined occupational cohort. An example of this approach was given in Table 6.7. In many instances subcohort analyses of an entire cohort may not be practical, especially when an expensive and time-

consuming exposure reconstruction effort is required. A more cost- and time-efficient alternative to a full subcohort analysis is to compare exposures of the cases with those of a sample of the non-cases, where both cases and controls are members of some defined occupational cohort. Typically, this involves identifying all or as many cases of the index disease(s) as can be ascertained from historical follow-up, and selecting a sample of other workers who were free of the index condition(s) at the times of the cases' diagnoses.

In a study of mortality outcomes, the date of death serves as the date of identification or diagnosis. The savings in time and cost for exposure assessment and data processing in a nested case-control study, relative to a subcohort analysis of an entire cohort, can be great. To illustrate, consider a cohort of 10,000 workers exposed to solvents from which 75 leukemia cases are identified during a 40-year historical follow-up. Exposure reconstruction for all 10,000 workers is an extremely labor-intensive effort, whereas exposure assessment and data processing for the 75 cases and 150 or 300 control workers can be accomplished much more efficiently. The savings becomes even more evident when there are multiple exposures of interest, which each engender detailed exposure assessments. In a study with a relatively small number of subjects, intensive efforts can be devoted to exposure reconstruction for each individual; this task can be unwieldy for a large cohort.

The diseases that are selected for nested case-control studies usually are those for which there are postulated a priori associations and those for which excesses are found from disease rate comparisons made between the cohort and an external reference population. Often in medical surveillance programs, apparent disease excesses emerge without prior evidence of toxicity, and these may prompt more in-depth analyses using the case-control design. As with disease cluster investigations, judgment concerning which diseases warrant further inquiry is needed to avoid unproductive expenditures of resources. In the absence of prior hypotheses or suspicions of toxicity associated with specific exposures, relatively stable, long-term trends of disease excess can serve as useful guides for decision-making.

The data in Table 6.11 are from a case-control study of fatal work-related injuries nested within a cohort of 22,000 Brazilian steel workers employed during 1977–1990.⁹ The 37 cases who died from work-related injuries were compared with a sample of control steel workers; four controls were randomly selected for each case. Data on cases' and controls' demographic factors, history of injuries, physical disabilities (e.g., hearing loss), psychiatric disorders, and previous injuries at work and elsewhere were abstracted from plant personnel, occupational hygiene, and medical records. Occupational histories for study subjects were classified with respect to chemical and physical hazards. Prominent associations with fatal injuries were detected for employment in jobs classified as having moderate to high levels of noise, heat, and vibration; associations with dusts, fumes, gases and vapors were

Occupational hazard	Cases	Controls	OR*	(95% CI)

Table 6.11 Nested case-control study of fatal work-related injuries in a cohort of 21,816 Brazilian steel workers

also identified (Table 6.11). This example clearly illustrates the chief advantage of the nested case-control design relative to a full cohort analysis: collection of occupational and non-occupational risk factor data was much more feasible than would have been the case had a similar effort been mounted for the entire cohort of 22,000 workers.

Case-control studies should yield estimates of exposure effects that are identical to those that would be obtained from a full exposure–response analysis of the base cohorts, provided that control sampling is performed in an unbiased manner. An absolute requirement for validity is that control selection should be made without respect to exposure status. Apart from this requirement, there is no one optimal method for control selection. It is generally sound practice to select controls such that they have similar distributions of age and gender as the cases. (The issue of confounding will be discussed in more depth later in this chapter.) In comparison with subcohort analyses, nested case-control studies may suffer from a loss of statistical precision by virtue of a reduced study size. However, statistical power can be increased by enlarging the study sample. This is usually accomplished by selecting more than one control per case, as the size of the case group is more likely to be fixed. Furthermore, the number of controls in the study may need to be enlarged if a goal of the study is to examine exposure effects in subgroups of the workforce (e.g., the effects of solvents on neurological disease risk separately for workers with and without metal exposures).

The foregoing discussion has emphasized the relative efficiency of the nested case-control design. This efficiency is realized when the time and cost required for exposure assessment and data management increase in proportion to the number of subjects in the analysis. However, there would be no need for a nested case-control study in situa-

tions where all of the pertinent work history and exposure data have already been compiled and assembled for analysis. Instead, a full cohort analysis would be preferred for reasons of statistical power and simplicity in explaining the results.

Community-based case-control studies

When it is not possible or convenient to enumerate and follow a defined occupational cohort, or when the disease of interest is especially rare so that only a prohibitively large cohort would be effective, community-based case-control studies provide a valuable alternative. For example, studies of soft tissue sarcoma among agricultural workers cannot be conducted easily in cohort studies because cohorts of such workers are usually difficult to enumerate, and the soft tissue sarcomas are very rare diseases. The frequency of exposure in the community is an important determinant of the success of the study, as some exposures may be too rare for evaluation. Consequently, the choice of study setting can be crucial. Thus, for example, towns in the Appalachian Mountains would be more suitable locations than large metropolitan areas in California for community-based studies of coal dust and non-malignant respiratory disease.

Community-based studies encompass research that is truly based in a community (i.e., surveys conducted among a defined population base), as well as studies that are conducted in hospital settings or other places where cases of disease are diagnosed and registered. Irrespective of the source of subjects, the design of community-based case-control studies is similar to that of nested case-control studies; exposure history profiles of index cases are compared with those of persons free of disease at the times when the cases' diagnoses are made. The difference between the two types of case-control studies is the source of subjects – persons identified from the population-at-large, or from disease registries in community-based studies.

Traditionally, most community-based studies have been conducted among hospital patients, which provided the source of both cases and controls. Controls may also be selected from the population-at-large, and are suitably compared with hospital cases when controls are sampled from the same population base that provides the hospital or clinic catchment area. As an illustration, Seidler et al.¹⁰ conducted a case-control study of Parkinson's disease in Germany in which the exposures of cases identified from neurology clinics were compared with exposures of controls selected from the same regions where the clinics were located. Findings for pesticide exposures indicated associations with long-term use of herbicides and insecticides, including organochlorine compounds (Table 6.12).

Increasingly, there has been a trend toward using population-based disease registries to identify cases, and population rosters as sources of controls. Population-based disease registries greatly facilitate community-based case-control studies because they offer improved case ascertainment and diagnostic standardization over what are ordinarily available from studies relying on death certificates or hospital diagnosis logs for case accrual. National or provincial vital

Table 6.12 Community-based case-control study of agricultural exposure and Parkinson's disease in Germany

statistics bureaus, which provide death certificate data, can also be regarded as special cases of disease registries. In some instances, exposure data can be inferred from occupations listed on death certificates, thus obviating the need for contacting next-of-kin.

A decided strength of community-based case-control studies is that they typically are designed to obtain data on a wide range of factors, including occupational and non-occupational exposures. Thus, it is often possible to obtain data on potentially confounding factors that are seldom accessible in industry-based studies, which ordinarily rely solely on personnel and exposure records. However, the principal disadvantage of many community-based studies is that exposure data are often determined from questionnaires administered to subjects or to proxy respondents, and thus may not offer quantified data on specific agents as can be obtained in most industry-based studies. This is especially true for studies in which occupational exposure information is inferred from occupations recorded on death certificates.

Cross-sectional studies

Epidemiologic studies of non-fatal outcomes frequently use a cross-sectional design in which health status is compared among worker groups classified with respect to exposure. Outcomes of interest can include overt clinical diseases, symptoms, or variations in physiologic measures. As the name implies, cross-sectional studies assess exposure/disease associations at a single point in time. As will be discussed below, exposure and health evaluations can be extended to multiple points in time, in which instance the study effectively assumes a cohort design.

An illustrative example of a typical cross-sectional design is a study of semen quality among Canadian lead smelters.¹¹ Total sperm count and sperm concentration were reduced markedly with increasing blood lead levels measured at the time of the study, although no consistent associations were observed for either sperm motility or morphology (Table 6.13). It is noteworthy that this cross-sectional study is conceptually similar to an exposure subgroup analysis that would be performed in a cohort study, except that there is no follow-up over time. In this

	Blood lead concentration (µg/dL)			
	<15	15–24	25–39	≥40
Number of workers	32	46	29	12
Total sperm (million cells)*	186	153	137	89
Sperm concentration (million cells/mm ³)*	79.1	56.5	62.7	44.4
Motile sperm (%)*	45.8	56.4	56.3	36.8
Abnormal morphology (%)*	17.7	18.4	17.3	16.2

* Geometric mean.

Table 6.13 Semen quality among Canadian lead smelter workers

study, an effort was made to determine possible effects of chronic lead exposure by examining trends of semen quality parameters in relation to past lead exposures, but only among men whose most recent blood lead concentration was less than 40 µg/dL – similar associations were noted for chronic exposure as were observed for recent lead level.¹¹

The lack of follow-up in a cross-sectional study can be a major hindrance to interpreting causal relations. Specifically, the concurrent measurement of exposure and health status can produce misleading results if changes in the latter influence exposure status. For example, a study of pulmonary function among workers exposed to metal-working fluids could show an inverse association with exposure if the appearance of respiratory symptoms causes workers either to leave employment altogether or to transfer to less heavily exposed jobs. Another significant limitation of many cross-sectional studies is that usually only currently employed workers are included; workers who previously had left employment, perhaps because of exposure-induced impaired health, may be the most relevant study subjects for detecting true exposure effects.

An improvement to the simple one-time cross-sectional study is a longitudinal follow-up with repeated measurements of exposure and health outcomes. The example of pulmonary function among Chinese cotton textile workers¹ partially fits this description (Table 6.1). Workers can be selected for repeated measures studies on the basis of past exposure, much in the same manner that cohorts of workers exposed to extraordinary exposure circumstances are assembled for cohort mortality studies (e.g., the dioxin-exposed workers in Table 6.4).

Repeated measures studies customarily involve assessments of physiologic function changes (e.g., lung function, nerve conduction velocity, semen quality), but may also include longitudinal evaluations of symptom prevalence. Such studies are more effectively conducted when there is a documented change of exposure in the workplace and the effect(s) of interest is thought to be reversible. A study from Sweden¹² took advantage of a 'natural experiment', caused by closure of a styrene-reinforced plastics plant, to examine post-exposure nervous system effects (Table 6.14). Questionnaires were administered one week and 7 months after exposure among workers with relatively low and high styrene exposures. The reductions over time in symptom prevalence in the heavily exposed workers suggest reversibility of effects.

Symptom	High exposure group (n = 9)		Low exposure group (n = 8)	
	1st exam*	2nd exam ⁺	1st exam*	2nd exam ⁺
Abnormal tiredness	9	0	5	0
Heart palpitations	4	0	2	1

Table 6.14 Nervous system symptoms among styrene-exposed workers following cessation of exposure

Attrition of the study population in a repeated measures survey, due to absenteeism, turnover of the workplace, or workers' refusals to continue participation, can pose a serious logistical problem. Losses or withdrawals of study subjects, per se, will not bias the study unless attrition is related both to health and exposure status. To illustrate, consider a hypothetical longitudinal study of pulmonary function in a dusty workplace in which subject attrition is proportionally greater among workers who have FEV₁ values less than 80% of predicted. If attrition among subjects with low FEV₁ values occurs equally across dust exposure levels, then the net effect will not be a bias, but rather a reduced statistical power to estimate a dose-response association because the study population will be over-represented with unaffected workers. On the other hand, the study would underestimate the effect of dust exposure on lung function if subject attrition were proportionally greatest among impaired workers in the highest exposure categories (i.e., biasing the study towards a negative result).

The likelihood of a successful longitudinal repeated measures study can be increased by attending to several practical considerations in the planning of the project. As a general guideline, the measurements should be relatively non-invasive and rapid. Blood, breath, or urine samples can be obtained readily on a routine basis, provided that workers understand the purposes of the tests, and the results are transmitted to workers within a reasonable period of time. Increasing application of molecular genetic markers in epidemiologic research to identify susceptible individuals in a population poses ethical concerns that need to be addressed and explained at the outset of research. Incorporating useful and interpretable clinical measurements, such as serum cholesterol, in a study involving more exotic tests can greatly improve worker interest in participating.

Long complicated test batteries, such as those used to measure neurobehavioral function, may be administered successfully on one occasion, but on repeated testing, participation will diminish in direct proportion to the time and effort required of subjects. One way to circumvent this problem is to obtain as much baseline data as necessary during the initial survey, but then to limit data collection for the repeat surveys to the minimally required informa-

tion. Thus, the initial test battery results can serve as baseline data, and changes in the most relevant parameters can be assessed subsequently. So-called 'learning effects' whereby subjects improve their test performance due to increased familiarity can be mitigated by sufficient training at the baseline survey.

Repeated measures studies are most readily conducted as part of routine medical and exposure surveillance programs. Unfortunately, such programs are usually only affordable by large industries. Studying workers from work sites where exposures are frequently excessive and worker turnover tends to be high poses a more formidable, but important challenge.

TYPES AND SOURCES OF BIAS IN EPIDEMIOLOGIC RESEARCH

Virtually all occupational epidemiologic research studies are observational rather than experimental. Thus, epidemiologic studies are prone to a variety of potential biases that may undermine validity. It is convenient to classify epidemiologic biases into three broad types: selection bias, information bias, and confounding. The distinctions between these categories are not always sharp, as some biases have aspects of more than one type. Nonetheless, this taxonomy provides a useful framework for reviewing the topic of bias. Throughout this discussion, the term bias is used to denote distortion of study results such that observed associations are either spuriously over- or under-estimated.

Selection bias

Improper selection of study subjects can create bias in an epidemiologic study, irrespective of study design. However, in order to simplify the discussion, selection bias will be considered separately for cohort, case-control, and cross-sectional studies.

In cohort studies, selection bias is most commonly the result of inappropriate comparison groups. The most familiar form of such bias is known as the 'healthy worker effect'. In mortality studies, the healthy worker effect is recognizable as a lower mortality risk among the cohort

compared to national or regional reference populations. Apparently reduced mortality rates from all causes combined, and more specifically from cardiovascular diseases, non-malignant respiratory diseases, diabetes, gastrointestinal diseases, and genitourinary diseases, are frequently observed among occupational cohorts. The explanation for this phenomenon is that industrial cohorts include workers who are healthy enough to gain and maintain employment, whereas national or regional (external) reference populations include persons unfit to work because of impaired health. In some industries, access to medical care is more readily obtainable than in the population-at-large, and this may account for some of the reduced mortality risk to the workforce. The healthy worker effect can be regarded as a form of selection bias because cohort members are selected preferentially on the basis of health status, either by themselves or as a result of job requirements.

An example of the healthy worker effect can be seen from a historical cohort mortality study of US electrical utility workers exposed to electromagnetic fields.¹³ Reduced mortality, relative to national rates, was observed for all causes combined, heart diseases, non-malignant respiratory diseases, diabetes, all malignant neoplasms, and for the diseases of greatest a priori interest, leukemia and brain cancer (Table 6.15). Despite the absence of a deficit of brain cancer for the cohort as a whole, there was a trend of increasing risk related to cumulative EMF exposure in the 2–10-year period preceding death.¹³

The healthy worker effect does not necessarily occur in all cohort mortality studies. Obvious exceptions would be cohorts exposed to widely disseminated workplace hazards. Notably, occupational cohort studies of workers from large industries or trade unions from the developed countries have dominated the literature. A somewhat different picture would be anticipated for cohort studies of workers identified from small, non-unionized workplaces, or from developing countries.

The most suitable means of minimizing healthy worker effect bias is to substitute comparisons between worker cohorts and national or regional populations with comparisons among worker subgroups (i.e., internal comparisons). An internal reference group can be defined as workers with low or minimal exposures to toxic agents. This approach was used in the cohort study of Chinese factory workers

exposed to benzene.⁶ However, care must be taken to avoid making inappropriate internal comparisons, as can occur when the least exposed workers are decidedly different in terms of lifestyle and sociodemographic factors than the more heavily exposed groups. An extreme case would be the inappropriate comparison of disease rates between office workers and heavily exposed production or maintenance workers. This problem can be mitigated somewhat by restricting comparisons to either 'blue collar' or 'white collar' groups, if such distinctions can be made.

However, difficulties can arise when internal comparisons are made. The most important is identification of a suitable reference group when exposures are relatively uniform across the cohort, or when the exposure data are too limited to permit meaningful exposure categorizations. A second difficulty is statistical in nature. The statistical precision of the outcome measure (e.g., relative risk) is dependent on the variability of the rates in the exposed and reference groups. Thus, disease rate comparisons made against a national population will have greater precision than comparisons made between subcohorts because the national rates are based on much larger numbers. This problem is an issue of statistical precision, rather than research validity. In fact, internal comparisons are generally more valid methods for assessing risk than external comparisons because the former minimize healthy worker effect bias and may reduce confounding from factors that differ between workers and the general population. In situations where there is a potential trade-off between validity and statistical precision (e.g., the choice between external and internal reference populations), validity concerns should take precedence.

An alternative approach to a strictly internal comparison analysis is to identify as a comparison group another occupational cohort not exposed to the agent(s) of concern or to agents that pose similar health risks, as was done in the study of Shanghai textile workers¹ (Table 6.1). This strategy has an intuitive appeal, although it is tantamount to conducting two studies, and hence the effort and resources required to enumerate and follow another cohort may at times be prohibitive. It may also prove difficult to identify a suitable occupational comparison group that is not exposed to hazardous agents for outcomes of interest.

The major issue relating to selection bias in case-control studies centers on the choice of controls. Certainly, controls in any case-control study should be selected 'blindly' without investigator knowledge of exposure history. The goal of a nested case-control study is to produce the same results (within sampling error) that would be obtained from a full cohort analysis. Accordingly, control selection should be made such that the nested case-control study mirrors the cohort design as closely as possible. Cohort studies measure temporal disease rate patterns in relation to exposure among an entire cohort. Therefore, case-control studies should be designed to evaluate a random sample of the cohort's experience, generally all of the cases and a sample of the remaining workers. This means that controls should be selected from among workers who do not have the index

Cause of death	Observed	Relative risk*
All causes	20,733	0.77
Heart disease	7768	0.76
Stroke	1244	0.73
Respiratory diseases	1178	0.69
Diabetes mellitus	219	0.56
Malignant neoplasms	4833	0.86
Leukemia	164	0.76
Brain cancer	151	0.95

* Compared to rates for US males, 1950–1988.

Table 6.15 Cause-specific mortality among US electric utility workers 1950–1988

disease, but additional exclusions on the basis of other diseases should not be imposed.

To illustrate, consider a nested case-control study conducted among asbestos-exposed workers designed to evaluate exposure-response trends for stomach cancer. Given past knowledge of associations between asbestos and pulmonary fibrosis and lung cancer, it might be tempting to eliminate persons known to have developed the latter diseases from the pool of eligible control workers. This would introduce a bias into the study, in that it would artificially lower the likelihood of identifying heavily exposed controls. The extent of the bias will depend on the frequency of pulmonary fibrosis and lung cancer in the cohort, but the general principle of avoiding health-related control selection biases applies to any case-control study.

In hospital-based case-control studies, controls are typically hospitalized patients with conditions other than the index disease. Ideally, one would select controls with a condition that is unrelated, either positively or negatively, to exposure. Identifying suitable control conditions may not always be possible if the exposure under study is potentially associated with a range of health outcomes. In order to avoid introducing selection bias, it may be necessary to select control patients randomly from a variety of services rather than to choose controls with a particular condition.

Controls selected from the community should be representative of the base population insofar as there should not be any *a priori* reasons to suspect unusual exposure patterns among them. Excluding community controls with diseases known or presumed to be related to the index disease is generally not advisable for the same reason mentioned for control selection in nested case-control studies.

Selection bias in cross-sectional studies, and longitudinal repeat measures studies, are the same as those discussed above. A variant of the healthy worker effect bias is particularly prominent in some cross-sectional studies, where the only workers available for study may include a disproportionate number of persons who are resistant to the effects of exposure. This is often found in studies of acute toxicity where the most responsive or sensitive workers are 'selected out' of exposure. One should attempt to obtain data on subjects' entire work histories, although this may be impractical in many instances. Recruitment of volunteer subjects in cross-sectional studies may be a source of selection bias, although bias will only occur when subject participation is related both to exposure and health status. This can usually be accomplished by explaining to workers that the purpose of the study is not necessarily to screen for disease, and that the validity of the findings depends on inclusion of workers with varying exposure and health status. By way of illustration, in the study of semen quality among lead smelter workers,¹¹ only 119 workers out of 2469 active and retired workers whose participation was invited donated semen samples. While this raises the possibility of selection (participation) bias it is reassuring that there were no systematic differences between semen donors and non-participants with respect to age, blood lead level, work assignment, or history of having sought fertility consultation.¹¹

Information bias

The main form of information bias is misclassification of either health or exposure status. Information bias can be considered to be either differential or non-differential. For example, exposure misclassification should be regarded as non-differential if the exposure classification error is similar for persons with and without disease. Likewise, misclassification of health status would be non-differential if the sensitivity and specificity of diagnoses were the same across exposure categories. The effect of non-differential misclassification of either exposure or health status is that relations between exposure and disease are usually underestimated. Thus, for example, the failure to detect a true contact dermatitis case due to beryllium in a study where exposure classification is equally erroneous for affected and unaffected workers is a case of 'noise in the system obscuring the signal'. On the other hand, misclassification that is differential can produce bias in either direction – toward over- or under-estimating effects. Thus, for example, in a study of mercury-related neurotoxicity, a more accurate exposure classification among affected than unaffected workers would produce an over-estimate of effect. In practice, one can seldom determine with any confidence whether misclassification is non-differential or differential. Generally, unless there is evidence to the contrary, it is most justifiable to assume that misclassification is non-differential because it is more likely that errors occur uniformly than in a systematic manner.

Health status classification is determined by diagnostic accuracy. Biases caused by differences in the quality of diagnoses can arise in cohort studies when the cohort has undergone more intensive medical scrutiny than an external comparison population. Diagnostic bias may also arise within a cohort if the most heavily exposed workers undergo more thorough medical evaluations than other workers. In general, however, differences in diagnostic accuracy between subgroups of a cohort, and hence biases, are less likely to occur in studies involving internal comparisons than those relying on external comparisons.

Misclassification of exposure is a pervasive concern in occupational epidemiology. The primary cause of exposure misclassification is inadequate or incomplete data on job histories or environmental exposure levels. Missing information includes not only data that cannot be retrieved or are truly absent (e.g., no monitoring had ever been performed), but also incomplete data on factors that affect exposure levels, such as changes in control measures and the use of personal protective equipment. This generalization applies to any industry- or community-based epidemiologic study. As mentioned earlier, exposure misclassification is generally non-differential with respect to health status. Thus, most observed associations will be biased toward observing no effect. It is possible to 'correct' observed associations statistically so as to take into account exposure misclassification by making assumptions about the sensitivity and specificity of exposure classification, and re-computing effect estimates. However, results that are corrected or adjusted for misclas-

sification should be reported along with, rather than instead of, the observed data, because the assumptions underlying the adjustments are only approximations of reality.

Inaccurate reporting of data by study subjects is another potential source of information bias. This is seldom an issue in cohort mortality or nested case-control studies because most or all of the data are obtained from recorded information rather than from subject interviews. On the other hand, health and exposure data are frequently obtained from subject interview in community-based case-control studies and cross-sectional studies. Faulty recall of exposures that is non-differential for diseased and healthy subjects (e.g., cases and controls) will tend to mask true associations, as discussed above. There are instances, however, when recall may be differential and the resulting biases will cause over-estimation of associations.

For example, it is possible that affected cases may have more reason to remember past exposures than healthy controls, in which case exposure classification would not be equivalent for the two groups. There is no one effective safeguard against reporting bias. Instead, investigators have tried a variety of approaches, including selecting as controls persons with other diseases presumed to be unrelated to the exposures of concern, asking unrelated questions to elicit patterns of over- or under-reporting, and, where possible, verifying self-reported health or exposure information against objective sources, such as employment personnel and medical records. Studies of diseases with cognitive impairment, of which Alzheimer's disease would be a prototype, pose challenges of obtaining valid interview data. Interviewing proxy respondents, typically spouses or offspring, may be required; in case-control studies, interviews of proxy respondents for controls, even when they have full cognitive capacity, is advisable in order to balance interview data quality.

Although subject interviews may be a source of bias in some instances, they are also one of the most valuable sources of direct information about exposure conditions and confounding factors. Workers can often provide much better insights into past working conditions than what can be gleaned from reviews of industrial hygiene and production records. In fact, information on the use of protective equipment is usually better determined from workers' self-reports than from other sources. The opportunity to collect data on lifestyle factors, one that seldom exists in strictly record-based investigations, is another decided advantage to worker interviews. The use of in-person interviews to obtain morbidity information has obvious clinical advantages.

Confounding

Biased results can be observed when the effects of the exposures under investigation cannot be disentangled from the effects of other, unmeasured variables. Confounding is thus defined as a mixing of effects of exposure with the effects of extraneous factors. Differences between exposed and comparisons groups in the distributions of age, gender,

race, and socioeconomic status may cause confounded results because these attributes are frequently related both to exposure and disease. The importance of these factors is widely acknowledged, and most epidemiologic studies include attempts to control confounding, in either the design or analysis phases.

In order for an extraneous factor to be a confounder, it must be associated with exposure and must be a risk factor for the disease under study. The second criterion implies that the confounder must be capable of inducing or contributing to disease etiology in the absence of the occupational exposure of concern. For example, cigarette smoke can cause lung cancer in the absence of asbestos, radon, or any other environmental lung carcinogen. A final requirement for confounding is that the suspected confounder should not be an intermediate step in the causal pathway of exposure leading to disease. Thus, for example, it would be inappropriate to consider impaired ventilatory capacity as a confounder in a study of coal dust and pulmonary disability.

There are several epidemiologic approaches to control (eliminate or minimize) confounding. It is always valuable to examine associations between the potential confounder(s) and the exposure(s) of interest. Weak or absent correlations of confounders and study exposures offer reassurance that confounding is likely to be minimal. In the semen quality study of lead smelter workers,¹¹ the distribution of age, smoking, alcohol use, and histories of delayed fertility and fertility consultation among subgroups of workers stratified by blood level was compared. Age was unrelated to exposure, whereas the other factors were either positively or negatively associated with exposure (Table 6.16). Subsequent analyses took these factors into account in the analysis. In addition, blood measurements of metals other than lead, such as zinc, cadmium, and thallium, enabled control in the analysis.¹¹

Control of confounding may be accomplished by limiting study subjects to persons who have identical histories of exposure to the putative confounder. For example, studies of indoor radon and environmental tobacco smoke have intentionally focused on persons who were never active cigarette smokers. However, restrictions of this type will preclude opportunities to examine interactions among causal factors, e.g., active smoking and radon on lung cancer risks. Often, control of confounding is attempted

	Blood lead concentration (µg/dL)			
	<15	15–24	25–39	≥40
No. workers	32	46	29	12
Age (mean)	41.4	38.2	40.7	41.8
Smokers (%)	12.5	13.0	6.9	33.3
≥10 Alcoholic beverages per week (%)	15.6	10.9	24.1	33.3
Delayed pregnancy (%)	18.5	18.6	15.4	8.3
Sought fertility consultation (%)	14.8	9.3	7.7	8.3

* Unable to achieve pregnancy with partner after trying ≥1 year.

Table 6.16 Characteristics of Canadian lead smelter workers who provided semen samples, by blood lead level

by statistical correction of the observed results, with corrections made for imbalances in the distributions of the confounder between study and comparison groups. Age adjustment is a well-known approach to correct results for age differences among exposure levels. This type of direct statistical adjustment requires that data on the confounder are available in sufficient detail for use in the analysis. By way of illustration, consider the data in Table 6.17 from a community-based case-control study of lung cancer and occupation in Germany.¹⁴ Relative risks for both unadjusted (crude) and adjusted smoking and asbestos exposure were computed for various occupational groupings. Fairly small differences between the two sets of results indicate that smoking and asbestos were not serious confounders in this study.

When there are no available data on smoking or other potential confounders, as is typically the case in many industry-based studies, then indirect methods of control can be used. The most commonly used technique is to estimate the extent of confounding that would be required for the observed effects to be attributable solely to confounding. This requires assuming a level of risk associated with the confounder, in the absence of the exposure of interest, and computing hypothetical values of effect estimates for a range of distributions of the confounder across exposure categories. The data in Table 6.18 illustrate this method.¹⁵ In this hypothetical example, lung cancer incidence is compared between an occupational cohort and a national reference population. The prevalence of smoking in the reference population is given as 50% non-smokers, 40%

moderate smokers, and 10% heavy smokers, and the corresponding relative risk are, respectively 1, 10, and 20. There will be no spurious excess or deficit in the observed relative risk among the cohort when it has the same smoking distribution as the reference population, whereas departures from this distribution will create biased relative risk estimates.

It is worth noting that a very skewed distribution of smoking, weighted toward more heavy smokers in the cohort than the reference population, is required to produce a relative risk as high as 2, which is merely an artifact of confounding. This approach is considered an indirect method of control of confounding because, unlike explicit adjustment procedures that make use of available data, this method is based on assumed associations of the confounder with exposure and disease risk. Ordinarily, direct adjustment is preferable to an indirect assessment of confounding, provided that the data on the confounder(s) are sufficiently complete and valid. The indirect method offers a convenient alternative when data quality is inadequate, to assess the potential impact of bias.

In some studies, factors other than age, gender, race or smoking can be considered as potential confounders, and their control can be accomplished with the same methods outlined above. Previous employment in hazardous industries and occupations, like smoking, is often of concern in industry-based studies. Additionally, one may want to isolate the hazardous effects of a single agent in a multi-exposure environment, in which case each exposure is considered in turn while treating the other exposures as confounders. For example, one might try to control for the effects of xylene when examining the neurotoxic effects of toluene in a study of painters. Although in principle, control of confounding from concurrent workplace exposures should be as attainable as control of lifestyle confounding, strong and sometimes complex correlations among many chemicals will complicate the process. Thus, for example, exposures to multiple chemicals may be so highly inter-correlated in an industry that control of mutual confounding may be impossible. In such instances, the best that can be done is to determine the crude (potentially confounded) effects of each exposure, and to make qualitative judgments as to which associations are most meaningful.

Occupational group	Relative risk	
	Crude	Adjusted*
Farmer, agricultural worker	1.26	1.31
Miner, quarryman	1.92	1.65
Bricklayer, carpenter	1.65	1.33
Unskilled worker	1.60	1.36
Stationary engine, heavy equipment operator	2.35	1.78
Administrative, clerical work	0.58	0.65
Medical, dental, veterinary	0.50	0.60

* Adjusted for smoking and asbestos exposure.

Table 6.17 Crude and adjusted relative risks from a community-based case-control study of lung cancer and occupations in Germany

Population fraction (%)			
Non-smokers	Moderate smokers*	Heavy smokers†	Bias in relative risk
60	35	5	0.78
50	40	10	1.00
40	45	15	1.22
30	50	20	1.43
0	65	35	2.08

* Assumed relative risk of 10 for moderate smokers.
† Assumed relative risk of 20 for heavy smokers.

ANALYZING EPIDEMIOLOGIC DATA

In occupational and environmental epidemiology, we are interested in the effects of exposures on the probability of the outcome, (e.g., the dose-response association). In this section, we briefly describe some general principles of data analysis. A more thorough treatment of statistical analysis methods can be found in other texts, such as Rothman and Greenland.¹⁶

Statistical methods are used to make inferences, based on a sample of subjects, about the magnitude of the true association between an exposure and a health outcome. All statistical methods, from the simple comparison of means to multivariate modeling, are based on probability

models. These models describe the probability of observing a particular health event or a particular value of a physiologic measurement. When the outcome is a health event, such as disease diagnosis, the exposure effect is usually expressed as a ratio of risks or rates, and is referred to as a relative risk. When the outcome is a physiologic measurement, such as pulmonary function or nerve conduction velocity, the effect of exposure is typically measured by the change in response per unit change in exposure.

Estimating relative risks and confidence levels

There are several reasons why the relative risk or the slope of a dose-response curve computed from the analysis of observed data may not be equal to the true underlying risk. We have discussed how confounding and other forms of bias can distort epidemiologic data so that the observed relative risk is misleading. However, even in the absence of confounding or other bias, risk may be imprecisely estimated because of statistical error. Two primary sources contribute to statistical error: errors in the measurement of study variables and sampling variability.

Sampling variability measures the spread of results derived from hypothetical repetitions of a study, each based on a random sample of the same size, from the same population (workforce or community), under identical conditions. The larger the sample size of the study, the less variability there will be among replicate samples. Sampling variability is reflected in the width of the confidence interval around the relative risk. The larger the study, the smaller the sampling variability, and the narrower the confidence intervals. As described further below, evaluating sampling variability is important in interpreting the results of an epidemiologic study. To attribute the findings of a small study to chance raises concerns about large sampling variability.

Hypothesis testing and study power

Inference is a procedure by which observed data from a sample are used to estimate a population parameter or to test a formal hypothesis about the value of that parameter. Hypothesis testing relies on a rigorous algorithm for deciding whether to reject the null hypothesis in favor of a specified alternative. The algorithm involves the calculation of a test statistic based on the data and a probability value (*P*-value) derived from the assumed probability distribution of the test statistic. The *P*-value is the probability of observing data as far from the null as was actually observed, given that the null hypothesis is true.

For example, a null hypothesis is typically stated as: there is no association between the exposure and the health outcome, i.e., the relative risk is 1.0. The analysis of epidemiologic data will result in an estimate of the relative risk and a *P*-value. If the data are inconsistent with the null hypothesis, the estimated relative risk will be different from the null value, the *P*-value will be small, and one will be inclined to reject the null hypothesis; an association

between exposure and outcome is therefore inferred. Although rigid rules for rejecting a null hypothesis, such as $P < 0.05$, are ill-advised, the *P*-value does provide a measure of the robustness of the inference. *P*-values are closely related to confidence intervals but are not entirely redundant. A *P*-value less than 0.05 is equivalent to a 95% confidence interval that excludes the value of relative risk under the null hypothesis (typically 1.0). Thus, one can formally test a hypothesis on the basis of a confidence interval. One cannot, however, distinguish a *P*-value of 0.10 (indicating data fairly consistent with the null) from a *P*-value of 0.30 (data more consistent with the null) based on a confidence interval alone.

The statistical power of a study is also related to the concept of a power. Power is the probability of rejecting the null hypothesis when it is false. In a small study, the estimated relative risk would need to be quite far from 1.0 in order to result in a *P*-value small enough to reject the null. Conversely, in a large study, the difference between the estimate and the null could be trivial and still result in a 'statistically significant' difference. The larger the sample size, the greater the statistical power. Of course, statistical significance is not necessarily synonymous with clinical or public health significance.

Building regression models

The estimation of an exposure effect often involves consideration of several extraneous risk factors that may be acting as confounders. For example, in the German community-based case-control study of occupations and lung cancer¹⁴ (Table 6.17), relative risk estimates were presented with and without adjustment for smoking and asbestos exposure. One way to control confounding in the analysis is to perform a separate exposure/outcome analysis for each level of the confounder (e.g., by age category). However, stratified analysis becomes a less effective way to address confounding as the number of confounders increases because the size of each stratum decreases. The decrease in sample size of each stratum increases sampling variability, and thus reduces the statistical power to identify underlying risk.

To address the problem of sparse data created by multiple confounders, epidemiologic studies commonly use multiple regression models to derive adjusted risk estimates. Regression models smooth across sparse strata by making statistical assumptions about the probability distribution of the outcome and the generic shape of the exposure-response curve.

A regression model is a function of the health outcome, *Y*, on a set of variables, X_i , that includes the primary exposure and potential confounders. For an outcome measured as a continuous variable, like pulmonary function, a linear regression model has the following general form:

$$E(Y) = \beta_0 + \beta_1 X_1 + \beta_2 X_2 + \dots + \beta_k X_k$$

where $E(Y)$ is the expected value, or mean value, of the outcome *Y* for every combination of specific values of the *X* variables. $E(Y)$ can also be written as $E(Y|X)$ to reflect the

fact that the value of $E(Y)$ is dependent on the values of X . When the outcome of an epidemiologic model is risk of a binary event, such as disease or cause of death, $E(Y)$ can be replaced by $R(x)$, or average risk. Analogous regression models can also be defined for modeling incidence rates.

The β coefficients of the X values are the regression parameters that specify the particular exposure–response curves that define the relationships. Each β can be interpreted as a slope, i.e., the change in Y , or change in risk or rate, associated with a unit change in a particular X variable. The β coefficient of the exposure of interest, is the primary exposure–response parameter. Because confounders are also present in the model, the estimate of the exposure effect has been adjusted for confounding.

Model specification concerns the generic shape of the curve defined by the form of the regression model. The most common forms of epidemiologic risk models are linear and exponential. The exponential risk model is linear on the logarithmic scale, and can be written either by taking an exponential function of the right-hand side of the model as follows:

$$R(x) = \exp(\beta_0 + \beta_1 X_1 + \beta_2 X_2 + \dots + \beta_k X_k)$$

or equivalently as:

$$\text{Log}(R(x)) = \beta_0 + \beta_1 X_1 + \beta_2 X_2 + \dots + \beta_k X_k$$

Once the form of the model has been selected, the model is ‘fit’ to the data and the parameters are estimated. Model fitting includes decisions about which variables need to be included in the model, as well as the calculation of the parameter estimates and their confidence intervals. The statistical method used to estimate regression parameters is called maximum likelihood. This method is based on the concept that the best estimates of the β parameters are those values that make the observed data most likely to have occurred under the structural constraints of the model.

Fitting models requires judgments about what variables to include. These judgments will affect the findings of a study because parameter estimates can change when other variables are added to or removed from the model. In fact, the presence of confounding is generally evaluated by comparing the β coefficient for exposure between models with and without the potential confounder included. A change in the magnitude of the exposure–response parameter estimate in the presence of an extraneous variable is evidence that confounding exists and needs to be controlled.

INTERPRETING EPIDEMIOLOGIC DATA

In one form or another, two related questions emerge from a review of epidemiologic findings. (1) Is the agent(s) hazardous? (2) If so, is there a safe level of exposure below which impaired health is unlikely to occur? These questions, or variations thereof, will inevitably be asked by

workers, employers, epidemiologists, clinicians, exposure assessment professionals, policy makers, lawyers, and the general public. Answers to these questions cannot usually be obtained from the results of a single study, as most studies can only add evidence to a body of information. Although there are some dramatic examples where causality is unambiguous, most studies fall far short of providing definitive data on disease risk or safe exposure levels. Therefore, the reviewer’s task in making sense of data is to evaluate the results from a single study, and to place them in context with findings from other epidemiologic, and at times, toxicologic studies of the same or related issues.

Some general guidelines for interpreting data and assessing causality can be stated, although these are by no means formal rules nor are they offered as a comprehensive list. Standard criteria for assessing causal associations in epidemiology include some necessary as well as some merely desirable conditions that, when met, improve confidence in interpreting data. One necessary condition is that exposure precedes disease. Desirable, although not always demonstrable, conditions are the strength and specificity of the association, evidence for a dose–response relation, biologic plausibility, absence of bias, internal consistency of the study findings, and consistency of results with prior epidemiologic and toxicologic research. Statistical significance (P -values) can aid interpretation, as discussed earlier. However, statistical significance can be a misleading concept in non-experimental research, and some have argued that there is no place for ‘ P -value testing’ in epidemiology. Too often, there has been a failure to appreciate that the nominal level of ‘significance’ (customarily, $P < 0.05$) is an arbitrary numerical boundary. Most epidemiologic studies generate large data sets, and hence large numbers of statistical evaluations. Cohort studies may typically involve assessments of risks for some 30 to 60 diseases. Likewise, case-control studies often include examinations of the effects of numerous exposures.

The number of statistical evaluations will also increase with data stratification, such that a given study may engender literally hundreds of comparisons. In such instances, the chance of detecting statistically significant results will increase with the number of statistical associations evaluated. Corrections of P -values for multiple tests have been proposed by some authors, although it is never clear just how many hypotheses are actually tested in a given study, or whether all tests of hypotheses should be treated equivalently. For example, in a study of risks related to asbestos, statistical testing (by P -value estimation or calculation of confidence intervals) may be conducted for established associations, such as with lung cancer, as well as for relations that have less support, such as for atherosclerotic vascular disease. The prior expectations for these two outcomes would be clearly different: a much smaller P -value for the lung cancer relative risk would be anticipated.

For these reasons, corrections for multiple testing have gone out of favor in observational epidemiology research. In general, statistical significance testing alone provides little guidance in discriminating between true and spurious associations. Similar cautions can be invoked for interpret-

ing confidence intervals. Like the nominal level of statistical significance, the choice of confidence interval width (90%, 95%, etc.) as a benchmark is arbitrary. Correcting confidence interval widths for multiple effect estimation would suffer the same ambiguities as correcting *P*-values for multiple testing. Thus, decision making regarding causation should emphasize other considerations, especially consistency with prior epidemiologic and experimental research, biologic coherence, and clinical interpretability.

Detecting the effects, presumably beneficial, of interventions, such as a reduction of exposure levels on disease and injury risks, can seldom be done in any one epidemiologic study, unless the study spans a very long time period. In contrast, the effects of interventions imposed to reduce the incidence or severity of acute health effects are usually more readily demonstrable. However, even when an apparent reduction in risk has been observed, alternative explanations, such as susceptible individuals leaving the workforce, should be considered before accepting the results at face value.

An example where there would be little doubt concerning a causal association is the cohort study of bone sarcoma among female radium dial painters¹⁷ summarized in Table 6.19. The rarity of the disease, the biologic plausibility of the association between a radioactive bone-seeking compound and bone malignancy, and obvious antecedent/consequent relation between the practice of ingesting radium and the occurrence of bone sarcoma, the strong dose-response trend, and the small chance that bias, especially confounding, distorted the findings, all argue in favor of causation.

Most epidemiologic studies, however, do not reach such clear-cut conclusions as the radium dial painters study. The following examples illustrate some of the complexities that arise when interpreting epidemiologic findings. Consider the data on leukemia and multiple myeloma in Table 6.20 derived from a historical cohort mortality study

of cancer among UK military personnel exposed to atomic weapons testing.¹⁸ Two cohorts were identified: the exposed group consisted of approximately 22,000 males who had participated in testing activities, and a comparison group including an equal number of military personnel in service at the same times as the exposed cohort, but not assigned to atomic weapons test areas. The two groups were matched according to gender, age, branch of armed service, and military rank. Mortality in both groups was compared against prevailing rates for UK males.

Two conflicting interpretations can be drawn from these data. Based strictly on comparisons with mortality rates for UK males, it would appear that there were no excesses of leukemia and multiple myeloma in the exposed group. However, direct comparisons between the two groups would support a conclusion of increased risks for both diseases (nearly two-fold for leukemia) in the exposed military personnel. The interpretation of the data depends principally on what is regarded as the more suitable reference population, the UK general population or the non-exposed military personnel. Insofar as the latter were probably more similar to the exposed group in regard to socioeconomic factors, access to medical care, and hence diagnostic certainty, comparisons with the non-exposed cohort should be more valid than general population comparisons. As such, the data are consistent with associations between leukemia and multiple myeloma and exposure to atmospheric nuclear tests, although other explanations, including chance and an unexplained deficit of hematologic malignancies in the non-exposed military personnel, could still be considered.

Reducing bias from confounding is necessary to ensure valid findings. Accordingly, epidemiologists pay substantial attention to minimizing confounding. Studies that do not take into account potential confounding factors in the design or analysis may be viewed with some degree of skepticism, although it is important to realize that very strong associations (e.g., relative risks of 2 and greater) that are based on reasonably stable statistical estimates are very unlikely to be spurious. This point should be evident by referring to Table 6.18, which shows that even a very potent extraneous risk factor (smoking in the case of lung cancer) would have to be highly related to the exposure under study in order to create a severe confounding bias. On the other hand, control of confounding becomes a substantially more important issue when there are relatively weak associations (relative risks of 1.5 and less) or the observed effects, irrespective of magnitude, are based on small numbers.

Factors that may be confounders should also be considered as possible modifiers of the hazards of occupational and environmental exposures. Thus, there may be synergistic (or in some cases, antagonistic) effects between various occupational or environmental exposures and host factors, including confounders, on disease risk. An illustration is provided from a case-control study of lung cancer and sugar cane farming in India.¹⁹ As shown in Table 6.21, the trend of lung cancer risk with cigarette smoking was considerably stronger among persons with a history of

Dose (μCi)	Cases	Person-yr	Rate per 1000 person-yr
0-99	0	29,936	0
100-249	2	1164	1.72
250-499	9	1249	7.21
500-999	8	610	13.1
1000-2499	15	419	36.8
≥2500	4	219	18.3

sugar cane farming, and there was a nearly six-fold elevated risk in persons who farmed sugar cane and had the largest pack-years of smoking compared with non-farmers who never smoked. However, interactions among workplace exposures on disease and injury risks can be difficult to detect in many instances, particularly when exposures are strongly intercorrelated.

Consistency of an association can be an elusive concept in epidemiologic studies. Consistency can be considered as internal to a particular study, or in reference to external information, such as data from prior research. Internal consistency would be indicated when exposure is equally potent, or at least qualitatively similar in effect, for various members of the study population (e.g., for males and females). Of course, departure from homogeneity of effect may be related to dose–effect relations, in which case an argument for causation is strengthened. Alternatively, differences in effect that are not dose-dependent may have some other plausible explanation, such as the requirement for a potentiating factor (e.g., alcohol consumption and hepatotoxicity).

However, there are no ready explanations for heterogeneity of effect in many instances. As an illustration, consider the data in Table 6.22 from a community-based case-control study of primary liver cancer. The data are both internally consistent and inconsistent; the results do not vary depending on the control group considered, stomach cancer or myocardial infarction cases, yet the effects for males and females are in opposite directions. There are numerous possible speculative explanations for the data, many of which were considered by the investigators. These include unmeasured confounding (e.g., hepatitis B or C infection), differential exposure misclassification, or true gender differences in susceptibility. The possibility of different types of solvent exposures among men and women, namely a higher prevalence of chlorinated solvent exposures (e.g., perchloroethylene) among women than men, is also a candidate explanation. This illustrates the importance of seeking exposure information for specific substances. Regrettably, limited exposure data in many epidemiologic studies only permit insights into patterns of

associations with broad categories or agents, rather than with specific substances.

Consistency of findings across studies is also an important criterion for assessing causation. In deciding whether or not an association exists between an occupational exposure and a particular health outcome, one ultimately synthesizes information from the available literature. This can be an informal process, in which the reviewer determines which evidence is most suitable for the question at hand. A more formal approach, known as ‘meta-analysis,’ involves weighting the data from multiple studies to derive a single best estimate of the strength of association. Approaches for ‘meta-analysis’ have been developed for this purpose.²⁰

Epidemiologic data generally refer to groups, but can also contribute significantly to clinical determinations of risks and causal attribution for individuals, provided that the strengths and limitations of the research that generates the data are appreciated. Mutually reinforcing substantive and technical advances in epidemiology and clinical medicine should continue to facilitate the integration and interaction between both disciplines.

Chapter 7

Biologic Markers in Occupational and Environmental Medicine

Carmen J Marsit, Anthony D LaMontagne, Karl T Kelsey

INTRODUCTION

A biologic marker, or biomarker, is any substance, structure, or process that can be measured in the human body or human body products, and that may influence or predict disease.¹ Traditionally, in occupational medicine, biomarkers of exposure – or internal dose – have been used most frequently (e.g., lead in blood, cadmium in urine). Personal exposure to over 100 different chemicals in the workplace can be assessed in biologic media.² In addition to exposure or dose, biomarkers can also be used to assess biologic effects or to identify susceptibilities to the effects of specific exposures. Markers of susceptibility are the newest and most rapidly expanding class of biomarkers in occupational medicine, and in contrast to most biomarkers of exposure and effect, these are typically inherited or acquired genetic properties of a given individual.³

In occupational and environmental medical practice, biomarkers of exposure and effect related to hazardous substance exposures are most widely used, though biomarkers of dietary intake, tobacco smoke exposure, biologic agents, and a wide range of other agents are also important. Biomarkers of susceptibility, though the most active area of biomarker research currently, are rarely used in medical practice due to low or unknown predictive value of actual disease risk under common exposure conditions, as well as social and ethical problems raised by their use.⁴

This chapter will focus on biomarkers relevant to hazardous exposures and consequent risks and their use in occupational and environmental medicine. Interested readers are referred to other monographs on the rapidly evolving application of biomarkers in cancer and other chronic disease epidemiology contexts.^{1,5} However they are used, it is critical to understand the methodology behind the sample collection and the methods involved in generation of the values reported as well as the methods used for determination of the reference values.

Environmental vs biologic monitoring

Used in conjunction with environmental monitoring, biologic monitoring can help to more accurately determine individual levels of exposure. Environmental monitoring measures the ambient exposure of a chemical through sampling of the air or surfaces at the workplace.

This ambient monitoring has been used for many years and therefore accurate methods of sampling and detection exist for numerous exposures (see Chapter 4.1). Environmental monitoring can be useful to detect acute exposures to dangerous chemicals, to identify emission sources, to evaluate engineering control measures, to prevent overexposure, and to provide a more accurate monitoring of chemicals that demonstrate their effect at the site of contact such as skin, eye, or respiratory tract irritants. Exposure limits used in environmental monitoring have been established for approximately 700 potentially hazardous chemicals.

Interestingly, biologic levels of exposure predicted by modeling from environmental exposure levels often vary greatly from actual biomarker values reported upon testing markers. Such variability can be accounted for by the biologic and work practice variations between individuals. Table 7.1 summarizes the principal sources of this variability. All of these factors can greatly affect the biologic levels of a given chemical in individuals working in an environment with a single environmental exposure level.

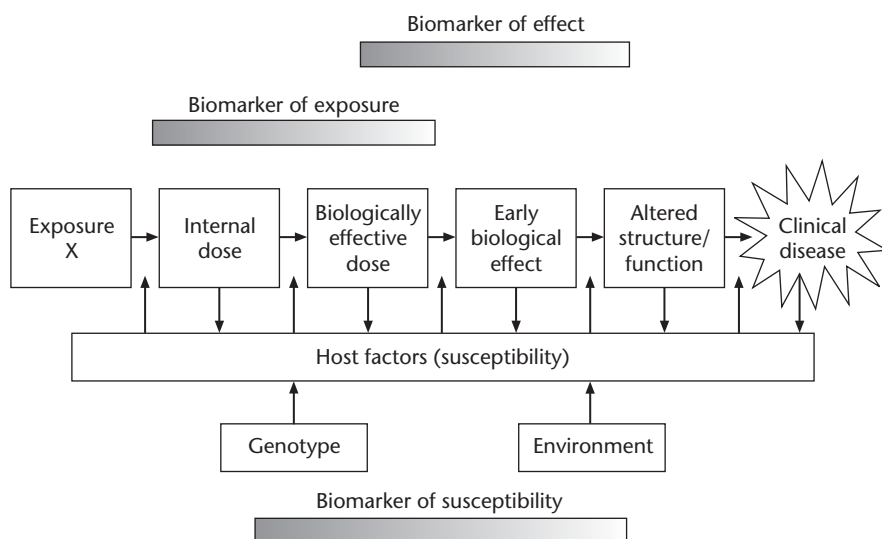

Also important to keep in mind is the fact that use of biomarkers will include measurements that reflect all sources of exposure, including occupational as well as background exposure from dietary habits, residence, and other lifestyle factors.

Due to the limitations as well as the strengths of both environmental and biologic monitoring, it is important that these two approaches be considered complementary and both important parts of a total occupational health program.

Biologic monitoring program

Biologic monitoring poses many challenges as well as advantages. The media being tested – blood, urine, or exhaled air – are complex mixtures that require powerful analytical tools to separate and quantitate the various biomarkers in question. Timing of sampling is also critical, as some chemicals may be quickly metabolized or excreted from the body, while others may be present for longer periods. Selection of the appropriate biomarker is also a key issue, as it must be specific to the chemical exposure and serve as an accurate measure of the exposure.

Point of variability	Potential mechanism
Route of exposure	Differences in uptake between respiratory and skin routes and differences in exposure routes between individuals
Respiration rate	Increased respiratory rate can significantly affect absorption
Metabolic and excretion rate	Normal variation in hepatic and renal function can account for individual variation
Genetic	Polymorphisms in metabolic enzymes may change their level of function
Adipose tissue level	Increased adipose tissue levels may allow greater accumulation of lipid-soluble compounds

Table 7.1 Sources of biologic variability in biomarker assessment**Figure 7.1:** Various interactions involved as an exposure progresses to clinical manifestation of disease. Adapted from Van Damme K, Casteleyn L, Heseltine E et al. Individual susceptibility and prevention of occupational disease: scientific and ethical issues. *J Occup Environ Med* 1995;37:91–9.

Biomarkers

Selection of an appropriate biomarker depends on many variables, including those referred to in Table 7.1. In assessing the biologic level of a chemical in the human body, there needs to be a thorough understanding of the route and level of absorption of the chemical, of the chemical properties of the substance, which can account for differences in the absorption and distribution (i.e. a lipophilic chemical is more likely to deposit in high lipid regions of the body such as fat or nerve tissue, while hydrophilic chemicals remain in the blood stream and visceral organs), as well as of the metabolism of the chemical and its excretion. Figure 7.1 schematically represents the various interactions involved as an exposure progresses to clinical manifestation of disease. Biomarkers have been classified into biomarkers of exposure, of effect, and of susceptibility, but, due to the complex interactions and biology of the progression from exposure to disease, the lines are somewhat blurred. A thorough knowledge of the agent in question can help to determine which type of biomarker, or combination of biomarkers, is most appropriate for the environment in question.

Biomarkers of exposure

A biomarker of exposure measures the exposure to a chemical independent of route of exposure. Table 7.2 discusses the important characteristics that define a useful biomarker of exposure. This type of biomarker can be further subdivided

into a biomarker of internal dose or a biomarker of effective dose.

The biomarker of internal dose reflects the amount of the chemical in question or its metabolite present in the biologic sample. These levels can be measured directly through analytical methods from urine, blood, exhaled air, feces, hair, nails, saliva, or breast milk. An example would be a measurement of S-phenylmercapturic acid or t,t-muconic acid levels in urine to assess benzene exposure.⁶ New developments now allow for assessment of organ or body exposure in vivo directly at the site of accumulation for selected agents. These methods utilize imaging techniques such as neutron activation that can identify cadmium burden of the kidney and x-ray fluorescence, which can evaluate lead content in bones. The biomarker of effective dose is used to directly estimate the exposure to the chemical in question through its interaction with the target site.⁷ Such a biomarker is the measurement of carboxyhemoglobin used to assess carbon monoxide exposure.

For the practicing occupational health and safety person on the shop floor (e.g., industrial hygienist or safety officer), air monitoring would be preferred if the goal is representative exposure assessment and exposure control with limited expense (preventative, group-level perspective). On the other hand, for the occupational medicine provider (e.g., occupational health nurse or physician), the ability to establish exposure or biologic effects for an individual, even in the absence of environmental monitoring data, is invaluable. To date relatively few

Characteristic	Notes
Correlation with exposure	Limits of quantitation and correlation must exist at exposure levels in industrial setting ²²
Correlation with target tissue dose	Sampled media must reflect target tissue exposure, as target tissue itself often cannot be sampled ²²⁻²⁵
Appearance is reversible	Helps to distinguish industrial exposure from background exposures. Also demonstrates effectiveness of exposure control methods, ^{22,23,26,31}
Influence of confounding and modifying factors is well characterized	Thorough knowledge of the physical, chemical, and metabolic properties of the chemicals and host factors response is needed for an accurate analysis ²⁵
Suitable for application in the workplace	Sampling methods should be minimally invasive, pose minimal risk, and be as convenient to workers as possible ²⁸⁻²⁹

Table 7.2 Characteristics of useful biomarkers of exposure¹²

biomarkers of exposure, such as blood lead levels or urinary excretion of certain metals, are routinely used in clinical practice.

Biomarkers of effect

These biomarkers measure reversible biochemical changes that occur after receipt of an internal dose. Although these are effects of exposure, they are less than the degree of change associated with injury or irreversible pathological effect and should not be considered health effects per se. In other words, these markers may predict adverse effects, yet they must be distinguished from tests that monitor true pathological effects. Some examples include the inhibition of specific enzymes by various chemicals (e.g., δ -aminolavulinic acid dehydratase which is inhibited by lead), or the production of antibodies to low molecular weight molecules. The measurement of protein or DNA adduct burden which can be correlated to aromatic amine or polycyclic aromatic hydrocarbon (PAH) levels in the blood and can reflect intensity of exposure as well as effective dose. Studies continue to provide new markers, such as presence of various proteins and enzymes in urine due to nephrotoxic chemicals, but the debate continues as to whether or not such markers should be considered adverse effects or rather markers of developing health consequences (thus questioning their role in workplace monitoring).

Biomarkers of susceptibility

Biomarkers of susceptibility provide an indication of an inherent or acquired ability of an organism to respond to the challenge of exposure to a specific xenobiotic substance.⁸ In other words, these biomarkers demonstrate the possible differences between individuals in metabolism, DNA repair mechanisms, immune responsiveness, or alterations of oncogenes' and tumor suppressor genes' activities, thereby providing an idea of how an individual will respond when confronted with an exposure. Such bio-markers may be able to identify 'susceptible' individuals who, through impaired or altered enzymatic functioning, may react adversely at low exposures to effective doses.⁹

Biomarkers that reflect differences in metabolism can be measured by administration of a test drug and observation of its clearance from the body. Alternatively, the genotype

of an individual can be determined using DNA collected from circulating lymphocytes in a blood sample. Using modern molecular biologic techniques, including the polymerase chain reaction (PCR), the polymorphisms, or genetic differences, of an individual, can be determined for various enzymes known to metabolize specific chemicals. Theoretically that individual's genotype could then be compared to a database of known polymorphisms to determine to what extent he or she can metabolize certain chemicals, thereby potentially determining how susceptible the individual is to an exposure and to what level he or she can be safely exposed.

Ideally, this type of biomarker could be used preventatively to assess possible risk. However, in reality most diseases are the result of multigenetic processes and thus risk of disease is likely related to complex interaction between exposure and multiple genetic markers. The genes encoding enzymes of the cytochrome P450 family, the glutathione S-transferases, and the N-acetyltransferases are some of the most widely studied and best documented polymorphic biomarkers, as these enzymes are involved in the early metabolic stages of various chemicals. They have also been shown to have polymorphisms, which lead to decreased activity and thus altered susceptibility to pathological disease.

Perhaps the most illustrative example of biomarkers of susceptibility involves the use of genetic testing for susceptibility to beryllium exposure. Particular HLA types may be important for an individual to mount an immunologic response to beryllium exposure.^{10,11} Workers who have a particular HLA subtype have been shown to be more susceptible to the adverse effects of beryllium exposure. However, the allele specific risks and positive and negative predictive values of these tests remain unclear. Thus genetic testing currently is not recommended as part of a preplacement exam for workers exposed to beryllium. Genetic testing does not substitute for the mandate that exposures should be minimized such that all workers be protected from exposure-related harm.

INSTITUTING A BIOLOGIC MONITORING PROGRAM

Several key issues need to be addressed when instituting a biologic monitoring program, as such a program needs

1. Determinate must be present in an available biologic medium and should be suitable for sampling
2. The sampling method must be convenient and acceptable to the population being tested
3. The sampling method must produce representative and useful samples for analysis
4. A method of analysis of the biomarker must exist that is practical, accurate, and reproducible
5. A plan of action should be established for responding to aberrant results

Table 7.3 Criteria for choosing and implementing a biomarker

to produce meaningful results that can impact the safety of the working environment but be implemented in a convenient and cost-effective manner.¹² Table 7.3 lists conditions to be considered in choosing a biomarker and instituting its use in biologic monitoring. Considering these conditions can lead to the appropriate sampling and analysis conditions.

Sampling

In order to obtain accurate monitoring of exposures, the timing and appropriateness of sampling must be considered for each type of exposure. Chemicals that are rapidly cleared from the body may require more immediate sampling such as sampling during or at the end of a working shift, while those with longer residence times can be sampled more randomly.

The collection method may also play a key role in the accurate analysis of a biomarker. It is advisable to consult with the lab performing the analysis to determine appropriate sampling and storage conditions of samples. Inappropriate sampling containers may contaminate the sample or adsorb the sample, and improper storage can lead to deterioration of the analyte. Also, the appropriate preservatives (in urine or blood sampling) or anticoagulants (blood sampling) need to be added as directed by the analyzing lab.¹³

In some cases, specifically for chemicals that can accumulate in the body or for which there is substantial inter-individual variability, baseline testing may need to be performed. Examples of such exposures include cadmium, polychlorinated biphenyls (PCBs), and lead, which show bioaccumulation and pseudocholinesterase in plasma, which is highly variable between individuals.¹³

Most commonly, blood, urine, and exhaled air are used as the media for analysis. Hair and fingernails have also been used, but their utility is somewhat limited, while the use of adipose tissue has proven difficult for sample collection outside a clinical setting.

Blood

Blood serves as the transportation route for chemicals and their metabolites throughout the body, and therefore is often the most accurate medium for biomarker sampling. On the other hand, volatile compounds and substances

with short half-times should not be determined with blood sampling. One advantage of blood monitoring is that the composition of blood varies little between individuals and thus correction for individual differences is not usually necessary. Also, obtaining specimens is relatively straightforward and can be accomplished with little risk of contamination, but must only be done by trained individuals, as it is an invasive procedure. The dynamic equilibrium of the analyte within various parts of the body must also be considered, as the concentration of the chemical can vary depending on route of exposure, metabolism timing and efficiency, and excretion.¹⁴

Urine

Urine sampling can be the easiest method of body fluid sampling, and can be used for detection of various hydrophilic chemicals, metals, and metabolites. A 24-hour urine collection provides the most accurate assessment, as this will eliminate error based on urine output and concentration. If 24-hour screens are impractical and spot checks are to be used, corrections must be made dependent on the concentration, which can be done by adjusting levels to a standardized specific gravity or urine creatinine level. Urine levels of chemicals that are targeted to the kidney (such as cadmium) may not reflect an accurate level of exposure, and urine sampling would be inappropriate for workers with advanced renal disease.¹⁵

Exhaled air

Exhaled air monitoring has limited use for determining levels of volatile chemicals. The sampling involves breathing into a plastic bag, which is then exhausted through a charcoal filter onto which the analyte is adsorbed and can then be analyzed. This approach is not useful for aerosols, or for gases or vapors that decompose upon contact with body tissues or that are highly water soluble (such as alcohols). Workers with emphysema should not be monitored with exhaled air sampling.¹⁶

Analysis

The analysis of the biomarker in the sample media needs to be performed by a qualified laboratory. Table 7.4 lists some criteria to be considered when choosing the laboratory for analysis. National and international certification and quality assurance programs continue to be sponsored by the United States government as well as the World Health Organization. In 1992, the Clinical Laboratory Improvement Amendments (CLIA) guidelines were introduced and apply to biologic monitoring data. These guidelines include strict management of sampling, transportation, handling, storage, and evaluation of specimens including accurate analytical quality assurance and method verification.

The laboratory should provide all information on the sample collection method, containers, and sources of contamination. They may also be able to offer 'back-

ground' and 'normal' levels which they have gathered from unexposed populations, although it is important to the laboratory's definition of 'normal' (i.e. is it a normal level for workers or for non-occupational exposures?). Some laboratories may provide sample collection equipment and service and may deliver and pick up samples. These types of considerations may affect the convenience and cost of instituting a biologic monitoring program.

Interpretation

The analytical result obtained from the biologic monitoring program indicated the level of a biomarker in the given biologic media at the time of sampling. Again, thorough understanding of the biologic response of the human body to the agent is necessary to extrapolate these data to understand exposure. Further, the sensitivity and

specificity of the biomarker should be well established. Moreover, use of the biomarker assumes that there is a quantitative relationship between biomarker level and exposure, or at least that presence of a biomarker above its background level indicates an exposure.¹⁷

In order for judgments to be made about the exposure levels indicated through biologic monitoring, a series of reference values must be utilized. These values can help an environmental health clinician in consultation with industrial hygienists to determine whether or not action needs to be taken because of biologic exposure levels being reported in the workplace population. Various values have been reported due to a variety of methods used to derive these values. Table 7.5 discusses the various biologic exposure indices as well as their derivation and possible usage. A thorough understanding of these values and their derivations is necessary for their correct interpretation. Generally, the Biologischer Arbeitsstoff-Toleranz-Wert (BAT) and exposure equivalents for carcinogenic materials (EKA) values are based on health consequences and are generally used by physicians while the biologic exposure indices (BEI) as well as the biomonitoring action level (BAL) are based on external exposure and are considered tools of industrial hygiene.¹⁸ Therefore, if a worker's biologic exposure persistently exceeds the BEI value, this may not indicate potential health consequences, but if exposure results from a group of workers consistently exceed the BEI, further investigation and possible corrective action may be needed.¹⁹

Analytical accuracy	Must be assessed through intra- and inter-laboratory QA
Convenience	Processing methods should rely on convenient sampling and sample preparations on site
Turnaround time	Timely indications of possible exposures so that corrective actions can be quickly undertaken
Cost	Cannot be prohibitive

Table 7.4 Characteristics of analysis lab

Values index	Organization	Derivation	Usage
Biologic exposure indices (BEI)	American Conference of Governmental Hygienists (ACGIH)	Internal dose arising from inhalation exposure at the TLV concentration* ³⁰	Represents the highest acceptable internal dose that will not typically result in future health consequences
Biologischer Arbeitsstoff-Toleranz-Wert (BAT)	German independent scientists of various disciplines	Maximal permissible quantity of a chemical compound, its metabolites, or any deviation from the norm of biological parameters induced by these substances based on exposed human beings ²⁷	Provides an absolute ceiling value for healthy individuals not to be exceeded [†]
Exposure equivalents for carcinogenic materials (EKA)	German independent scientists of various disciplines	Internal dose arising from inhalation exposure alone for carcinogenic materials without BAT value ⁶	Relates external exposure to internal dose, but does not imply any safe limit
Biomonitoring action level (BAL)	Finnish Institute of Occupational Health (FIOH)	Some based on health outcomes. Others extrapolated from external exposure limits or based on good working habits ³¹	Provide levels that even if at or below for an entire lifetime, no negative health consequences would be expected
Human biologic monitoring (HBM) values	Commission on Human Biological Monitoring (Germany)	Based on human toxicologic and epidemiologic evidence ²⁰	HBM I – level at or below which there is no adverse effect. HBM II – level at or above for which there is increased risk for adverse health effects in susceptible individuals [‡]

* A small number of these values do not reflect this derivation and are derived based on levels which result in prevention of systemic health risk.
† No BAT value is given for carcinogenic substances as no value can be considered harmless.
‡ Reference values also exist which demonstrate the upper margin of the current background exposure level in a given population and can identify subjects at risk.

Table 7.5 Monitoring reference values for exposure biomarkers

Also important for consideration in interpretation of biologic monitoring data is the significance of background levels of exposure and the ability to distinguish this exposure from that associated with occupational exposure. Individuals can be exposed to a variety of chemicals depending on their residence, air quality in the home or work community, dietary habits, hobbies, and most importantly smoking habits, these exposures can affect the biologic levels observed in the tested population. Finally, it is important to note that the reference values, including the BEI and BAT, are for occupational exposure based on an average workday of exposure, and therefore do not apply to residential or other non-occupational sources of exposure.⁶ On the other hand, the HBM reference values can be utilized as warnings for increased exposure and for the potential of negative health consequences in susceptible populations who may require medical action to abrogate the exposure. These values vary depending on the age group and sex of the population being tested and are meant to reflect the exposure outside of occupational exposure and therefore can be applied to background and environmental exposure situations.²⁰

SOCIAL AND ETHICAL ISSUES

Biomarker use must be carefully considered, specifically incorporating safeguards essential for insuring that they are used ethically and in a socially responsible manner. The most obvious potential problem is presented by the use of genetic markers. The US Office of Technology Assessment determined in the 1980s that there was relatively sparse use of genetic testing in the workplace.⁴ This seems wise, given the still investigative nature of most markers. Where genetic testing is used, there are also important questions that are related to the Americans with Disabilities Act of 1990. This legislative act highlights the primacy of exposure control in the workplace. Regardless of technical advances in terms of predictive value, social advances will be required in areas such as privacy protection, rate retention for workers with identified susceptibilities (analogous to OSHA's medical removal protections for high blood lead levels), and accommodations made for identified susceptibilities in order to facilitate the use of susceptibility markers in the future.⁴ The strategy for reducing occupational disease should continue to be through modification of the workplace and not modification of the workforce.²¹

Chapter 8

Impairment and Disability

Philip Harber

Evaluating work ability and disability requires both clinical and environmental expertise. Disability and impairment are not static; rather, they are subject to intervention. The extent of disability is determined by several factors: severity of the impairment itself, concurrent impairments in other systems, efficacy of medical care, job demand, ability to adjust job demands as needed, attitude of the worker, policies of the employer, and social context.

Evaluating the match between a person and the job requires understanding of both the individual's clinical condition and the stressors imposed by work. Five general questions may be asked in assessing occupational disability. These questions are summarized in Table 8.1. Certain jobs are sufficiently arduous or have sufficiently frequent risk that they are inappropriate for nearly all workers. This chapter, however, focuses on evaluation of the individual for jobs that are not inherently unacceptably dangerous.

GENERAL CONCEPTS

Several general concepts are involved in the evaluation of an individual's ability/disability. This section will define basic terms.

An *impairment* is the loss of physiologic function or anatomic structure, such as decreased maximal strength or loss of a hand. Traditionally, physicians have emphasized assessment of impairment.

A *handicap* is the specific activity that may not be performed (e.g., the person cannot walk one flight of stairs, cannot use a respirator, cannot calculate change). In the United States, the term 'handicap' is used less frequently, and the distinction between disability and handicap is less clear.

A *disability* is the impact of the impairment or handicap on the person's life. Disability may be assessed in several spheres. *Job-specific disability* describes the inability of a person to do a specific job, typically his or her current or most recent job. *General occupational disability* relates to the inability to do most jobs in the economy. Disability may also be described in terms of the activities of daily living (ADL) without reference to a specific occupation. For example, can the person live independently? As discussed below, the extent of disability depends on many factors besides the actual impairment, and it is common that two individuals may have similar impairments but different consequent disabilities.

A disability may be characterized as either *permanent* or *temporary*, depending on anticipated healing or response to treatment. Furthermore, a disability may be characterized as partial or total. *Total disability* usually implies that the

individual is unable to do any substantial work. *Diagnosis* usually refers to a description of the underlying etiology (the traditional medical diagnosis). Unfortunately, many physicians limit their evaluation to establishment of the diagnosis rather than considering its functional impact. *Accommodation* is the process of making workplace adjustments to permit a person with impairment to continue working. Even when impairment cannot be eliminated by medical treatment following an injury or an illness, a physician may serve as a member of an interdisciplinary team to significantly diminish the consequent disability.

Whole-person impairment considers the impact of combined impairments from several organ systems on the total person. In some instances, two non-total impairments may combine to become completely impairing. For example, the patient with an otherwise compensated psychiatric impairment may become totally impaired if a back injury occurs.

There also are several concepts that relate to the administrative and legal aspects of evaluation. Several administrative/legal systems require reducing complex patient and worksite factors into a single number upon which to determine the size of an award of benefits. *Percent disability* is a legal concept, not a medical reality. It applies a single number to the individual; this number is commonly used by agencies to determine directly the amount of financial award. The specific method for calculating this award varies. Some systems base this award on impairment (physiologic and anatomic loss), whereas others are truly disability based, such as an estimation of the loss of wage-earning capacity. Another administrative term is *apportionment*, in which the patient's impairment or disability is ascribed in a quantitative fashion to different causes. Ascribing a certain degree of the current impairment or disability to a job as a welder and the remainder to smoking is an example. A *preclusion* represents an activity or exposure that is not recommended for the individual. Such preclusions may be for chemical exposures, physical job demands, or even workplace emotional stressors, that result in work restrictions.

Clinical evaluation of disability requires an assessment of five basic factors, outlined in Table 8.1 and discussed in detail below.

A. Can the worker do the job?

Determination of whether or not a worker is currently capable of performing a particular job necessitates evaluation of both the worker and the job characteristics. Only after both the worker and the job have been carefully assessed is it

1. Can the worker do the job?
2. Should the worker do the job (i.e., what is his or her risk of future illness)?
3. What is the extent of deviation from normality (impairment)?
4. How can the job be modified to accommodate the worker?
5. Can the worker's health be modified to meet job requirements?

Table 8.1 Basic questions

possible to comment specifically on the match between the two. If the clinician has sufficient understanding of the job demands he/she may comment upon ability to do the specific job.

Evaluation of a person's current capability to do a job are commonly performed in three contexts: (1) preplacement examination, in which a potential worker is evaluated prospectively to determine whether or not he or she can do a job; (2) fitness-for-duty evaluation, in which a worker who is currently employed in a job is evaluated to determine whether or not he or she should remain in the job; and (3) disability compensation evaluation, in which job-related disability is determined to guide a legal decision about financial payment. Although the contexts differ, the same scientific principles apply.

Characterizing the individual

In evaluating whether or not someone can do a job, each individual must be assessed *individually*. Information about classes of workers should not be applied to evaluating a particular worker–job match. For example, although women may on *average* be able to supply less muscular force for lifting than men, it is inappropriate to exclude a woman from a job requiring heavy lifting without carefully evaluating her specific strength. Similar comments apply to the aging worker and individuals who have known impairments.

Preplacement medical assessment determines whether or not an individual can meet the basic job requirements; the medical evaluation is not aimed at selecting the best worker (this is a personnel decision).^{1,2} In the United States, the Americans with Disabilities Act (ADA) defines the information that may be collected and how it should be used. Information that is collected should be relevant to the job. If additional medical information is collected (as part of a baseline evaluation or for general health purposes), the clinician must not allow irrelevant information to affect the placement recommendation.

The information to be collected must be carefully selected based on knowledge of the job rather than relying on a generic preplacement examination. Each worker's specific medical history may lead to individualization of testing. In the United States, several Occupational Safety and Health Administration (OSHA) regulations require specified examinations soon after placement, and many incorporate these specified examinations into the general preplacement examination. In addition, different situations warrant different clinical emphases. For example, lower extremity sensation and reflexes warrant special attention for baseline documentation for jobs stressing the low back,

whereas testing for Phalen's and Tinel's signs is warranted when there is likely to be repetitive wrist motion.

Considerations for compensation disability evaluation are similar, but the examiner is generally afforded more leeway in choosing tests.

Characterizing the job

The job must be described adequately to determine whether or not the worker can do it. Assessment of disability must include evaluation of the job in addition to examination of the individual.³ In those instances in which a global rather than job-specific disability assessment is performed, the examiner must have a clear concept of the average and the minimal demand jobs in the economy.

Job-specific work characterization information can be obtained from many sources. For example, the worker may provide descriptions when seeking information supplied by the employer. Other methods include a worksite visit, discussions with coworkers, or viewing of videotapes about the job. Review of industrial hygiene data is useful for evaluating the chemical environment. Finally, occupational medicine textbooks and industrial process books include useful information.

When the physician does not have sufficient work characterization information on which to base a *disability* recommendation, the report should be explicitly limited to a description of *impairment, handicap, or work ability* with the clear understanding that translation to disability is to be done by others. For example, a clinician may express ability (e.g., 'can lift 20 pounds 5 times an hour') or handicap ('cannot lift more than 20 pounds') rather than job-specific ability ('cannot work at a specific position at a specific company').

B. Should the worker take the job? (Future risk assessment)

While the previous section addressed whether or not an individual can do a job *at the current time*, this section deals with the more difficult question of assessing future risk. The clinician's role is to make an assessment and provide advice; the worker and the employer have the ultimate responsibility for actually making the decision about whether or not the estimated risk is acceptable. This decision is affected by non-medical considerations, including the availability of alternative work or alternative workers with lower risk, and the potential benefits of the work. Also, there is a societal acceptance of differential risk for various occupations; for example, a higher risk is thought to be more acceptable for astronauts, US presidents, and soldiers than for schoolteachers and physicians. Assessment of the significance of future risk is guided by several principles: (1) likelihood that an adverse event will occur; (2) severity of the effect; (3) temporality regarding how soon the event will occur; and (4) public impact or the extent to which the public would be placed at risk if an event occurs. Thus, a police officer with angina and a high likelihood of developing a myocardial infarction in the near future while chasing a felon would carry far more

weight than an unlikely skin irritation developing in the far future.

Certain risk estimates are generic for the job or industry, but characteristics of a specific worker may significantly modify the generic risk associated with a job. These individual risk modifications arise in the following ways.

1. Sensitization to a specific agent

An allergic, chemical or biologic agent-specific sensitization generally precludes a worker from a job with a high probability of exposure to that particular agent. Even if the worker has no current impairment, disability for specific jobs may exist because of the necessity to avoid certain chemicals. Such allergic sensitization may be manifested by asthma, allergic rhinitis, or contact dermatitis. Once sensitized, low levels of exposure may produce active disease, and typical regulatory standards cannot be relied on for protection.

2. High risk of recurrence of a previous injury or illness

Often, a worker who has had previous injury is more likely to have a recurrence than are his or her coworkers. Each situation must be individually evaluated to assess specific risk rather than simply assuming that previous illness predicts future illness. One should determine whether the original injury indicated a particular individual susceptibility, or occurred purely by chance. Furthermore, one must determine whether the individual risk factor leading to the original illness or injury still exists, has been corrected, or is subject to modification. For example, inadequate strength for a job can lead to back injuries; however, strength may be improved by training, and therefore, an injury that occurred in an untrained individual does not indicate that the risk persists. In addition, the previous injury may have been due to unusually adverse working conditions that are unlikely to be found in any other situation on the job.

3. High risk of total disability in the event of a second injury

An existing impairment, whether due to occupational or non-occupational factors, may sufficiently limit the person's physiologic reserve that any additional loss, even one that is transient, would be unacceptable. This concept applies to traumatic loss (e.g., a worker with only one hand is at very high risk for incapacitation should any injury occur to the remaining hand), physiologic loss (destruction of lung tissue by asbestosis or emphysema markedly exaggerates the effect of any subsequent fibrosis), or psychiatric loss (a usually minor workplace psychosocial stressor may completely disable an otherwise compensated individual). Assessments, therefore, require evaluation of the potential for subsequent injury.

Many states have second injury laws to protect employers against large expenses incurred by employing partially disabled workers. In the absence of such laws, however, there is strong incentive to discriminate against the partially impaired worker at the time of hiring and placement.

4. High risk of developing an unrelated problem

A previous injury or illness may increase the risk of developing a new, unrelated problem at work. For example, occupational hearing loss may increase the risk of subsequent bodily injury if it interferes with a worker's ability to hear warnings or oncoming traffic. Similarly, reactive airways dysfunction syndrome (RADS), which was induced by a single high-level exposure to a specific agent such as sulfur dioxide, may leave a worker more susceptible to a variety of non-specific respiratory irritants.

5. Difficulty in discerning job-related health effects in cases of pre-existing impairment

A pre-existing impairment may interfere with the ability to screen for health effects. For instance, approximately 5% of workers exposed to certain isocyanates become sensitized and develop asthma. A worker in an isocyanate facility who develops even mild wheezing will likely be detectable by spirometry surveillance programs or by symptom reporting, whereas occupational sensitization would be much more difficult to detect in the worker with pre-existing wheezing. Similarly, the increasing reliance on early symptom reporting for secondary prevention of cumulative trauma disorders is complicated by the presence of pre-existing symptoms. In such instances, it is difficult to determine whether a symptom is new or simply a manifestation of existing dysfunction. These limitations may be minimized by obtaining appropriate baseline clinical information.

6. Psychologic sensitization

Individuals may encounter considerable difficulty in returning to former work because of significant fear of a recurrent episode after recovering from the effects of one earlier accident. For example, a worker who sustained major burns (from which he or she has fully recovered) following rupture of a steam line may have sufficient fear to preclude him or her from working in a power or steam plant. Similarly, a worker who has experienced high-level exposure to a toxic material with a strong odor may subsequently feel anxiety in the presence of non-specific odors, having learned to associate odor with danger.⁴

7. Increased risk to coworkers or the general public

A previous impairment or injury may increase the future risk to coworkers or the general public without necessarily increasing the risk to the worker personally. The important distinction between future risk to self versus others has been made by the ADA, which differentially emphasizes risk to others. For example, a schoolteacher with paranoia or a narcoleptic police dispatcher represents future risk not to himself (or herself) but to others.

Because preplacement evaluation and job-specific disability assessment are fundamentally the same, the same principles guide both. Preclusions frequently are specified in the course of a disability evaluation and are based on the evaluator's opinion about future risk. As such, they are frequently called 'prophylactic preclusions'. These preclu-

sions are used as the basis for determining monetary awards in several disability compensations systems.

In describing a work limitation, the evaluator should clearly differentiate a prophylactic preclusion, based on an estimate of future risk, from the determination that the worker is currently incapable of performing the job tasks. The evaluator also should describe the rationale for such recommended preclusions as well as the estimated probability of an adverse effect if the preclusion is not followed. Furthermore, to the greatest extent possible, the recommended preclusions should be carefully described. A frequently used phrase, such as ‘precluded from exposure to gases, mists, and fumes’, would effectively preclude the individual from life on earth, since air is a gas. Similarly, ‘precluded from moderate lifting’ is far too vague to be helpful. In addition to specifying a recommended weight limitation for lifting, the evaluator also should comment on frequency; for example, ‘Lifting 25 pounds once a shift is not likely to produce recurrent injury and is thus acceptable, but lifting 25 pounds 100 times per hour is risky’.

C. Quantifying impairment: how much function has the patient lost?

Here, the emphasis is on the decrement rather than on the residual abilities or future risk. Therefore, in answering this question as part of a disability evaluation, it is necessary to provide an assessment of the functional ability at two times: prior to the injury and currently. Some disability evaluation systems, such as the United States Social Security Disability Insurance System, are based solely on the individual’s current functional ability, whereas most workers’ compensation systems are concerned with the *loss of function due to work*. Simply subtracting current function from pre-hire function often does not adequately evaluate the functional loss due to work, because aging and other unrelated factors also might produce loss. These factors should be delineated as carefully as possible. Even though factors other than work may have caused some decrement in function, an additional impairment component due to work may represent the proximate cause, or the proverbial ‘straw that broke the camel’s back’ and create disability for a job.

Retrospective evaluation of preinjury status with precision is often difficult. Several approaches may be used to estimate the individual’s preinjury function; these approaches are summarized in Table 8.2 and include the following.

1. Available preinjury objective data

Where available, such objective information is particularly useful. For example, the worker may have participated

Preinjury objective data
Prior activities
Intraindividual comparisons (e.g. right vs. left)
Population norms
Self-reported status

Table 8.2 Methods of estimating preinjury functional status

in an annual medical surveillance program involving pulmonary function testing, thereby providing objective information about his or her preinjury status. The results of periodic medical examinations or preplacement examinations may be similarly useful. Medical testing performed outside the occupational setting by the personal physician or as part of insurance or military service examinations also may be available.

2. Objective evidence of prior activities indicating a high functional level

Life activities prior to the injury may imply a specific level of functioning. For example, having worked successfully in a heavy manual materials handling job suggests the absence of pre-existing back impairment and may imply a preinjury strength that is greater than average. Similarly, marathon running suggests high cardiopulmonary fitness. Evaluation of loss of cognitive function is more challenging; given the wide range of cognitive ability (e.g., as measured by IQ testing) in a population, it is difficult to determine whether someone who has low-normal function always functioned at that level or has had a significant loss. Educational attainment and occupational achievement may provide insight into preillness capability. However, before concluding that poor prior educational/vocational attainment indicates a low premorbid cognitive ability, one must consider if opportunity and cultural barriers, rather than low ability, account for the low attainment.

3. Intraindividual comparison

For certain functions, the person may serve as an internal reference (e.g., the general symmetry of muscle bulk and strength allows comparison of one side to another). Range of motion evaluations should compare the affected side to the contralateral side. Comparisons of the left and right sides should be made soon after onset of the impairment. A delay of many years may lead to secondary disuse or overuse of the unaffected side.

4. Comparison to population norms

Statistical description of the distribution of many specific functional characteristics is available. When there are no data about the individual’s preinjury functional status, one may compare the patient’s current result with the relevant population average and make the assumption that prior to injury, he or she was ‘average’. Such general comparisons must be interpreted with caution. Working populations should not be assumed to be ‘average’. Unhealthy individuals are often less likely to apply for or be placed in jobs than healthy applicants (‘healthy worker effect’) or to remain in a demanding job (‘survivor effect’). For example, individuals with naturally low lung function may tend to leave jobs requiring heavy exertion, and individuals with airway hyper-responsiveness will leave jobs entailing exposures that produce bronchospasm (e.g., grain dust exposure), thereby leaving working populations that have higher-than-average functional availability for the given job.

Conversely, the reference values may have been derived from subjects selected for above-average health. To under-

stand the limitations of this approach, consider the following example. There are predicted values for pulmonary function tests such as spirometry. These predictions are often based on regression equations derived from empiric testing of carefully selected 'normal' individuals. Cigarette smokers, persons with asthma or other respiratory symptoms, and those who perform suboptimally on the tests were excluded. Therefore, the predicted values do not reflect average results for a typical community population, because those with naturally occurring disease and smokers were excluded. Therefore, an unselected community population should not automatically be expected to have average values equal to those that are predicted.

Thus, the source of the reference population and factors affecting selection of workers must be considered. Reference values based on atypically fit subjects may overestimate expected values; similarly the 'healthy worker' and 'survivor' effects may increase expected values for some worker groups above usual reference values.⁵⁻⁷ Furthermore, there is considerable interpersonal variation in ability even among the carefully selected study population, requiring that a *range* of normality, rather than a single value, be defined. For arbitrary reasons, this has traditionally been set at a value that creates a 5% false-positive rate for each test (i.e., 5% of the carefully selected normal population would still have values outside this range). Population norms of muscle strength are even more complex because the job itself may have a significant training effect, leading to increased muscle strength in comparison to overall population averages. For these reasons, population averages as the estimate of preinjury functional status must be used cautiously, and clinical judgment must be employed to make necessary adjustments.

5. Self-reported status

Subjective information collected from the worker also facilitates evaluating prior function. Clinical assessments of function loss using self-reported status should be conducted where possible. Family and friends also may provide significantly useful subjective data. This information is especially helpful when changes in central nervous system functional status are evaluated.

The loss should be carefully described. However, unlike the preplacement testing situation, more detailed, individualized testing is traditionally acceptable for impairment assessment when the assessment is part of a compensation disability evaluation. Testing should be as objective as possible, and optimal patient cooperation must be obtained. When appropriate, physicians should state in a written report that adequate testing could not be performed for technical reasons or due to lack of full cooperation. Whenever possible, clinical evaluation and testing results should be recorded in a way that permits external validation and review. For example, spirometry tracings should be incorporated in reports; raw psychometric data, rather than just a final interpretation of results, also should be available for review.

In addition to simply listing results of current function evaluation and estimated prior function, physicians should

describe which findings are the most important. For example, loss of FEV₁ is more significant than loss of FEF_{25-75%}, and loss of dominant hand function is more important than loss of function of the non-dominant hand.

For occupational disease and cumulative trauma disorders, functional loss is frequently multifactorial and the clinician is asked to apportion the functional loss to multiple causes. For example, aging and cigarette smoking cause decline in lung function and may confuse the evaluation of loss of lung function due to cotton dust exposure (chronic byssinosis). Unfortunately, there is difficulty in simply applying the average excess decline in lung function found in cigarette smokers and assuming that any loss above this level is due to the occupational exposure. Only a minority of smokers develop high rates of decline of lung function; therefore, applying the average annual excess decline among smokers would underestimate the effects of byssinosis in some and overestimate it in other cotton dust-exposed workers. Unlike smoking, aging significantly affects all individuals and should be accounted for using standard reference equations provide an age adjustment.

When attempting to ascribe functional loss to certain jobs, estimates of the level of risk associated with each job must be evaluated. For illness related to chemical exposure, one must consider dose, exposure levels, frequency, mitigating factors (personal protective equipment such as respirators), and the time course of exposure relative to the onset of disease. In essence, one must apply epidemiologic and toxicologic approaches to the individual rather than to populations or laboratory animals.

D. Accommodation: how can the job be modified to decrease the worker's disability?

Modification of a job may significantly decrease the extent of occupational disability. Such possibilities should be considered in most occupational disability evaluations. Modifications such as creating a flexible work pace or work schedule may convert a disabled worker to an able worker. Providing mechanical assist devices may permit a worker to use any residual abilities; similarly, coworkers may be assigned a small number of relatively heavy tasks to permit a partially impaired individual to remain in the workforce. Modification of chemical exposures also may be accomplished; for example, a worker may be transferred to another department that does not deal with a specific chemical agent or process.

The psychosocial and organizational structure of the worksite also may be improved to decrease occupational disability. For example, education of the immediate supervisor about the worker's specific limitations and residual abilities can facilitate the worker's re-entry to the workforce. Upper management (and often union) support may be needed to encourage the immediate line supervisor to become an ally in returning someone to modified work.

E. Can the worker's condition be modified to decrease occupational disability?

There are four ways in which changes to the worker can affect the degree of disability. The first two apply directly to the injury- or illness-related impairment, the third applies to the individual's psychologic response to the injury, and the fourth applies to the occupational disability per se.

1. Natural course of the illness

Many illnesses and injuries are not static but change over time. For example, certain diseases, such as progressive massive fibrosis or severe asbestosis, may progress even after exposure ceases, whereas many others, such as post-irritant tracheobronchitis, may improve with time. Most musculoskeletal strains and sprains also improve with time. Therefore, one must carefully consider the point in the natural history of the illness at which the evaluation is being performed.

2. Medical treatment

Proper medical treatment may modify the level of impairment and, consequently, the disability. Therefore, in addition to assessing current functional status, physicians should consider the extent to which improved treatment would modify the functional condition. In some instances, treatment may be directed at the injury itself (operative repair of a fracture, bronchodilator therapy); in other situations, the individual may require medical rehabilitation (physiatry, physical therapy). Treatment of coexisting conditions also may decrease the disability consequent to the occupationally related problem.

Hence, impairment should be assessed in its current state as well as on the assumption that the patient will receive optimal medical treatment. Some residual uncertainty about future impairment always exists, because an individual's response to therapy is often variable. The clinician should indicate if the worker has obtained 'maximal medical improvement'. For these reasons, the evaluating physician should consider whether the patient is in a 'permanent and stationary' status. If so, then a 'permanent disability/impairment' may be described.

3. Improvement of psychologic effects

Occupational illnesses or injuries may lead to secondary psychiatric or psychologic effects. For example, the inability to go to work may significantly affect an individual's self-image, or fear of subsequent workplace events may lead to inability to work even if the primary illness has ameliorated. These psychologic effects are not permanent in most instances and can be managed with appropriate treatment. The management includes both medical and psychologic treatment, as well as altering attitudes at the workplace and managing physical factors, as described earlier.

4. Vocational training

Often, a worker who has received maximal medical treatment may still improve his or her disability status through

vocational rehabilitation. The individual's remaining skills and abilities may often be redirected into other productive areas. Vocational rehabilitation is best begun as soon as it is clear that a worker will not be capable of returning to the former job and that he or she is not totally disabled for all work.

INTEGRATED DISABILITY PREVENTION

Worker productivity is reduced by injuries and illnesses, whether or not caused by work exposures. The indirect costs of worker disability include reduced productivity, necessity to hire and train new employees, and reduced morale. Therefore, there is increasing recognition of the value of efforts to reduce disability, whether or not consequent to work itself. Integrated disability management programs do not distinguish between workers compensation and group health, but apply similar approaches to optimize worker functional status.

Disability is the end result of many factors. Figure 8.1 demonstrates schematically the factors that affect disability. Exposure to workplace hazards or personal health conditions can gradually or acutely produce pathophysiologic effects (injury), which lead to a clinically diagnosable condition (e.g., asthma, low back strain) and its consequent impairment. The latter may resolve or leave some degree of permanent impairment. This in turn interferes with the ability to do certain tasks, such as lifting specific poundage (the handicap). This produces work disability if the job cannot be done without the task. In considering disability, clinicians should recognize the critical importance of functional assessment, rather than the medical diagnosis per se.

The likelihood and extent of permanent disability are significantly modified by factors external to this direct sequence from injury to disability. The dashed boxes in Figure 8.1 show these factors. Each is a potential site for preventive intervention.

As shown in Figure 8.1, most of the aspects influencing disability are the same whether the medical problem is of occupational or non-occupational origin. Regrettably, some compensation systems penalize workers for any contribution not due to a work hazard and therefore discourage attention to many relevant issues.

Efforts to prevent occupational disability may be directed at various points. Effective approaches towards prevention of occupational injury/illness are discussed throughout this book. Although the term 'disability management' is popular, 'disability prevention' is more consistent with primary, secondary, and tertiary prevention approaches for most occupational problems. Some methods are directed at individual workers/patients, whereas others focus upon the work environment or policies. Disability prevention approaches should be considered soon after an injury has occurred; once a pattern of disability has been established, it is difficult to change.

By appropriate early interventions, secondary prevention limits the extent of disability following an injury.

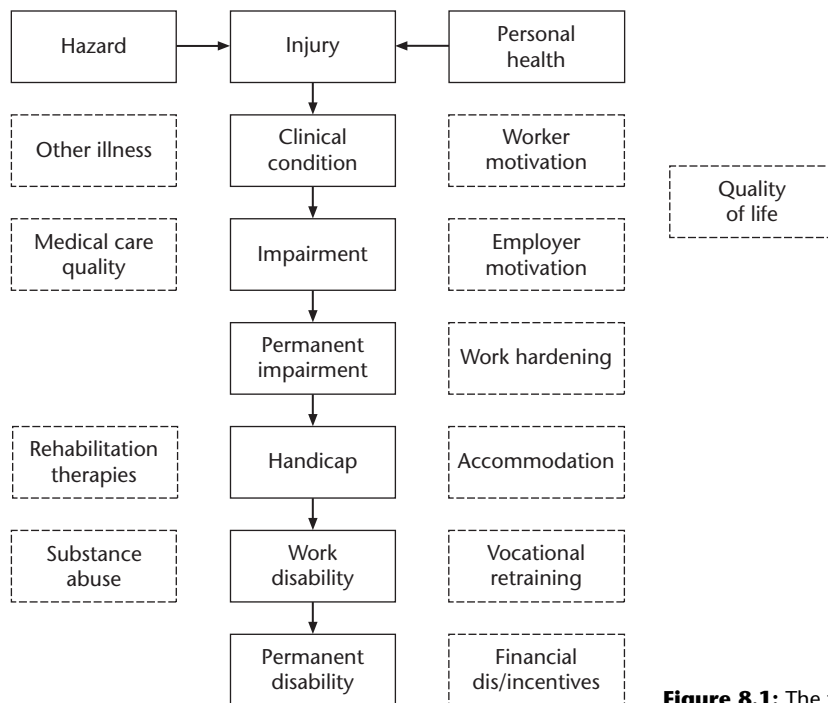

Figure 8.1: The factors that affect disability.

Reducing impairment by good medical care (e.g., optimizing medications for reactive airways disease syndrome) and avoiding unnecessary surgery (e.g., inappropriate lumbar fusions) will reduce the consequent disability.^{10,11} Methods as simple as occasional telephone calls from coworkers and supervisors increase the likelihood of effective return to work after a back injury.

Secondary prevention efforts include establishing policies which encourage job accommodation and availability of limited duty. They also include programs addressing factors such as drug/alcohol abuse that tend to prolong disability. The quality of work life affects both employer and patient motivation to return to work. For example, worker assessment of the quality of work life was a major determinant of disability due to back pain.^{8,9}

Identifying social factors, whether at home or work, which tend to prolong the period of disability may lead to effective secondary prevention efforts. Numerous studies have shown that perception of work stress affects extent of disability after reporting a back injury.¹²⁻¹⁴ For example, this may involve remediation of worksite stressors such as lack of respect for workers, inconsistent management, lack of autonomy, or conflicts with specific supervisors or coworkers. Personal stressors, such as alcohol abuse or a dysfunctional family situation, are also subject to intervention. When the period of disability seems inappropriately long, clinicians must consider the possibility of ‘medicalization’ of personnel issues, a situation in which managers or workers camouflage personnel issues as clinical issues.

Traditional functionally oriented therapies (such as physical and occupational therapy) may be supplemented by job task-specific rehabilitation.¹⁵ Such ‘work hardening’ should be based upon understanding the specific types of job demands and emphasize strengthening the most rele-

vant functions. Work hardening may be helpful even for physical aspects not involved in the injury itself, if deconditioning has occurred while the affected anatomic area heals.

Tertiary disability prevention methods include vocational rehabilitation such as training for a new occupation. Modification of the job (accommodation) by reassigning or modifying the tasks leading to disability can be effective. Eliminating employer and employee disincentives to work (e.g., by ‘second injury laws’) reduce disability.

Policies that affect disability must be carefully formulated. The ‘indirect’ cost of occupational injury/illness (e.g., reduced productivity) often exceeds the cost of direct medical care and workers compensation payments; ‘cost containment’ efforts which delay care may therefore actually increase the total cost of an injury. Rigid work rules, which assign lighter jobs solely on seniority, may reduce the flexibility necessary for accommodation.

EXAMPLES: IMPAIRMENT AND DISABILITY RELATED TO LOW BACK, PULMONARY DISORDERS AND PAIN

The earlier sections outlined general principles underlying disability assessment. Specific methods are appropriate for evaluation of each organ system, and several examples are presented here. Nevertheless, the impairment and disability evaluator must recognize the person as a whole rather than simply as a collection of individual systems. An approach to impairment assessment is provided, using back disability as a prototype. Evaluation of low back

impairment, despite a plethora of physical examinations and laboratory tests, still relies heavily on subjective factors from both the patient's and the examiners' standpoint.

Low back

Acute and cumulative trauma injury to the low back is the most costly occupational health problem in industry in the United States (see Chapter 23.4). It occurs both as a consequence of single specifically identifiable events as well as from repetitive strain. Most low back problems are relatively limited in their impact, with return to work occurring in less than 2 weeks. However, a small proportion of workers with low back injuries have prolonged or even permanent total inability to work. Many such injuries affect manual materials handling workers with limited alternative skills. However, trained service sector professionals, such as nurses, also have very high rates of low back injury.

Early workers' compensations systems were oriented toward acute traumatic loss (e.g., amputation) and did not address anything as subjective as low back pain. Therefore, the discovery of the entity of herniated nucleus pulposus (HNP) in the early part of the century provided the rationale for including this large group of occupational problems. Occupational back pain was believed to be the consequence of an acute rupture of the annulus, with herniation of the disc and compression of neural structures. To be considered work related and compensable, the pain had to begin following a specific identifiable incident, in which the annulus was acutely torn. In this theory the disc herniation was believed to be both necessary and sufficient to diagnose and explain the impairment. Workers with gradual onset of pain or those without a disc herniation on myelography were believed not to have demonstrable impairment. Unfortunately, this attractively simple scheme is incorrect. Repetitive overuse can contribute significantly to occupational low back pain without a single severe incident.

Current disability

The best way to determine whether or not an individual currently is capable of doing a job with demands on low back function is to have the individual attempt the work. If this approach is not feasible, work simulation also may be conducted, often in a clinical setting. In many cases, work limitation due to back pain is related to decreased lifting ability and, therefore, evaluation tends to focus on this area. The type of lifting associated with a particular job may be characterized by several parameters; these are shown in Table 8.3. These lifting parameters are very

Weight lifted
Frequency of lift
Starting position for lift
Vertical travel
Body position relative to starting and final positions
Load factors (size, shape, handles, footing)

Table 8.3 Parameters describing lifting jobs

comparable to those recommended in the National Institute for Occupational Safety and Health (NIOSH) manual materials handling guides. However, they must be supplemented by information about whether the lift is typically one-handed or two-handed, or in the sagittal plane or asymmetrical.

Most jobs involve heterogeneity of lifting tasks. In some instances, the current ability of an individual to do a particular job is determined by the most arduous of the tasks, even if this task is performed only once or twice a day. In other circumstances, typical work is performed at high repetition rates throughout the day. In the latter case, the work simulation test, which is used to determine whether or not a worker is able to do a particular job, must not be based on the ability to generate a single forceful lift.

Unfortunately, work simulation is generally impractical. The evaluator frequently does not have adequate information about the job. Furthermore, there is considerable concern about performing significant lifting tasks as part of the disability evaluation. Clinicians may be appropriately concerned about the possibility of further exacerbation of injury as a consequence of the testing. Moreover, this testing is subject to motivational factors. A worker who strongly desires a particular job placement may tolerate an otherwise unacceptable level of discomfort during the preplacement simulation test, and conversely, a worker who seeks compensation may have a subtle bias in the opposite direction. Therefore, rather than relying on direct workplace or workplace simulation testing, more indirect methods are commonly used.

An intermediate approach is to determine whether or not the worker has strength and endurance comparable to typical workers who are currently successfully performing the work. Specific methods for determining strength are described in more detail later. Although strength often may be measured conveniently in a clinical setting, it is more difficult to evaluate the strength of workers in a particular job for comparison purposes. Nevertheless, there are published data about the typical strength of certain working populations. In addition, the strength data are incorporated in several commercially available computer programs for easy use.

Relative perceived exertion (RPE) techniques also may be applicable in the absence of concern about secondary gain.¹⁶ Workers are remarkably good at describing the work demands, and a series of formal scales (RPE) can be used for this purpose. Instead of measuring strength, a worker may be evaluated by performing several typical tasks in the clinical setting and being asked how the tasks compare with the worker's perception of his or her former job.

In actual practice, clinical judgment by clinicians without direct knowledge of the workplace often is the basis for determining whether or not impairment leads to current disability. To improve the usual situation, in which the clinician has neither the time nor the training to conduct a worksite survey to determine the specific lifting requirements, as much useful information as possible should be provided. There is a tradition that requires physicians to 'pigeonhole' disability evaluatees into vaguely characterized

categories such as 'capable of light lifting' or 'capable of very heavy lifting'. Even specifying the duration in hours per day is inadequate unless the frequency per hour is also described. Positional terms such as kneeling, stooping, and bending also require quantitation to be of any use to the clinical evaluator.

Future risk

Assessment of future risk and recommendation of consequent preclusions are more difficult than description of current disability. Previous episodes of severe impairment are a significant predictor of future risk. Certain clinical diagnoses imply a high degree of instability and consequent elevated risk. For example, an untreated large herniated disc that is beginning to impinge on the spinal canal or neural foramina warrants particular caution.

Current muscle strength is believed by many to be a modifier of future risk and is recommended by NIOSH for preplacement testing in manual materials handling tests. There is at least one study that has shown validity of the concept that a worker's strength in relation to the job requirement is a major predictor of future risk.¹⁷ Although this study has not been specifically validated for workers with existing impairment, it is reasonable to assume that strength testing will play an increasingly important role in assessing disability due to low back disorders.

Extent of loss

Several approaches are available to estimate the loss of function (impairment) due to low back problems. As discussed previously, antecedent (preinjury) status may be assessed by several methods. In some instances, previous medical data such as strength testing and preplacement physical examination data, or both, may be available for comparison. The ability of the individual to have conducted heavy work prior to the illness is frequently the best indicator of a high functional status. Moreover, there are population norms available for specific measures of strength and range of motion.

Evaluation of current functional status has several functional components: subjective statements made by the patient, medical diagnoses, range of motion testing, and performance testing. Each of these components can and should be used in effectively comparing current function with previous function. There are two commonly used methods for summarizing and rating impairment related to back disorders – range of motion (ROM) and diagnosis related estimated (DRE). The former approach (ROM) has been traditionally used and is based largely upon reduction in the measured range of motion of the spine also considering associated neurologic deficits. Measurement of range of motion requires attention to detail and it is dependent upon adequate cooperation of the patient. Many feel that accuracy is enhanced by use of an inclinometer rather than by visual estimation or use of a goniometer. An inclinometer measures deviation from the vertical plane and is similar to levels used by carpenters. Spinal motion is measured in three planes: extension–flexion; axial rotation, and frontal motion. The

measurement should be repeated several times to estimate consistency.

The other method, DRE, depends upon assigning diagnostic categories. According to the AMA Guidelines, the following factors are considered: muscle spasm, muscle guarding, spinal motion asymmetry, radicular pain, reflex abnormality, weakness, hyperesthesia, atrophy, electrodiagnostic abnormality, motion segment integrity loss, cauda equina syndrome, urodynamic abnormalities. The DRE method is particularly useful when there has been a specific, well-defined injury. Conversely, the ROM approach is preferable when it is not possible to delineate a specific diagnosis or injury. Increasingly, the DRE method is preferred. The medical evaluation also helps determine if impairment is likely to be permanent. Some disorders may be expected to improve with treatment, whereas others, even if less severe, may not (e.g., nerve root impingement versus chronic musculoligamentous strain without specific remediable lesion).

Strength measurements are also employed to assess functional status and impairment performance. Relatively simple equipment can often give very useful information. By the same token, expensive, computerized equipment may give misleading results unless carefully calibrated and maintained and unless the clinician interpreting the results fully understands the basis for the printed results. Strength testing techniques fall into three general categories: static, performance, and dynamic. In a static strength test, the subject exerts force against a non-moving object (typically a grab bar) that is attached to a force transducer.^{18,19} Performance-based strength measurements are similar to work simulation methods described earlier. However, for this type of testing, the subject modifies the load to be lifted. For example, the subject may be asked to place unmarked lead weights into a tote box, modifying the number of weights upward or downward until the lift can be comfortably accomplished. Dynamic testing measures strength while the region is in motion. Equipment for this method typically is expensive and provides a large number of graphs and data points. For dynamic testing, the subject is directly linked to the measurement apparatus that controls the motion. Dynamic testing has the advantage of measuring strength throughout the range of lumbosacral spine motion rather than only in one or two positions. While these techniques produce many graphic displays, that may seem impressive, they have not been as widely validated as the isometric methods.

Certain caveats apply to ROM testing and strength testing. The subject must be motivated, and instructions must be clear. The subject should be instructed to produce good efforts but not to risk injury. Repeatability must be determined. In the absence of specific coaching, it is very difficult for a malingerer to exert consistently only 75% of his or her true capability.

Possibility of accommodation

Modification of the job to accommodate workers with low back impairments may often be accomplished. This modification may range from transferring the individual to

lighter work or providing mechanical assist devices. Permitting self-pacing also is very useful. In some situations, such as nursing, having a second person available when lifting also may be useful. In assessing possible jobsite modifications, the full cooperation of the patient must be enlisted in order to avoid the opposing dangers of lack of motivation due to fear of re-injury and risk of injury due to overzealous return to work.

Worker treatment also plays a very important role. In addition to specific medical treatment for the underlying back disorder, there has been considerable interest in worker training for impaired workers. Various programs, commonly called ‘work hardening’ or ‘back’ schools, have been widely used. Limited outcome data, rather than randomized clinical trials to assess their efficacy, suggest they are useful in some cases. In general, such programs incorporate a combination of physical training, worker education, and psychologic motivation. The truly effective programs typically include specific knowledge of the work-site for which the subject is being rehabilitated rather than applying broad generic methods. For instance, the stressors and techniques for a railroad crew worker are quite different from those for a back-impaired office worker.

Subjective aspects

Despite the existence of many objective physical examinations and laboratory tests, evaluation of low back disorders still must consider the subjective reports of the patient about his or her pain. Pain may be described in terms of its severity, frequency, precipitating events, and impact. The severity description should include the patient’s own words as well as traditional qualifiers such as ‘mild’ or ‘severe’. The quality of the pain should also be described, using the patient’s own words. There are formal pain scales that, when integrated with a clinical interview, have some value for workers who are socioculturally comparable to the population for whom the scales were developed. The frequency of pain also should be described. This description should include discussion of typical number of days per week during which it occurs, as well as the number of episodes per day.

The duration of pain for average episodes and for more severe episodes also should be reported. In addition, the clinician should query whether or not the onset is predictable. Precipitating factors should be evaluated. Is the pain brought on by simply tying shoes or does it require carrying a 20-pound grocery sack? Does it occur with short duration of exertion or only with prolonged, repetitive exertion? Are there certain positions that precipitate the pain? Does sitting for prolonged periods induce it? To what extent does anxiety or stress bring out the pain?

Establishment of a medical diagnosis also is important.²⁰ Low back disorders actually represent a very heterogeneous group of underlying pathophysiologic sequences (see Chapter 23.4). In addition to regional disorders causing back pain, the pain may be a manifestation of a significant underlying disease unrelated to the low back. The disability evaluation may be the only opportunity for a second opinion or, in some instances, may be the only chance for a specialty evaluation.

History of injury
Distribution of pain in a dermatomal pattern
Muscle spasm
Specific signs on examination
Limitation of range of motion
Observation in a structured setting
Reflex asymmetry
Muscle weakness or atrophy
Thermography
Chiropractic evaluation
Discography
Magnetic resonance imaging
CAT scanning
Electromyography
Nerve conduction studies
Lumbar spine radiographs

Table 8.4 Historical list of objective methods of evaluation of low back pain

Many methods have been proposed for ‘objective’ evaluation of low back pain. Some of these methods are listed in Table 8.4. Unfortunately, many of these methods have not been well validated. In addition, the most objective of these methods primarily apply to low back disorders that involve neural damage (either to the spinal cord or peripheral nerves at the root). The majority of patients with low back disorders do not have demonstrable abnormalities of spinal canal or foraminal encroachment.

Assessment of pulmonary impairment and disability

The pulmonary system may be objectively assessed by numerous functional tests as well as imaging studies. However, even though current functional status may generally be objectively and reasonably precisely measured, determination of impairment (functional loss) and disability/work ability are still somewhat imprecise.²¹⁻²³

Spirometry, static lung volume, diffusing capacity of the lung for carbon monoxide, methacholine challenge testing, and cardiopulmonary exercise testing allow characterization of the physiologic status. These methods are discussed elsewhere (see Chapter 19.1). These tests are not necessary in every case and should be used selectively.²⁴ For example, exercise testing is necessary only when the pulmonary function testing is equivocal. If spirometry and diffusing capacity are both strikingly abnormal, exercise testing is unlikely to yield additional information for assessing impairment.²⁵ Methacholine challenge testing is particularly useful for determining the extent of impairment in individuals with asthma.

In general, a careful history and physical examination should be supplemented with determination of ventilatory (spirometry) and diffusing capacity in nearly all cases. If asthma is a concern, yet spirometry is normal, methacholine challenge may be performed. Similarly, if the basic tests are equivocal or the extent of dyspnea is markedly greater than the degree of abnormality of the basic tests, exercise testing may be useful. There are several well-accepted guidelines for test performance and interpretation.

Determining impairment requires comparing current physiologic status with the condition which would have been present in the absence of respiratory disease/injury. In some instances, the patient had spirometry or other lung function tests performed prior to a specific injury. In many situations, however, the current results must be compared to population norms rather than results for the specific individual. Because the range of 'normal' is large, this introduces some uncertainty; this is particularly true with highly variable tests such as the forced expiratory flow over the mid vital capacity range (FEF_{25-75%}).

Translating clinical pulmonary function tests into work ability/disability determinations requires understanding of the job. Both the typical and the maximal exertion levels must be considered. Most persons can maintain approximately 50% of the maximal attainable oxygen consumption for prolonged time periods but can perform work at higher levels of exertion for briefer episodes.^{21,23} Individuals with asthma are more sensitive than others to workplace irritants. Although they may have nearly normal spirometry on the date of clinical testing, workplace conditions may cause reduction in lung function.

Occupational asthma due to allergic sensitization to workplace chemical or biologic agents generally precludes any continued exposure.²⁶ Once sensitized, even low-level exposure can be adverse. Thus, an individual may be disabled for his/her usual job even though lung function testing performed when non-exposed may be normal. For this reason, clear diagnostic distinction between occupational asthma due to allergic sensitization and occupational asthma due to high levels of irritants (such as reactive airways dysfunction syndrome or asthma without latency) is essential. The former situation usually precludes continued work in the specific job, but the latter situation may permit work if irritant levels are controlled to acceptable levels.

Occupational asthma also illustrates the importance of considering adequacy of medical therapy. A person with asthma who is receiving inadequate treatment cannot be evaluated for permanent impairment until appropriate therapy is characterized.

Respiratory disorders, therefore, illustrate the importance of considering workplace as well as clinical factors in assessing impairment. Despite objective testing of function, characterization of the workplace is also important.

Pain

Assessment of pain in the absence of definite objective abnormalities may be complex. The basis of pain itself is poorly understood and probably depends upon a combination of physical and psychologic factors. Pain-related behavior reflects the impact of pain on an individual's life; in some instances, pain becomes chronic as the person's life is organized around this central aspect. It is not surprising that there are frequent differences of opinion in the assessment of impairment in disability related to pain per se. Some syndromes such as the chronic regional pain syndromes (e.g. reflex sympathetic dystrophy) are controversial and depend very heavily on subjective findings. To

the extent possible, evaluating physicians should be as objective as possible, describing the areas of pain and the impact on life, and avoiding advocacy for or against the 'validity' of symptoms.

While malingering (intentional deception, often for the purpose of financial gain) occurs, it is present in a small minority of individuals claiming disability. Although estimates of the proportion of malingerers among chronic pain subjects have ranged from 1% to 10%, the data supporting this are weak.²⁷ Although not foolproof, several clinical signs (commonly called the Waddell signs) are suggestive that an organic basis is absent.²⁸ For example, compression of the head while standing is unlikely to produce back pain in most cases on a purely organic basis.

GENERAL APPROACH TO EVALUATION

The principles outlined in the first section and the specific organ system examples discussed subsequently illustrate the breadth of approaches that are necessary for impairment and disability assessment. Such an evaluation must be performed as objectively as possible. In theory, since the underlying principles are the same, a clinician should reach the same conclusions about the impairment and disability of a specific patient whether the patient is being seen for a preplacement evaluation or a disability evaluation.

Impairment and disability evaluations are frequently performed in the context of an administrative, regulatory, or legal procedure. Therefore, the examiner should define the specific needs of the overall system of which the evaluation is part. Table 8.5 lists several questions about the role of the particular evaluation to guide report prepara-

1. Why was I selected as examiner?
2. To whom does the report go? Will it be used as a medicolegal document?
3. How 'technical' should the report be? Will it be read by a physician, or is it primarily for non-clinicians?
4. Who is paying for the evaluation? Will they fund extensive documentation?
5. What is the scope of the report (whole person or simply one organ system or one injury)?
6. Is impairment alone the concern, or is disability also to be discussed?
7. Should ability to do a specific job (e.g., most recent) be discussed or is evaluation more generic?
8. Must non-occupational and occupationally caused illness be differentiated?
9. Should my opinions about causation be stated?
10. Will there be another opportunity to evaluate the patient again, or must this truly be a *final* report?
11. Are there particular 'rating terms' that I must use in specific senses? If so, were these terms defined in writing for me?
12. If the problem is occupational, must I prepare a separate report to public health authorities?
13. What specific documentation must be included (e.g., hard copies of spirometry, specific statement listing each staff member who spoke with patient)?
14. How shall the results be communicated to the patient?
15. Am I allowed to treat the patient now or in the future?

Table 8.5 Questions for perspective on preparing reports

tion. Because the medical role is only part of the disability assessment process, effective communication is essential, and the written report should be carefully prepared and reviewed prior to submission; it should not be dashed off as an afterthought following the examination.

Answering the specific questions posed at the time of referral is important. The evaluator should determine whether impairment, disability, or handicap should be addressed. There should be clear separation of subjective and objective data. The rationale for conclusions reached should be stated. When there is some residual uncertainty, this factor also should be identified. In some instances, the physician is simply an information transducer (e.g., reporting the FEV₁ or the ROM of the left elbow) and no conclusions are requested. Other systems request the physician's opinion as well as objective fact. In these circumstances, the physician's opinion should be identified as such. Furthermore, when issues of causation are involved, clinicians should feel comfortable in carefully delineating their area of expertise and commenting only within that area. For example, many cardiologists can very effectively describe the functional impact of a cardiomyopathy but have not had sufficient training in epidemiology, toxicology, or industrial hygiene to discuss whether or not a putative cobalt exposure at work produced a cardiomyopathy.

Finally, certain terms have very specific meanings in many administrative systems. The written reports of physicians are often interpreted extremely literally by individuals who seek to translate specific terms into administrative action or compensation. Therefore, the report should be carefully composed and specific words should be used with appropriate clarification. For example, in many of the workers' compensation systems in the United States, the choice between the adverbs 'probably' and 'possibly' describing causation may determine if a compensatory award is made. Similarly, in some systems, ordered terms such as 'slight,' 'moderate' and 'severe' have very specific meanings and should be used in the context of the system. When uncertain of the specific meaning of one of these terms, the examiner may append a phrase illustrating his or her meaning, such as, 'He has *moderate* pain in the knee, such that he walks more slowly but does not have to remain in a chair'. Amplifying terms in this fashion defers the responsibility for assigning specific ratings to the program administrators.

Role of guidelines and standards

Guidelines and formal standards are used in several ways as summarized in Table 8.6. They may be purely advisory, offering educational suggestions, or they may be mandatory, defining precisely how the clinician must proceed. Some are translational, providing tables to inter-convert clinical and administrative systems or impairment and disability. They may also serve legal purposes. Even if somewhat arbitrary, the presence of standards fosters consistency (and hence fairness) among individuals.

There are many published sets of guidelines for assessment and rating. The most comprehensive and influential

Education of clinicians
Suggestions to clinicians
Default procedures and rating scheme
Used unless clinician has a rationale for alternative
Quality assurance: defines minimum data requirements
Prescriptive
Mandatory without major rebuttal effort
Regulatory
Arbitrary but consistent
Translational
Converts impairment into disability by formula

Table 8.6 Utilization of guidelines and standards for assessing impairment and disability

set is the Guidelines to the Evaluation of Permanent Impairment of the American Medical Association (the 'AMA Guidelines'). The fifth edition was published in 2001. This work is comprehensive and includes sections for most organ systems (including mental). It represents the opinion of a series of expert committees appointed by the AMA. Prior to release, the AMA sent the Guidelines for external review. The AMA Guidelines offer a practically oriented approach to defining clinical data to be collected (history, exam, tests). They also contain numerous tables for converting clinical data into numerical summary indexes. For example, tables suggest using lung function tests to categorize patients into one of four classes of impairment. In addition, the Guidelines seek to provide a common scale across different body parts. The AMA Guidelines are widely accepted.²⁹

Several state workers' compensations systems and non-US entities also have produced rating guidelines. Unlike the AMA, some were produced by governmental agencies and carry regulatory force. In addition, professional organizations have produced organ system-specific guidelines for impairment and/or work ability/disability.³⁰

Although many of the sets of guidelines contain basic tables, they generally are not meant to be fully prescriptive. Rather, they permit (and encourage) clinicians to use good judgment and to consider additional relevant information. However, in some settings, their use is mandatory and fully prescriptive. This creates a problem when the Guidelines are updated.

The AMA Guidelines and many others explicitly are limited to translating clinical findings into rating of impairment per se rather than disability. The AMA Guidelines explicitly state that the rating scheme is for 'activities of daily living, excluding work'. The Guidelines state, 'impairment ratings are not intended for use as directed determinants of work disability'. Therefore, the percentage ratings and class system should not be directly translated into work disability assessments: 'Impairment percentages derived from the Guides should not be used as direct estimates of disability.' Thus, the impairment percentage ratings are not related to income loss or other measures of disability.

By contrast, several systems directly relate clinical findings into disability terms. The US Social Security Disability Insurance system uses tables of clinical test and examination results to discern applicants who are disabled for substantial

gainful employment. Certain state workers' compensation systems also seek to directly interrelate clinical findings into disability and consequent monetary awards. Others, such as California, allow clinicians or 'rating bureaus' to indicate the work loss due to the impairment.

Rating schemes: principles and validity

In a preplacement or fitness for duty evaluation, the clinician's focus is upon a specific individual, as is the case with most diagnostic and therapeutic considerations. However, often in assessing disability for compensation purposes, the clinician's role is not primarily as a patient advocate, but to document objectively and without bias. Generally, there is a non-clinical context for selecting the amount of awards (e.g., rating tables). The system seeks a fair balance among the rights of worker applicants, employers, and governments. There are often very disparate awards for the same impairment depending upon the social context. Workers' compensation benefits vary considerably among states. Where work causation is an issue, the standard of proof varies considerably, as does the underlying logic employed.³¹ In comparison to workers' compensation, tort awards often are larger but require a higher standard of proof.

The validity of assessment systems has received only limited attention.³ Most often, schemes are derived from consensus of expert opinion or political compromise rather than empiric data. However, some have provided limited evaluation by showing that there is a demonstrated correlation between adverse health impact associated with award or diagnosis.³²⁻³⁴ For instance, mortality is higher among applicants who receive awards than among those who do not.³⁵ In addition, the economic impact of a diagnosed disease has been evaluated in several studies by follow-up of cohorts of applicants.³⁶

Chapter 9

Social Issues in the Practice of Occupational and Environmental Medicine

Mark R Cullen, Linda Rosenstock

Individuals seek the services of an OEM practitioner for a broad array of reasons. In workplaces with in-house or contractual medical services, patient choice is limited to either utilizing these or seeking care elsewhere; in emergencies there is no option. For practitioners outside this setting, sources of referral include primary practitioners and other medical specialists, as well as such diverse parties as employers, lawyers, unions, insurance companies, and government agencies. Sometimes it is the patient who encourages the referral or who directly refers him- or herself.

The referral source may influence the context and basis for the evaluation. Patient expectations also have important ramifications, both during the diagnostic evaluation and after. Understanding the expectations of the patient and referring party early in the evaluation process is a central tenet of OEM practice.

In this chapter, we shall explore the major *non-biologic* issues – social, economic and legal – that arise in practice, and introduce the ethical responsibilities that accrue in this practice domain.

THE AGENDA OF PATIENTS AND THIRD PARTIES

The patient's agenda

There are three areas of relevant inquiry into understanding the patient's perception of and interest in an OEM examination: health perception and concern, job situation, and life situation.

Health perception

Individuals seek medical care generally because they have been injured, are experiencing symptoms or are concerned about future health risks. These are the most common reasons to seek OEM evaluation as well, whether the visit is mandated or voluntary. Changes in the societal view about chemicals and other hazards, notification requirements of new laws, wide public attention to certain hazards and extensive information available over the internet – of variable quality – have created more awareness about risk and, to some extent also, confusion. Individuals generally have too little knowledge to apply probabilistic reasoning and are often unsophisticated about the influence of dose on risk (see Chapters 1 and 5). At one end of the spectrum, patients may have been led to believe that a minor exposure has conferred an imminent risk of serious disease. At

the other end are disbelievers who deny or underestimate risks and fail to act appropriately, either in terms of limiting their exposures or undertaking recommended surveillance examinations.

Distorted perceptions of risk and harm may be closely linked to social issues, such as a community's fight against a toxic waste site or a union's struggle for a new contract. Misleading information may have come as well from a highly respected source within the patient's circle – including poorly informed physicians or other health professionals, however well intended. Moreover, correct information may sound disturbingly like information provided by an employer, a suspect polluter or the government, agents the patient may have come to mistrust.

For these reasons and more, it is important to know not only what the patient believes might be going on but the basis for that belief. Responses to this line of inquiry, ideally early in the evaluation process, often disclose the reason(s) for the visit and better define the context in which the clinician can perform most effectively.

Exploring the current job situation

In addition to being a potential source of health risk, work is also a central and crucial component of life for most adults, encompassing both positive and negative aspects. On the positive side, work provides a basis for identity and self-worth, an organizing principle for time, the primary source of income, and a series of relationships, including those with superiors, colleagues, and those supervised. On the negative side, work also provides one of the most enduring of life's stresses, a distraction from family and friends and a source of alienation and self-doubt.

Moreover, work is not necessarily constant in any of these features. Tasks and personnel fluctuate, responsibilities grow or diminish, and the economic picture is always subject to change, sometimes with minimal warning. Given this spectrum of roles that work may fulfill and its inherent variability, it is not surprising that social and personal factors related to work may impact patient management to a larger degree in OEM practice than in other specialties. For the clinician, the following two important questions should always be answered.

1. *To what extent are these work factors (above and beyond specific environmental health risks per se) responsible for the timing and presentation of illness?*

This question is central in several settings. An example is seen in the older worker who presents with a chronic or

slowly progressive disorder, such as mild central nervous system, musculoskeletal, or respiratory dysfunction. While these problems typically evolve over years, the timing of presentation often coincides with other disturbances or changes at work, such as increasing difficulty accomplishing former tasks (often with some attendant rebuke or discipline), threat of job security from younger workers, perceived obsolescence of the job itself, or the possibility of a plant closing or lay-off. Deeper concerns about the work situation also afflict displaced workers who have moved into unaccustomed jobs, as well as formerly unemployed persons who have been pressed into the job market unexpectedly by economic needs, such as former welfare recipients or 'housewives'.

Whatever the setting, correct diagnosis and treatment require that the clinician understand the patient's conscious or not so conscious agenda for seeking attention at the time they do. For older workers who are failing at their jobs, aggressive approaches at rehabilitation based solely on health considerations are doomed to fail. Assistance with the often traumatic but appropriate transition to the next phase of life is probably more likely to meet the needs of patient and employer alike. For younger or transitional workers, early health concerns may be important signs of a constitutional mismatch between worker and job. In these instances, blind focus on treatment and return to work without consideration of larger issues may lead to costly and ineffective treatment options.

2. To what extent will work factors limit the range of options available for managing a work-related – or non-work related – health problem?

The willingness and ability of patient and employer to accept medical recommendations that dictate any but the most temporary or trivial change in work depend on many factors unrelated to health. Often, the patient is well aware of these constraints and will explicitly discuss them with the physician. Sometimes, however, they are couched in terms of health, leading to denial or exaggeration of certain complaints based on how the patient perceives they might translate into treatment recommendations. For example, if a patient is struggling with a particular supervisor, factors attributed to that supervisor or work area may be accentuated to the exclusion of other important environmental issues at the workplace. Likewise, a task that is frustrating or onerous might be presented as painful or dangerous. The best approach for the clinician to take is to attempt to elicit these non-health-related factors about the patient's job as early and as explicitly as possible. Such knowledge offers the best way to avoid confounding diagnostic issues by social factors and to focus clinical choices.

Exploring the home and family situation

Although knowledge of family is crucial in the practice of medicine generally and is a usual part of every clinical history, home and family considerations have special importance in the practice of OEM. Work may be a major family stressor because the demands of the individual's job compete against those of his or her family for time and energy. In some cases the earliest effects of work-related

illnesses, such as noise-induced hearing loss or central nervous system dysfunction due to metals, solvents, or pesticides, may be first recognized because of their impact on family functioning rather than work functioning. Conversely, stresses within the family may result in changes in work performance, which, in turn, may enhance stresses on the job. Further, perception of risk may differ between those in the work environment, where certain hazards are seemingly accepted, and the family setting, where the possibility of illness or injury is deemed threatening or even unacceptable.

A special consideration in occupational practice is the impact occupational injury or disease may have on family dynamic. A spouse, currently not working or underemployed, may find him- or herself pressed into the role of primary household provider. With family roles other dynamics may also change, stressing primary dependency needs or other dysfunctional responses. These pressures can enormously impact the perception of the patient about what is going on, and the range of options perceived by the patient and family as acceptable. Such stressors may also serve to delay recovery (in patients prone to dependency) or lead to inappropriate risk taking before full recovery (in patients averse to being dependent).

In environmental health outside the workplace, the family takes on a whole new dimension. Here, the home itself may be the focus of concern, because of a hazardous substance perceived to be in the air, walls and furnishings, or water supply. This threat to family health may have symbolic importance that in some cases exceeds health risk or impact. Not only is the home important symbolically, it is often the foundation of the family's economic and social security. People are not easily moved from their homes, even under the direst environmental threats. The prospect of reduced property values based on environmental risk also sharply heightens the sense of threat. The fact that levels of harm or risk from contaminants in or near the home often are modest compared with those in the industrial workplace must never translate into a lesser level of concern or attention paid by clinicians.

Environmental concerns in and around the home also severely stress family dynamics and roles. Often there are issues of blame and responsibility for contamination lurking below the surface, e.g., 'it was *your* idea to build that', or 'it was *you* who wanted to move here', etc. Moreover, the house may have different meanings or value to different family members, whose differing responses to the threat may prove dysfunctional or problematic as therapeutic choices are considered. As in the occupational situation, the most important ramification for practice is to explore these issues in every case, and deeply in circumstances where evident issues surface.

The agenda of third parties

As noted above, OEM is unique among medical specialties in the high fraction of patient referrals initiated by non-physicians, such as employers, insurance companies, and lawyers. Even when patients are referred by physi-

cians, the underlying agendas of outside parties often account for the referrals. Of course the interests of these parties, like the special interests of the patient and family addressed above, do not alter the actual diagnosis or risk. However, like the agendas of the patient, the interests of these parties may serve to distort reality or limit access to information and could, unless recognized, interfere with the clinician's ability to make a correct diagnosis or risk assessment.

Beyond the diagnostic stage, the interests of outside parties have an impact on the range of therapeutic choices, whatever the correct diagnosis. For example, a lawyer or outside advisor might be advising the patient that return to modified work would result in diminished worker compensation payments in the future, resulting in patient resistance to this option. For all these reasons, the current or potential interest or perceptions of each of the major third parties, including employers, lawyers, and insurance carriers, must always be assessed as part of the evaluation of any significant occupational or environmental medical problem.

THE ETHICS OF OCCUPATIONAL AND ENVIRONMENTAL MEDICINE PRACTICE

Relatively little attention has been given to ethical issues faced by physicians who provide healthcare to workers or to those with other environmental concerns or risks. Until now, the focus of the limited ethical debate has largely centered on occupational physicians employed by industry. This focus has neglected the important role of primary care physicians, who frequently face the same ethical dilemmas and are often the point of first contact with the patient. The following discussion identifies ethical issues to be considered by providers regardless of practice setting, recognizing that the dynamic legal and regulatory environment surrounding OEM practice may introduce further complexities.

Ethical problems arise often for physicians who provide health services to workers, although many would argue that it is the frequency rather than the nature of the issues that distinguishes the practice of OEM from other specialties. In fact, the ethical principles universal to all clinical medicine can be applied reasonably to the circumstances of providing healthcare to individuals with known or suspected occupational and environmental conditions. All of these issues, as well as special issues in OEM, such as preplacement or independent medical examinations, are discussed in greater detail in Chapter 55. The following section provides an overview of the principles as applied to six aspects of OEM practice.

Awareness of occupational and environmental health

Physicians are understandably challenged and even intimidated when considering the rapidly changing and grow-

ing field of occupational and environmental medicine, and discerning strategies to incorporate relevant material into traditional clinical practice. Increasingly, the patient brings questions of environmental concern to the physician's attention. And physicians, although seen as trusted sources of information, have become identified by patients as generally not well informed about these matters. Many factors have been identified as contributing to physicians' inadequate knowledge about and underinvolvement in the occupational and environmental health arena, including: insufficient medical education; isolation of many of these services and reimbursement from mainstream medical practice; and the increasingly complex array of potential exposures and known, let alone suspected, health effects arising from them.

Nonetheless, the physician in OEM, as in other areas of medicine, has an ethical obligation to be as informed as possible and, perhaps most importantly, to recognize when his or her own knowledge or experience is insufficient to resolve the problem and consultation is needed. In much the same way that a generalist might ask a cardiologist for assistance with a case, physicians faced with potential occupational and environmental health problems that are beyond their own capabilities or resources should seek professionals with appropriate expertise. This minimum standard, maintaining awareness about occupational and environmental health risks or conditions, is a fundamental ethical principle and one that, at least in the United States, is likely to be accompanied by legal responsibility as well. Judicial opinion has held that the physician exploring a health problem that may have an occupational basis bears a responsibility to inquire fully into the work history of a patient.

The physician-patient relationship

The physician-patient relationship is the foundation on which virtually all activities in clinical medicine rest. This relationship is frequently challenged in occupational and environmental medicine practice, but ethical and legal considerations common to general medical practice can be applied even to situations seemingly unique to this field.

Loyalty

Long a basic tenet of medical ethics in general, the primary loyalty of a physician is to his/her patient. Although there is evidence to substantiate the concern among workers that physicians employed by industry have not always followed this dictum, the issue of loyalty is by no means confined to the company physician. Physicians in all aspects of clinical practice may face the challenge of having payment and referral sources shape the nature of their interaction with the patient; pressure to respond to competing needs is sometimes explicit and often implicit. Whether the pressure arises from the direct financial interest of an employer or cost containment effort of an insurance carrier or preferred provider organization, the response to it may not always serve the patient's best interests.

Physicians providing occupational and, to a lesser extent, environmental health services must appreciate that although ideally both the patient's and any third party's interests are best served by the same good medical practice and preventive interventions, these ends can and do at times come in conflict. In these challenging but not infrequent situations, the physician must rely on the primary ethical responsibility to serve the patient's needs first. This mandate is derived from the larger context of the physician–patient relationship, although a possible exception is the setting of preplacement examinations, which is discussed later in this section.

Confidentiality

The patient's right to confidentiality in all aspects of the physician–patient relationship is another basic principle of medical care. Perhaps more than in most areas of specialization, the disclosure of information about evaluation and treatment of known or suspected occupational or environmental conditions has the potential to cause serious harm to the individual and may affect the individual's employment security. Although recent regulatory efforts in the United States and elsewhere have tried to ensure that information obtained from medical records cannot be used to block hiring or continued employment, the information can still be seriously damaging. In caring for individuals with occupational and environmental conditions, once a doctor–patient relationship is formed, the usual rules of confidentiality should apply.

Confidentiality refers to both the written and verbal release of information. Medical records should be maintained to optimize protection; patients should sign a release form for any information that is to be disclosed to a third party (and he or she should have a reasonable understanding of the implications of doing so), and no record should be released to a third party unless the patient has signed a release form. Just as important, patients must be informed of the special circumstances in which confidentiality cannot be protected. For example, once a workers' compensation claim is filed, confidentiality can no longer be protected in reference to information relating to that claim because the employer and appropriate agencies have legal access to it. Medical records can be subpoenaed, as will often happen if the patient becomes involved in litigation such as third-party liability. Mandatory reporting of occupational diseases in many countries and jurisdictions contributes another breach of the usual confidence; the patient should be so advised.

The over-riding ethical obligation to maintain patient confidentiality is not absolute, and there are situations other than those legally mandated in which it may be more appropriate to reveal than withhold information that the patient wishes to be kept confidential. Such decisions to violate confidentiality undoubtedly should be rare and need serious consideration on a case-by-case basis. In addition, the circumstances in which they may arise are not unique to OEM. They fall in two general categories: either in the patient's best interests or because of an over-riding duty to protect the public health (such as notification

of contacts in venereal disease cases). What arises more commonly in OEM practice than in virtually all other fields is that the detection of disease or hazardous exposures in one person may point to the probability that the same problem may arise with other coworkers, household members, and community residents. In instances in which concern about others is sufficiently high, consideration must be given to the serious step of breaching confidentiality.

Patient advocacy and conflicts of interest

Practitioners who provide occupational or environmental medicine services, particularly those who do so in the context of a broader general practice, may face the challenge of making objective decisions about patient illnesses and employability when they have a personal, emotional, or financial interest in these patients and their families. This potential conflict, of course, is not unique to the occupational or environmental health arena; society relies on physicians to undertake a number of activities that are aimed primarily at societal welfare rather than the benefit of individual patients or their families.

Included in these are physical examinations for insurance, participation in sports, or disability purposes. Here, it is either the public at large or some subset, including special interest groups, who ask the physician to make judgments that may differ from an individual patient's desires or interests. The physician often can decline to perform such evaluations; however, this approach is not always possible and, even when it is, does not necessarily result in an equitable solution. The best approach to use in cases in which patient advocacy may conflict with the physician's objectively performing an appropriate and reasonably requested social function is to apply ethical principles of loyalty and confidentiality and to inform the patient fully of explicit and implicit uses of such information. The specific circumstance of medical screening that may stress the physician–patient relationship either for or against advocacy is discussed in Chapter 3.

Disclosure to patients

Another fundamental aspect of the physician–patient relationship is informing patients fully about their conditions, including reasons for and against various diagnostic and therapeutic strategies. In conditions related to occupational or environmental factors, this requires full discussion about the implications of undertaking evaluations, including legal or other constraints on protecting confidentiality, and the implications of treatment interventions. The last-mentioned issue is particularly important given the major impact of therapeutic choices that may include job or home modification or relocation so that the individual can avoid continued hazardous exposure. The physician has a responsibility to discuss the range of reasonable choices, acknowledging that sometimes the optimal medical choice may be forsaken for one less ideal

because of the social, economic, or legal ramifications. Included in the ethical responsibilities of disclosure are providing information and participating as dictated by local custom and regulations in the workers' compensation process, however irksome.

Reporting to third parties

In addition to disclosing information about environmental risks to the patient, the physician has an ethical and occasionally legally mandated responsibility to notify third parties (e.g., employers, agencies, insurance carriers) who would benefit from information derived from the physician-patient relationship. The potential to instigate meaningful preventive activities by undertaking this follow-up of suspected or known occupational or environmental diseases or risks is one of the most satisfying aspects of clinical practice in OEM. In the United States, legal responsibilities to report these conditions vary considerably from state to state; however, independent from legal mandates, physicians should identify the most appropriate means to report these risks or conditions.

Examples of reporting include: notifying local or state health departments, regulatory agencies, employers, and unions; publishing in scientific journals; and, in certain instances, informing the public through the media. Which, if any, of these avenues should be pursued depends on numerous factors, including the seriousness of the risk and the likelihood of occurrence in others. Unless there are extraordinary reasons to do otherwise, all actions should be taken with full respect for the promise of confidentiality inherent in the physician-patient relationship. The following sections are a brief overview of those parties the physician should consider contacting in dealing with cases of known or suspected occupational and environmental diseases or hazards.

Employers

After a thorough discussion with the patient about the implications of doing so, the employer, whenever feasible, should be informed about workplace hazards or conditions. The employer is in the best position to undertake preventive action and further environmental or medical assessment as needed. In addition, the employer may be able to provide the physician with additional data on the nature and intensity of exposures that will enhance clinical evaluation of the patient.

Labor unions

In occupational health practice many patients will be members of labor unions. Unions vary in the extent to which they become involved in workplace health and safety issues. In some instances the union may be able to provide valuable exposure information and may directly or indirectly identify other coworkers at risk. They also may be well positioned to optimize the likelihood of appropriate interventions. As with other third parties, the patient must first consent before anything is reported to a union.

Health agencies and referral centers

Local, regional, and national health agencies play variable roles in occupational or environmental health issues. In some settings, the health agency may be the best place to report initially a known or suspected hazard, with subsequent appropriate follow-up delegated to the agency. In other instances, specialty referral centers, such as those affiliated with academic medical centers and hospitals, are best equipped to follow up the results of an individual evaluation. In the United States, the National Institute for Occupational Safety and Health (NIOSH), in addition to its training and research functions, provides consultation services about hazardous workplaces, a function also provided by some state and local health departments.

Regulatory agencies

A number of regulatory agencies, such as the Occupational Safety and Health Administration (OSHA) in the United States, can provide assistance to the physician and respond to reports of occupational hazards or unsafe conditions. In some situations OSHA or its equivalent may be able to provide, on employer request, consultation about workplace hazards without threat of reprisal for violations of the law or best practice. On the other hand, if circumstances warrant and after confidentiality considerations have been reviewed, a physician may file a complaint about a workplace hazard, which, in turn, should generate a regulatory inspection. Although such complaints can be made anonymously, the physician should appreciate and advise the patient that the nature of the complaint may nonetheless result in their identification and possible subsequent harm.

Similarly, agencies that are involved in control of the non-workplace environment, such as the federal Environmental Protection Agency (EPA) and related state and local agencies in the United States, may be contacted. In both occupational or other environmental settings, these agencies may also have valuable information about exposures and results of past investigations or monitoring that may aid the physician in the clinical assessment.

News media

Often parties impacted by environmental or occupational hazards, or their health providers, may perceive the news media as a particularly rapid and effective means of disseminating information. While this is undoubtedly true, it must be borne in mind that such media are neither peer reviewed nor without their own strong agendas – for drama, conflict, human interest and polarization. While this may make good copy, it often serves to confuse issues and inflame already complex health situations. In general, practitioners should resort to this pathway only as a very last resort. Even when reporters directly approach the practitioner for information, extreme discretion is advised: what a clinician believes he or she has said may or may not be what a reporter has heard, or what his/her editor chooses to print or show on television as a soundbite. These issues are further discussed in Chapter 60.

Litigation

Hanging over many occupational and environmental health situations is litigation – actual, threatened or feared. Other than workers' compensation, a no-fault insurance scheme, the demands of litigation often lead to hyperpolarization and extreme responses, severely limiting clinical

options. These issues are discussed in detail in Chapters 56 and 57. For present purposes, suffice it to say that practitioners should always assess whether legal action is pending or anticipated, and appreciate the possible role(s) it may play in delimiting the behaviors of patient and third parties alike.

Chapter 10

Susceptible Populations

Jessica Herzstein

Our society has become increasingly concerned about the health consequences of exposure to chemical and physical agents in outdoor and indoor environments. As we acquire more knowledge regarding the basic adverse health effects of the spectrum of environmental exposures, it is becoming clear that certain groups are more susceptible to the toxicity of specific environmental exposures than is the general population. These susceptible groups may experience exposure-related health problems that others do not have at all, or the health effects may be more severe or occur earlier in time or at a lower exposure levels than is seen in the general population.

Public policy is beginning to reflect the need to consider differences in vulnerability among subpopulations. For example, USEPA cancer guidelines promote the incorporation of information on susceptibility.¹ The Presidential Commission on Risk Assessment and Risk Management has recommended that the USEPA use accurate data on susceptible populations, including molecular epidemiology and other population-based information, to determine the magnitude of variability in disease risk. Human risk assessment methodology in current use does not usually include measures of susceptibility.² Another example of public policy responding to the potential for health effects in a vulnerable population is the agreement by USEPA and manufacturers to eliminate the application of the insecticide chlorpyrifos in places where children could be exposed (homes, schools, day-care centers, stores, etc.). The 1996 Food Quality Protection Act requires EPA to review pesticides to ensure they meet new standards specifically designed to protect children.³ The review of chlorpyrifos is part of that process.

Strategies to improve environmental health have focused on reduction of exposure in the workplace and in the indoor and outdoor environment. Societal interventions to lower risk have addressed the population as a whole (e.g., all persons with exposure above the maximum contaminant level (MCL) to arsenic or trichloroethylene (TCE)) and have not focused on genetic and acquired differences among individuals, which may allow development of more effective policies. Assuming similar biologic responses from all persons for a specified dose of a toxic agent may not offer sufficient protection for certain subgroups.⁴ Default safety factors used in human risk assessment are controversial and may be overprotective or underprotective of certain segments of the population. Developing standards for environmental quality that protect the average person has been criticized for overlooking vulnerable groups who may suffer significant harm

from low-level exposures. Principles for applying greater precaution to children's environmental health policy have been proposed.⁵ More mechanistic information is needed in order to understand how genetics, behavior, and age influence an individual's response to an environmental agent.

The goal of this chapter is to review major subgroups within the larger population who may be particularly susceptible to environmental exposures. Existing data on common exposures that may cause increased toxicity for certain groups are summarized, emphasizing those populations at risk and exposures on which some empirical information is currently available or on which a risk-exposure relationship is anticipated on theoretical grounds. For most environmental chemicals, data on susceptible subgroups have not been collected. Most of the existing data are controversial or preliminary. Research focusing on identification of markers for host susceptibility has identified promising areas but also significant limitations. To date, markers for host susceptibility have minimal clinical applications.⁶

As a caveat, it must be emphasized at the outset that host-response differences are highly complex. In many areas, only one aspect of an obviously multifaceted problem has been studied. In turn, studies have conspicuous methodological flaws. Issues such as dose and duration of exposure, documentation of exposure, and presence of confounding factors arise with most of the populations and hazards studied. Therefore, no attempt is made to offer definitive answers to these important questions, nor should any of the following information be applied dogmatically in practice. Although clinicians need to know how these adverse effects can be recognized early, treated, and prevented - and policy makers need to ensure protection from environmental hazards for some sensitive populations - the main objective here is to define the scientific basis for the role host factors play in response to specific environmental agents.

A person's response to environmental agents is affected by physiologic variables including exposure routes and absorption (respiratory minute ventilation, dermal penetration, etc.), pharmacokinetics (distribution, metabolism, excretion) and pharmacodynamics (receptor density and specificity, target organ). These variables are each significantly affected by constitutive factors (genetics, age, gender, ethnicity) and acquired factors (altered health state, effects of previous or concurrent exposures, diet, exercise, and stress). To simplify these complex sets of possibilities, three main groups of host factors are presented:

Behavioral, genetic, and lifestyle factors
Genetic factors
Tobacco smoking
Ethanol intake
Stress
Dietary intake
Age-defined populations
Fetus and child
Air pollution
Indoor air pollution
Carcinogens
Neurotoxins
The elderly
Neurotoxicants
Air pollution
Carcinogen exposure
Risks associated with pre-existing conditions
Chronic lung disease
Asthma
COPD
Heart disease
Diabetes
Obesity

Table 10.1 Host factors modifying environmental susceptibility

personal (lifestyle, genetic, behavioral), age related, and underlying disease related. These factors are summarized in Table 10.1.

GENETIC, BEHAVIORAL, AND LIFESTYLE FACTORS

Genetic factors

In contrast to the increasing amount of data about the effect of biologic phenotypes on risk of environmental susceptibility, scant empiric data exist regarding the relationship between genotype and disease susceptibility. It is widely recognized by experimentalists and epidemiologists that hosts vary enormously in their response to comparable doses of environmental agents. However, the number of genetic polymorphisms or identifiable genetic differences that have been pinpointed to explain such differences are few. Susceptibility occurring on the basis of genetic variation is likely to play an increasingly important role in risk assessment. Genetic modulation of exposure risk incorporates the concept that following exposure at

low levels, disease can be detected only among sensitive genotypes. These genotypic subgroups may herald risks for the greater population.

A great deal of research now focuses on genetic polymorphisms impacting the risk of cancer. The polymorphisms involving metabolic enzyme genes, cell cycle control genes and DNA repair have complex effects and their specific roles in different cancers are unclear. Areas of promising work in polymorphisms affecting lung cancer include the following: myeloperoxidase-induced metabolism of benzo[a]pyrene which results in DNA adducts and mutation; glutathione S-transferase which activates and deactivates carcinogens and can promote elimination of anticarcinogens such as isothiocyanates; and DNA repair genes. Understanding which are the common genes impacting cancer risk has been a slow process involving a few genes at a time in case control studies. Future work will likely benefit from advances such as nested cohorts, non-invasive specimen collection, and rapid genotyping.

Susceptibility genes, defined as common polymorphic genes found in over 1% of the population, affect activation and detoxification of environmental agents. Specific environmental exposures are required to induce disease associated with susceptibility genes. Although only a modest risk of disease is associated with carrying these genes, they pose an important public health problem because large numbers of people can be affected. An overview of common polymorphisms that interact with environmental agents to cause cancer and other diseases is presented in Table 10.2.⁷⁻⁹ Differences in the expression of these enzymes are likely to yield differences in susceptibility to both carcinogenic and non-carcinogenic exposures. The onset and the severity of the resulting disease are determined by the combination of genetic and environmental factors.

Epidemiologic studies of polymorphic metabolic genes have concentrated on cancer. Less than 20% of long-term smokers develop lung cancer in their lifetime. Genetically determined factors that negate the effects of environmental carcinogens may explain differences in susceptibility. Lung cancer risk is dependent on the dose of tobacco carcinogens. This dose is modulated by genetic polymorphisms in the enzymes that activate and detoxify these carcinogens, as well as by the efficiency of host cells in

Cancer: metabolic (activation and inactivation)	Cancer: DNA repair	Non-cancer
cyt P450 (CYP)-dependent oxygenase systems (PAHs and lung cancer)	DNA repair capability measured as mutagen sensitivity (e.g. to bleomycin) (Ataxia telangiectasis, Fanconi's anemia, xeroderma pigmentosum)	Paraoxonase: inactivation of toxic metabolite (paraoxon) of organophosphate & carbamate pesticides (neurologic disease)
Glutathione S-transferase (GST)		Alpha antitrypsin (emphysema)
(a) metabolize mutagenic intermediates of CYP-mediated oxygenation reactions		HLA alleles (may be associated by beryllium oxide-induced lung disease and acid anhydride-induced asthma)
(b) metabolize PAH constituents of tobacco smoke (lung cancer and bladder cancer)		Aminolevulinatase dehydratase (lead retention)

Table 10.2 Genetic polymorphisms associated with environmentally related disease

monitoring and repairing DNA damage caused by tobacco carcinogen. Recent research has shown that individuals with susceptible genotypes tend to develop lung cancer at earlier ages and with lower levels of tobacco exposure than do individuals with non-susceptible genotypes.¹⁰ Forthcoming technology will enable the performance of large-scale and low-cost genotyping of nested cohorts and will allow the identification of smokers with the highest risk of developing cancer. These individuals would be candidates for the most intensive preventive interventions.

The metabolism of xenobiotics involves hydrolysis, oxidation and other reactions that lead to the formation of compounds that are more hydrophilic. The enzymes involved in the biotransformation reactions include cytochrome P450 (CYP), alcohol dehydrogenase, aldehyde dehydrogenase and glutathione S-transferase (GST). Bladder cancer and lung cancer occur at a higher frequency among persons with defective GST genes. Fifty to sixty percent of Caucasians and 30% of African-Americans are homozygous for the null allele of GSTM1; this is associated with a higher risk for lung and bladder cancer and possibly skin and colon cancer. The elevated cancer risk requires gene-environment interaction; non-smokers with GSTM1 null phenotype do not show elevated risk, whereas smokers with the phenotype have a 2–6 times higher cancer risk. GSTM1 homozygous null phenotype has also been associated with a statistically significant lung cancer risk in never-smoking women exposed to high levels of environmental tobacco smoke (ETS).¹¹

The CYP family of enzymes includes many genetic variants and a wide spectrum of interindividual variability exists in humans, resulting in up to a 10-fold difference in metabolic activity by CYP. Smoking-induced lung cancer has been associated with altered genotypes in several CYP450 enzymes.¹² CYP2E1 metabolizes over 80 xenobiotic substances, including nitrosamines and chlorinated solvents. A wide range of interindividual variability (10–50-fold) as well as inter-racial variability has been observed with CYP2E1 activity. Molecular markers have documented differences in these metabolic genes among certain populations. Lacking data relating polymorphisms directly to enzymatic activity, the markers are not currently useful clinically for predicting disease risk.

An individual's genetic make-up also plays an important role in determining his or her susceptibility to environmentally related illness other than cancer. For example, the increased sensitivity of some persons to the effects of lead may be due to the existence of genetic polymorphisms in delta-aminolevulinic acid dehydratase (ALAD). Individuals with ALAD1 allele are more likely to experience toxicity with lead exposure. Notably, lead workers have a higher prevalence of the ALAD2 allele.⁸ Occasionally, a genetic predisposition may require an environmental exposure for expression of disease. For example, multiple sclerosis appears to require the combination of a specific genetic factor and exposure to an unidentified environmental factor prior to adulthood. Also, males with the X-linked glucose-6-phosphate dehydrogenase deficiency are predisposed to hemolytic crises from a number of oxidizing

drugs, naphthalene, and fava beans. Such individuals are more likely than others to develop hemolysis following exposure to oxidizing chemicals in the workplace (documented with trinitrotoluene).

Inherited homozygous α_1 -antitrypsin deficiency is associated with a markedly increased risk of pulmonary emphysema. Persons with the heterozygous carrier state may be at increased risk of obstructive lung disease if they are tobacco smokers. Tobacco smoke has been shown to decrease the lung's capacity to inhibit proteolytic enzyme action. There is evidence to support the hypothesis that amyotrophic lateral sclerosis, a degenerative neurological disease of unknown etiology, involves genetically determined metabolic pathways that increase susceptibility to one or more environmental toxins. Genetic susceptibility, in combination with environmental exposures, may play a role in many common diseases, such as coronary artery disease, diabetes, asthma, peptic ulcer disease, and breast, colon, and lung cancers.

The N-acetyltransferase phenotype is another example of the potential effect of genetic differences in toxin metabolism on carcinogenesis. Arylamines, a class of potent bladder carcinogens, are detoxified by N-acetylation. Persons with bladder cancer have been shown to have an increased prevalence of the slow acetylator phenotype. Thus, in this case, genetic control of the rate of metabolism of xenobiotics may affect the risk of carcinogenesis. The acetylator phenotype is known to play an important role in interactions between chemicals in the environment and in drug-chemical interactions. The metabolism of tobacco and alcohol-derived carcinogens may also be genetically determined. Large interindividual differences have been found in both the activity and DNA binding of benzo[a]pyrene, a potent carcinogen in cigarette smoke, likely due to inherited differences in the P450 enzyme system responsible for its metabolism.

Another important process in carcinogenesis, the ability of cells to repair DNA damage, may also be affected by environmental exposures. The best-studied example of a heritable genetic abnormality associated with a markedly increased susceptibility to environmentally induced cancer is the autosomal recessive disease xeroderma pigmentosum. Persons with this disease develop multiple skin cancers in sunlight-exposed areas of the body, often within the first few years of life. The somatic cells from these patients have a defect in the repair process for DNA base-pair damage induced by ultraviolet light. The cells are highly sensitive to a variety of carcinogenic chemicals and ultraviolet light.

Behavioral and lifestyle factors

Tobacco

Tobacco use, alone or in combination with alcohol, is the most important cause of cancer in developed countries. Active smoking or direct exposure to other tobacco products accounts for almost all cases of tobacco-related cancer. However, non-smokers who are exposed to sidestream

smoke from burning tobacco and to mainstream smoke exhaled by smokers appear to have a small increase in risk of lung cancer and perhaps other cancers.

Active smoking is associated with the development of chronic obstructive lung disease and cardiovascular disease. There also is evidence that tobacco smoking increases a person's risk of chronic lung disease associated with other air-borne exposures. A number of possible mechanisms for interactions between tobacco smoke and other environmental pollutants have been theorized. Cigarette smoke can increase exposure to other inhaled carcinogens by altering the normal mechanism of absorption, distribution, and clearance. The irritants in cigarette smoke – including hydrogen cyanide, acrolein, formaldehyde, and nitrogen oxides – induce ciliostasis, thereby impairing clearance and permitting larger doses of pollutants access to the lungs. In addition, aerosols are deposited differently in the lungs of smokers than in the lungs of non-smokers. Tobacco aerosols enhance particle deposition in the central regions of the lungs. Lung clearance mechanisms are less efficient here than in the upper respiratory tract. Smokers, for example, have dramatically increased long-term retention of some dusts in the lung compared with non-smokers.

There is evidence that lung cancer occurs at a higher frequency in a susceptible subgroup of smokers and former smokers. Current research aims to identify who is susceptible (e.g., testing for genetic polymorphisms and in-vitro assays for mutagen sensitivity) and then focus on behavioral change, chemoprevention and other primary and secondary prevention methods in this high-risk population.

The cigarette smoker is considered to be susceptible to an environmental exposure if there is an additive effect or greater-than-additive effect (synergism) between smoking and the exposure. Such synergism has been documented for a wide range of respiratory toxins. Grain dust and cotton dust act synergistically with smoking to increase coughing and phlegm production. Additive effects have been observed with smoking and the development of symptoms and decrements in lung function with exposure to grain dust, coal dust, and other agents. Less-than-additive effects also may exist; tobacco smoking may reduce the risk of the non-malignant effects of silica exposure.

In occupational settings with heavy long-term exposures to asbestos, tobacco and asbestos have been shown to act synergistically to cause an increase in lung cancer rates. Among insulators, for example, the risk of lung cancer increases 10-fold with tobacco smoking, 5-fold with occupational asbestos exposure, and 50-fold with both exposures. Asbestos is present in the ambient environment and in many buildings. The cancer risk associated with low-level ambient asbestos exposure superimposed on tobacco smoking has not been well defined.

The relative excess of proteases over antiproteases in the lung in smokers has been associated with the development of emphysema and chronic airflow obstruction. One theory is that exposure to environmental agents other than tobacco may increase the relative excess of proteolytic enzymes in the lung parenchyma and, thus, increase the risk of emphysema in smokers who already have an excess

of proteases. Environmental agents also could interact with the effects of smoking to cause a deterioration in the level of chronic airflow obstruction by contributing to airway pathology. A wide range of agents can exacerbate airways disease, including respiratory irritants such as oxides of nitrogen, ozone, chlorine, and sulfur dioxide (SO₂).

Smoking may enhance systemic effects of toxins as well. The cigarette, or its smoke, may interact with physical or chemical agents, causing new adverse effects. For example, polymer fume fever, which develops in some Teflon manufacturing workers, is caused by the transformation of inert fluorocarbon polymers into toxic decomposition (pyrolysis) products by the heat of burning cigarettes (see also Chapter 41). Tobacco can serve as a vector for entry of chemicals into the body by inhalation or by ingestion. Smokers exposed to agents such as lead, mercury, carbonyl, organotin, inorganic fluoride, methyl parathion, boron trifluoride, and formaldehyde have developed more systemic effects than similarly exposed non-smokers. Tobacco smoke has been reported to increase the risk of development of sensitization by inhaled occupational asthmagens. Smokers also may be more susceptible to infectious agents in the environment. Studies of smokers reveal an increase in incidence of respiratory infections as well as impairment of bactericidal activity such as macrophage phagocytosis.

Alcohol consumption

Alcohol consumption is now known to be a major factor affecting human susceptibility to a broad spectrum of environmental and industrial contaminants. The health of persons who are not heavy drinkers may be affected by the interaction of ethanol with pollutants and drugs. For example, beer may modify the metabolism of nitrosamines and theoretically increase cancer risk. The interactions of alcohol with inorganic agents and with a wide variety of organic drugs, industrial chemicals, and pollutants have been reviewed in depth.¹³ The interaction of alcohol with a few important environmental agents affecting the liver, kidneys, heart, and carcinogenesis is presented here.

Ethanol can enhance the hepatotoxic effects of some chemicals. Ethanol potentiates the toxicity of carbon tetrachloride in humans and animals. Administration of ethanol concomitant with carbon tetrachloride has been shown to increase the toxicity of the latter, probably through induction of the mixed function oxidase (P450) system. It is likely that a similar toxicity pattern exists for ethanol combined with other hepatotoxic agents, especially those that require bioactivation in the liver (such as the solvent trichloroethylene, TCE).

Alcohol consumption (or exposure to alcohols in industry) can potentiate the toxic effects of chemicals on organs other than the liver. For example, induction of the mixed function oxidase system by alcohol may enhance the bioactivation of carbon disulfide, resulting in increased neurotoxicity and hepatotoxicity. Acute ethanol consumption also magnifies the central nervous system effects of TCE.¹⁴

Ethanol may act to enhance the potency of a number of different chemical carcinogens. Animal studies suggest

that the increased incidence of cancer among alcoholics may be attributed partially to the enhanced ability of these individuals to bioactivate procarcinogens (such as benzo[a]pyrene and dimethylnitrosamine) in the intestines. Investigators using animal models have concluded that ethanol can increase the rate of formation of toxic metabolites from benzene. Animal data suggest that ingestion of ethanol enhances the hematotoxicity of inhaled benzene. Extensive studies have shown that alcohol also may directly affect carcinogenesis at different stages of initiation and promotion. Chronic ethanol exposure results in an up to 10-fold induction of CYP2E1 activity. This has the potential to increase the formation and elimination of toxic metabolites. Some authors have recommended that physicians warn heavy alcohol users regarding a potential increase in adverse health effects from environmental chemicals.¹⁵

AGE-DEFINED POPULATIONS

The extent to which those at the extremes of age (the young and the elderly) may be more susceptible to certain toxins and why is addressed in this section. Because these subpopulations include a high proportion of the total population, a very large sector of society may be placed at risk when exposures occur. The United States government has generally taken into account the susceptibilities of the very young in establishing national exposure standards. For example, the Environmental Protection Agency (EPA) has set a drinking standard for nitrate that minimizes the risk of nitrite-induced methemoglobinemia in infants, the most susceptible group. The EPA, the Food and Drug Administration (FDA), and the Consumer Product Safety Commission have attempted to reduce exposure to lead in drinking water, food, ambient air, and paints in order to protect children from irreversible neurological damage.. Although in theory the elderly may be more susceptible to environmental exposures for a number of reasons¹⁶ there is a paucity of research in this area and, therefore, very little regulatory policy.

The fetus and child

Exposures during the prenatal and childhood periods may result in more frequent or severe adverse health effects, or both, than do exposures of adults. The current areas of concern regarding the susceptibility of children include (1) respiratory effects of outdoor and indoor air pollutant exposure, (2) cancer caused by environmental exposures, and (3) the neuropsychologic effects of metals such as lead. The potential for increased sensitivity of the fetus, infant, and child to adverse effects from environmental exposures may be attributed to several mechanisms (see Table 10.3). These critical periods of developmental vulnerability deserve particular attention, given the potential risk to the entire population.

Recently, risk exposure experts and other scientists have challenged the assumption that children are more susceptible to environmental toxins than adults.^{17,18} Sensitivity

Mechanism	Example
High number of rapidly dividing cells (fetus)	Radiation injury
Immaturity of enzyme activity (infant), e.g. superoxide dismutase, methemoglobin	Oxidant injury
Increased absorption (GI, dermal, inhalation) per unit weight	Lead absorption
Immature blood-brain barrier (developing endothelial capillaries)	Lead-induced CNS injury
Immature immune system (infants)	Deficient antibody response
Increased exposure	Environmental exposure Indoor air pollution Lead dust and paint chips
Reference: Calabrese 1986, ³¹ Kane 1985 ⁴⁴	

Table 10.3 Enhanced susceptibility of the young

to a risk is a function of exposure and susceptibility. The following issues have been raised: (1) young animals are not always more sensitive to chemical-induced carcinogenesis, (2) rates of metabolism and clearance (e.g., of xenobiotics) are generally faster in children than in adults, (3) knowledge of dose-response relationships is too limited to predict whether stricter regulations improve children's health (current exposure levels may be below a threshold for effect), (4) data on children's actual exposures are inadequate to assess risk and therefore default assumptions are utilized. Agreement exists that additional research data are needed to accurately assess both the exposure and the inherent susceptibility of children.

The report *Pesticides in the diets of infants and children* written by the National Research Council in 1993¹⁹ brought international attention to the susceptibility of children and the lack of scientific research and data in this area. In 1996, the EPA developed the National Agenda to Protect Children's Health from Environmental Threats. The National Agenda mandates that the EPA ensure that its standards protect children, and instructs the agency to broaden research, policies and education in this area. The Food Quality Protection Act (1996) is the first environmental law to require explicit analysis of risk to children in establishing standards for pesticide residues in food.³ The 1997 Presidential Executive Order 13045 on Children's Environmental Health (1997) requires federal agencies to consider 'disproportionate risks' to children related to environmental health or safety in their programs and policies.²⁰

In-utero exposures

The fetus is particularly susceptible to a number of environmental toxins. The precise point of fetal development may determine the degree of risk (see also Chapter 27.2). Toxic agents usually exert the greatest risk for injury and malformations if exposure occurs during the embryonic period, when organogenesis is taking place. For most organs, this period occurs between the third and ninth weeks of gestation. The main development of the brain occurs later, between the eighth and fifteenth weeks of

gestation. Earlier exposures may increase the risk for spontaneous abortion, whereas later exposures may affect growth and development.

Intrauterine lead exposure causes greater chronic and irreversible neurotoxicity at lower levels than occurs in late childhood or adulthood (see Chapter 39.8). The greatest risk to humans from ionizing radiation occurs during the in-utero period. Studies of persons exposed in the atomic bombings of Hiroshima and Nagasaki have documented that the brain is most susceptible to radiation injury during fetal development. Exposure to radiation during this period increases the risk of mental retardation, small head size, seizure disorder, and poor performance on standardized tests of intelligence.

All forms of mercury can cross the placenta, with bioavailability to the fetus. The major concern rests with organic forms of mercury (e.g. alkyl mercury) the critical target organ of which is the brain. In-utero exposures can cause abnormal neuronal migration and disordered neuronal organization; psychomotor retardation may result. The threshold for neurological adverse effects is lower for prenatal than for adult exposure. Rates of neonatal exposure can also be significantly increased by nursing. The resulting neurotoxicity is usually irreversible.

Exposure to solvents in drinking water has been variably reported to increase the rates of spontaneous abortion and congenital anomalies by unknown mechanisms. Similar findings have been observed in studies of pregnant women occupationally exposed to solvents. In animal studies, there is evidence that solvents can be fetotoxic, although they usually are not teratogenic. Ethylene glycol ethers in particular have documented reproductive toxicity.

The fetus is particularly susceptible to acute toxicity from carbon monoxide (CO). CO readily crosses the placenta from the maternal bloodstream to the uterine bloodstream. The fetus is highly sensitive to CO-induced hypoxia. Low levels of CO (resulting in carboxyhemoglobin levels of 4% and greater) appear to be associated with deficits in cognitive and motor functions; such concentrations are without apparent effects in healthy children and adults. Neurologic sequelae reported include mental retardation, microcephaly, and cerebral atrophy.

The rapidly dividing cells of the fetus may increase its susceptibility to carcinogens. The fetus appears highly

sensitive to direct-acting alkylating agents, for example. However, fetuses may have lower levels of enzymes that activate procarcinogens and, therefore, may be more resistant to certain carcinogens. Other variables also affect fetal susceptibility to carcinogens. These variables include the differential transport of active metabolites from mother to fetus across the placenta, the status of cell differentiation in various tissues, and the capacity for immunosurveillance. In general, the fetal and infant stages of development should be considered highly susceptible to carcinogens until there is greater understanding of the fetal response to specific carcinogens.

Inhaled toxins

There is growing evidence that air pollutants may have a special impact on children's health. Of particular concern is the accumulating scientific data suggesting that (1) respiratory illness in childhood is a risk factor for the subsequent development of respiratory illness in adulthood and (2) lower respiratory tract illness in children may be a risk factor for chronic airways obstruction. The latter hypothesis holds that airway damage occurs during a vulnerable developmental stage and is followed by an excessive rate of decline in FEV₁ over many years, resulting in fixed airways disease.

The effects of air pollution on healthy children have been researched at length during the past four decades and have been reviewed by Angle²¹ and Balme²² and summarized by the World Health Organization.²³ Issues of particular interest have been the incidence and severity of respiratory symptoms, the reversibility of symptoms, the magnitude and duration of pulmonary function decrements, and the effect on the lungs' growth and development. The data concerning these potential health risks and how they relate to some common air contaminants are summarized in Table 10.4.

The impact of air pollution on the developing lungs of children has been partially substantiated by animal studies demonstrating effects on growth and airway function; human data are consistent with these animal studies. The Six Cities Study of Air Pollution and Health is an ongoing prospective epidemiologic study that began in 1974, which compares the health of populations living in cities with high pollutant levels with those living in less polluted areas.

Population at risk	Exposure	Effect
Children and infants	SO ₂ particulates, suspended sulfates, low-level air pollution	Increased rate of respiratory illness (Ware et al, ⁴⁵ Jaakkol et al ⁴⁶)
Children and infants	Acute pollution episodes with SO ₂ and total suspended particulate	Acute decrements in pulmonary function (Dockery et al, ⁴⁷ Dassen et al ⁴⁸)
Preadolescent children	Particulate pollution	Increase in chronic cough and chest illness (Speizer, ⁴⁹ Dockery et al ⁵⁰)
	Fine particles	Acute respiratory symptoms (Schwartz J ⁵¹)
	SO ₂	Persistent cough (Chapman et al, ⁵² Dodge et al ⁵³)
Children and adolescents	O ₃	Reduction in lung function (Spektor et al, ⁵⁴ Castillejos et al, ⁵⁵ Kinney, ⁵⁶ Braun-Fahrlander ⁵⁷)
Children	Air pollution	Reduction in single breath nitrogen test (Detels et al ⁵⁸)

Table 10.4 Effects of outdoor air pollution on normal children

The study has documented a strong association between rates of chronic cough, bronchitis, and chest illness in preadolescent children and measurements of pollution, including acid aerosols, SO₂ and NO₂. Asthma, persistent wheeze, hay fever and measurements of pulmonary function were not associated with any pollutant concentrations. Other studies also have documented an association between SO₂ exposures and persistent cough in children.

Studies assessing the impact of ambient NO₂ exposures on health have suggested an increase in respiratory symptoms in children, but these results have been controversial owing to simultaneous exposures to other pollutants and unreliability of the method for monitoring NO₂. Data from several epidemiologic studies of school-aged children suggest that low-concentration ozone exposure is associated with small short-term, reversible decrements in lung function and also may affect the rate of lung growth in children.

Fine particulates (e.g., particulate matter less than 10 µm in diameter, termed PM 10) are increasingly recognized as a potential source of serious adverse health effects, both systemically and in the respiratory tract. They constitute a diverse mixture of pollutants, including arsenic, lead, sulfates, and carcinogens, not yet covered by federal standards for ambient air quality. Suspended sulfates, a major component of acid aerosols, have been related to respiratory tract infections and decreased lung function in children. Unlike the larger particles, fine particulates are frequently deposited in the alveoli and they may be carriers of toxic and carcinogenic vapors, even if the particulates themselves are inert. The particulates also interfere with the ciliary-mucosal filter system in the bronchial airways, thus promoting the potential toxicity of other inhaled toxins. The lung clearance mechanisms in small airways, which protect airways in adults, function less effectively in the early years of life.

An ongoing prospective study²⁴ in 12 California communities is assessing children's respiratory health following chronic exposure to respirable particles (PM10 and PM2.5), O₃ and NO₂. Results after 4 years show a decrease in lung function growth among children living in polluted areas as compared with children who breathe cleaner air, and the effects are more pronounced in areas with higher pollutant levels. Children with decrements in lung function may be more susceptible to respiratory disease and may be more likely to develop respiratory conditions as adults.

Indoor air pollution (see also Chapter 50) is of particular concern for children because children spend a large percentage of time in the home during the first 5 years. The home environment contains many potential sources of air pollution. CO, NO₂, and other particulates are produced by cigarette smoke. Similar compounds and SO₂ are produced by combustion of biomass fuels and accumulate, for example, with the use of improperly vented wood or coal fireplaces or stoves, gas cooking stoves, kerosene heaters, or malfunctioning furnaces. Volatile organic compounds, asbestos fibers, radon gas, and aeroallergens also may be present in indoor air.

Children have been found to be susceptible to a number of health effects attributable at least in part to indoor air pollutants. Some of the major exposures and associated health effects are summarized in Table 10.5. It is important to keep in mind that conflicting data exist on most of these exposure-effect associations. Three products of incomplete combustion (NO₂, CO, and SO₂) are important contaminants of indoor air. CO can be measured in almost all indoor environments, especially in winter, and may on occasion exceed the National Ambient Air Quality Standards set by the EPA. Overt CO poisoning of pregnant

women causes severe adverse effects on the fetus. Ambient exposure to CO is thought to cause the reduced birth weight of infants that is seen following exposure to environmental tobacco smoke (ETS); sensitivity to CO after birth has not been established.

NO₂ levels are frequently higher in the home than outdoors owing to cigarette smoking and the use of gas stoves. Whether or not children who live in homes with gas stoves have altered lung function or an increased incidence of respiratory illness is controversial, although a number of epidemiologic studies have addressed this issue. There is evidence that school children may develop increased respiratory symptoms and, in some studies, decreased pulmonary function in atmospheres with mildly elevated concentrations of SO₂ and particulates.

Volatile organic compounds are common constituents of indoor air. Formaldehyde has been associated with an increased risk of the development of chronic respiratory symptoms and transient decrements in lung function. Infants have been reported to develop restlessness, red eyes, diarrhea, vomiting, rhinorrhea, and cough in homes with elevated levels of volatile organic compounds in the air. Apnea has been documented following exposure of animals to chemical irritants. Knowledge of these factors has raised the possibility that home air contaminants may contribute to the sudden infant death syndrome.

Exposure of children to aeroallergens such as house-dust mite allergens is increasingly recognized to be an important determinant of the subsequent development of asthma and atopic sensitization. The expression of genetic factors such as atopy and allergic disease may require environmental triggers in childhood in order to induce allergic responses.

Environmental tobacco smoke (ETS) poses a health risk for infants and children (see Table 10.5). National data estimate that approximately 50% of children aged 5 years and under are exposed to environmental tobacco smoke in their homes.²⁵ Studies have examined prenatal exposure, acute respiratory illness morbidity, chronic respiratory symptoms, asthma and bronchial responsiveness, and pulmonary function of children in relation to ETS exposures. ETS exposure of young children increases the symptoms of respiratory disease.²⁶ Maternal smoking during pregnancy has been associated with an increased risk for childhood asthma. ETS exposure among children is associated with an increased prevalence and severity of asthma.^{27,28} ETS exposure appears to increase the severity of asthma in those with pre-existing airways disease.

A reduction in lung growth during childhood may be a risk factor for chronic obstructive lung diseases. This predisposition may occur as a result of reduced peak lung volumes or accelerated ventilatory loss. The infants of smoking parents have increased rates of lower respiratory infections. It has been hypothesized that the altered pulmonary function in smoke-exposed children may result from these recurrent infections.

Children exposed to tobacco smoke in the home have increased rates of chronic ear infections and middle ear

effusions. Persistent ear infections may be more likely to develop in children with nasal allergies and recurrent otitis media who are exposed to ETS. Increased frequency of tonsillectomy and adenoidectomy has been identified in children exposed to ETS.

Parental smoking, including maternal smoking during pregnancy, has been associated with changes in neurodevelopment and child behavior, particularly hyperactivity, in a number of studies.²⁹ The many unexplored social, demographic, and psychologic confounding variables preclude any conclusion about a causal relationship.

Carcinogens

The young are at increased risk of tumor development following exposure to certain carcinogens. Elevated relative risks have been reported for radiation-induced thyroid tumors, skin cancer, adult-onset leukemia, and vinyl chloride-induced angiosarcoma.

Prenatally exposed survivors of the atomic bombings in Japan appear to be more susceptible to radiation-induced cancer than those who were exposed after birth. Controversy remains over whether or not preconception exposure (maternal or paternal) to ionizing radiation can cause genetic mutations or heritable effects. Epidemiologic studies have failed to document a relationship between low-frequency magnetic fields in the home and outdoors with childhood cancer.

Transplacental carcinogenesis has occurred with diethylstilbestrol and could theoretically occur with other environmental exposures. In addition to chemicals and ionizing radiation, children may be at increased risk of developing cancer compared with adults following exposure to sunlight. Analyses of the relationship between ultraviolet light and melanoma suggest that childhood exposures may be disproportionately important. Children also may be particularly susceptible to carcinogens, such as aflatoxins and nitrites, found in food. Despite these several associations and theoretical reasons for suspecting that children are at greater risk from carcinogen exposure, empiric data for excess risk do not exist for most carcinogens.

Interindividual differences are known to play a role in susceptibility to environmental insults that increase cancer risk (e.g., asbestos, alcohol, and tobacco). Heritable differences in susceptibility have been identified at almost every stage of carcinogenesis, including metabolism of carcinogens, DNA repair, and proto-oncogene and tumor suppressor gene expression⁹ (see Table 10.3).

Neurotoxins

There is growing evidence that the young are more susceptible than adults to the neurotoxic effects of a variety of agents including lead, mercury, organophosphate insecticides, and anesthetics and analgesics. A number of factors may explain this increased susceptibility. Children absorb a larger dose per unit of body weight of toxins through the gastrointestinal and respiratory tracts than adults do. Examples include increased absorption of lead and retention of larger amounts of mercury in the brain. The

extended period of central nervous system development, beginning in the ninth week of gestation and extending into the early school years, results in a long 'window' of susceptibility.

The developing fetus has even greater sensitivity to lead exposure than do other age groups. There is no impediment to the transplacental transport of lead; umbilical cord blood lead levels are equal to those in maternal blood. There is evidence that the fetal brain is more sensitive than the mature brain to the effects of lead. Lead can more easily penetrate the developing endothelial cells of the capillaries and reach the brain's neurons and astrocytes. In addition, the immature blood-brain barrier may allow greater access of lead to the central nervous system. Most importantly, most of the neuropsychologic damage that infants and children may suffer when they are exposed to lead is irreversible (see Chapter 39.8).

At present, there are few additional empiric data on the differential effects of neurotoxins in the young. However, it remains prudent public policy to presume that children are particularly susceptible, based on the experience with lead and the compelling theoretical concerns.

The elderly

The proportion of persons in developed countries who are aged 65 or older is growing at a rapid rate. According to census projections, this proportion will increase in the United States from 12% in 1986 to 22% in 2050. The elderly are known to be more vulnerable than the rest of the population to a number of factors, including adverse side effects of drugs, thermal stress, and infections. However, very little scientific information exists concerning how or the extent to which an elderly person is more susceptible to adverse effects from a potentially hazardous environmental exposure. It is clear that the susceptibility of the human body to disease changes throughout the lifespan, but our knowledge of the underlying mechanisms is limited.

It has been suggested that because the elderly develop toxicity from drugs at lower doses than younger adults, they may be more susceptible to toxic chemicals present in home, work, and outdoor environments.^{30,31} Environmental agents (termed gerontogens) also may be capable of accelerating the onset or rate, or both, of progression of certain aging processes.

The elderly person may be at increased risk for adverse effects following an environmental exposure for a number of reasons. Some proposed mechanisms underlying this susceptibility of the aged are listed in Table 10.6. For example, the cellular and biochemical responses of lung epithelium to oxidant damage are age dependent. Older animals are less protected from oxidant injury to the lung than are younger animals. One hypothesis is that older cells have higher basal levels of peroxidation of lipid membranes than younger cells. Decreased tissue dietary antioxidants such as vitamin E also may contribute to the increased susceptibility of older animals to lung injury.

Mechanism	Outcome
Changes in physiologic, biochemical, immune, homeostatic parameters	Diminished inherent protective mechanisms; immunosenescence Aging cells have an intrinsic sensitivity to certain toxins High total exposure dose
Long exposure period to toxin (increasing lifespan) Survival of years or decades since exposure began	Latency period exceeded and toxic effect is manifest Effects of complex chemical interactions become manifest
Diminished functional reserve	Acute exposure is more likely to cause adverse effects
Decreased xenobiotic metabolism, increased production of toxic metabolites, reduced successful chromosome repair	Potential of the toxin's effects

Table 10.6 Enhanced susceptibility of the elderly

Sensitivity to free radicals also appears to be age related. Free radical stress may be more prevalent in aged animals, and the aging process may allow the unrepaired damage caused by free radicals to accumulate. The elderly have lower levels of superoxide dismutase, an important enzyme in antioxidant defense. These low levels may be a risk factor for oxidant pollutant toxicity; there is evidence that ozone and NO₂ cause pulmonary toxicity via free radicals. Xenobiotic-related effects, such as carcinogenicity (e.g., carbon tetrachloride), hepatotoxicity (e.g., carbon tetrachloride and ethanol), nephrotoxicity (e.g., gentamicin), pulmonary fibrosis (e.g., bleomycin), and cardiotoxicity (e.g., adriamycin), are all age related, and available evidence supports free radical mechanisms.

Despite the difficulty of assessing the potential for increased susceptibility of the elderly to xenobiotics, a number of agents have been identified that are more likely to cause adverse effects in older adults and the elderly, based on animal models. Various studies show higher rates of acute respiratory and neurological toxicities, cancer, and other health effects in older animals compared with younger animals following exposure to a variety of chemicals.

Neurotoxicants

The elderly are more susceptible to some neurotoxic effects of pharmaceuticals than are young individuals. Examples include elderly people's increased sensitivity to tardive dyskinesia after neuroleptic use and to neuroleptic malignant syndrome following the administration of dopamine antagonists. There is evidence that senescent loss in neurons causes increased vulnerability to neurotoxicants. The age-related cell attrition causes reduced structural redundancy and reserve in the nervous system. Thus, subclinical injury can occur without apparent associated impairment until the finite reserve is depleted, at which point subsequent neurotoxin exposure or further age-related neuronal loss causes more profound disturbances of longer duration than those seen in younger individuals.

Aging can cause metabolic alterations, as well as changes in cell number, which may compound the neurotoxic effects of exposures. Carbon disulfide, acrylamide, lead, and the pesticides chlordecone, methylbromide, and DDT appear likely to potentiate neurotoxicity in the elderly because they affect the catecholamine/indolamine balance that is already perturbed by aging. In addition, aging can result in reduced metabolism of toxic compounds and increased production of toxic metabolites.

Inhaled toxins/air pollution

Age is a factor affecting the susceptibility of the lung to diseases and its vulnerability to inhaled toxic materials. Our understanding of the functional and structural mechanisms underlying the susceptibility of the aged lung is limited. Differentiating between 'true' aging effects and changes caused by the damaging effects of repeated exposures to inhaled contaminants is extremely difficult. Age-related changes in the human respiratory system, including tissue structure and respiratory function, have been described in some detail.³² A decline occurs in elastic recoil of the lung and the decline is greater in smokers and in those who are susceptible to ETS. Multiple parameters decline with age, including resting arterial tension, diffusion capacity for carbon monoxide, maximum aerobic capacity with exercise and respiratory muscle strength.

In addition, immunosenescence causes an age-related decline in protective immunity against various infections as well as a less robust response to vaccinations. The impact of these parameters on susceptibility to environmental agents is not known. Age-related changes in aerosol

deposition are not well understood. Animal models have been developed to define aerosol deposition as a function of age, though interindividual variability is known to be high.

The aging process is an important variable in exposure to environmental toxins and the susceptibility to lung disease. Age-related decreases in pulmonary function, cough efficiency, mucociliary transport, and cell-mediated immunity are some changes that may affect susceptibility and certain types of lung injury. The association between exposure to ambient concentrations of air pollutants and a decline in lung function with age is controversial. Animal studies have shown an age-related sensitivity to the pulmonary toxicity of ozone and NO₂, as noted earlier. In addition, non-specific airway hyper-responsiveness increases with age and, therefore, the elderly are potentially at increased risk for irritant and bronchospastic effects of inhaled pollutants. In acute air pollution episodes such as those in Donora, Pennsylvania (1948), and in London (1952), the elderly had higher rates of illness and death. However, many of the affected elderly had pre-existing diseases.

Although the risks of particulate matter (PM) or PM combined with other air pollutants have been discussed as a predictor of asthma in children, there are other subpopulation effects (see Table 10.7). One of the most challenging debates has been to explain the 0.5% increase in death rates related to days where PM₁₀ levels increase by 10 ppm. This finding is reproduced in epidemiologic studies³³⁻³⁵ yet challenged by occupational studies of 'dusty' trades such as coal miners where this effect is not apparent. It has been hypothesized that the increased

Exposure	Outcome
Adults:	
Particulates	Increase in death rates and emergency room admissions Exacerbation of asthma Exacerbation of pneumonia Increased cardiovascular effects
NO ₂	Increased airway responsiveness (controversial)
O ₃	Increased inhaled antigen sensitivity
Polluted ambient air (low O ₃)	No change in lung function and symptoms
Polluted ambient air (O ₃ and particulates)	Decline in lung function in asthmatics and controls
SO ₂ (controlled exposure)	Small decline in lung function (versus purified air exposure): wheezing Increased airway responsiveness in asthmatics compared with non-asthmatics and atopics Increased bronchoconstriction with exercise
Sulfate aerosols (controlled exposure)	Decrease in lung function, no change in respiratory symptoms, increased airway responsiveness Increased respiratory symptoms, correlation with sulfate levels
Children:	
Particulates (epidemiologic studies)	Exacerbation of respiratory symptoms Change in pulmonary function Decrease in lung function growth
Adolescents:	
SO ₂ aerosols (controlled exposure)	Reversible decrements in lung function
O ₃ and SO ₂ in sequence	Decreased pulmonary function
O ₃ and NO ₂	No significant differences in pulmonary function change between asthmatics and healthy persons

Table 10.7 Responses to air pollutants in individuals with asthma

death (and emergency room admission) rates are in the elderly who are already debilitated, particularly with cardiovascular and respiratory diseases. Studies are currently underway to determine if such a susceptible subpopulation exists and if it may account for the increased morbidity and mortality seen on days with high ambient fine PM levels.

Carcinogens

The incidence of cancer increases markedly with age. This increased incidence can be partially attributed to the fact that cumulative exposure to toxins is related to the development of cancer. The longer duration of exposure accounts for the age-related increase in lung cancer in smokers. However, studies of people exposed to radiation from the bombs at Hiroshima and Nagasaki and from a single course of radiotherapy for ankylosing spondylitis reveal that the incidence of certain types of cancer (acute leukemia and lung cancer) was substantially higher in persons older than 50 years of age at the time of exposure, given the same exposure dose.

The age-dependent susceptibility to carcinogens and other environmental toxins is not universal. Animal studies suggest that this susceptibility is dependent on the chemical and the target organ; human data are sparse except for those on ionizing radiation.

POPULATIONS WITH PRE-EXISTING CONDITIONS

The healthiest workers have historically been selected for jobs with physical and/or chemical stressors. However, over time, many workers develop various chronic health problems related to work or other factors, bringing diseased individuals into contact with environmental risk factors. Legislation in the United States (the Americans with Disability Act) to protect the right to work of individuals with pre-existing diseases may further accentuate the potential for exacerbation of underlying disease in certain situations.

Unfortunately, at present, knowledge of the special risks from environmental exposures for those with specific diseases is very limited. This will severely hamper rational preventive practice, especially when the law requires that a worker be allowed to work unless good information is available to recommend otherwise. Such limitations in available data also interfere with providing effective advice to clinicians who must advise their patients with various ills how to cope with environmental stressors.

The remainder of this chapter reviews basic data regarding common medical problems whose interaction with environmental factors has been explored. For many others, including such common conditions as chronic renal and liver disease, specific data are totally lacking and the practitioner is forced to make judgments using conservative theory, based on knowledge of how each toxin is absorbed, metabolized, and excreted, and its target organs and effects at potentially excessive doses of exposure.

Chronic lung disease

Asthma

The prevalence of asthma is dramatically increasing in the western world. Scientists are focusing on identifying what risk factors account for this. The widening disparity in asthma prevalence between western industrialized countries and China, for example, has been explained as an interaction between susceptibility genes and new environmental exposures. Research suggests that environmental risk factors for disease may (1) exacerbate the effect of a genotype, (2) work with the genotype to increase risk, or (3) be acted upon (via increased gene expression or increased effect) by the genotype. Recent data³⁶ implicate obesity in the western world as an important risk factor for asthma. Differences in antibiotic use, diet, immunizations, parasite exposure, endotoxin exposure, host resistance, particulate air pollution, breast feeding, and sedentary lifestyle are also under investigation as possible factors contributing to the asthma epidemic.^{37,38} At this time we have too few data to draw definitive conclusions about which groups of children and adults are more likely to develop airways disease and why.

Persons with asthma and airway hyper-reactivity, as well as atopic and allergic persons, may develop bronchoconstriction following exposure to certain air pollutants, which are summarized in Table 10.7. Several types of investigation support this generalization. Controlled human exposure studies with low concentrations of SO₂ have demonstrated that asthmatics experience bronchoconstriction at significantly lower concentrations than do non-asthmatics. As has been documented by asthma outbreaks in cities, asthmatics are more sensitive than the general population to acute increases in air pollution. In Donora, Pennsylvania, in 1948, a thermal inversion layer trapped high levels of SO₂ and particulates and 80% of persons with asthma experienced exacerbations. Animal models have demonstrated that inhaled pollutants such as ozone, SO₂, and NO₂ can enhance IgE production and airway reactivity. Immunologically mediated responses, especially IgE-dependent mechanisms, are an integral component in the development of airway inflammation and therefore the onset, severity and persistence of asthma.³⁹

A spectrum of irritant gases, fumes, and particulates may precipitate respiratory symptoms in persons with asthma through a non-immunologic mechanism. Vapors of volatile organic compounds, including common solvents such as toluene and formaldehyde, are often found in indoor air. Acute exposure of asthmatics to these irritant compounds may result in mild decrements in lung function and bronchial irritation. ETS is an irritant that increases non-specific bronchial reactivity in asthmatics. Low concentrations of irritants (such as SO₂) may cause bronchoconstriction in exercising asthmatics. Persons with atopy or allergy are more sensitive to the effects of some irritant inhaled pollutants (e.g., ozone), even if the allergic individuals are asymptomatic (see Table 10.7).

Another major mechanism of asthmatic responses to environmental exposures involves sensitization to a specific agent through synthesis of IgE (or gamma G immunoglobulin, IgG) antibodies. Occupational asthma caused by animal proteins or bacterial enzymes in the detergent industry is an example of IgE-mediated asthma. Atopic individuals are more likely than non-allergic persons to become sensitized to these high-molecular-weight substances. However, in other exposure settings (for example, with polyurethane precursors or wood dust), there is no relationship between atopic status and the risk of hypersensitivity reactions (see Chapter 19.2).

Once an individual becomes asthmatic as a result of an environmental exposure, bronchospasm usually can be triggered by a variety of non-specific stimuli in the environment. A proportion of persons with new environmentally triggered asthma will have persistent airway hyper-reactivity and respiratory symptoms indefinitely after removal from the environment containing the sensitizing agent.

Table 10.7 reviews selected studies on the response of atopics and asthmatics to common air pollutants. Exposure to O_3 , a potent oxidant and cause of airway inflammation, has resulted in exacerbation of asthma in epidemiological studies, although sensitivity to O_3 is not seen in chamber studies of asthmatics. Chronic exposure to O_3 may cause a decrease in flow rates.^{40,41} Epidemiological studies have documented decrements in peak expiratory flow and lower respiratory symptoms associated with NO_2 exposure. Data from controlled exposures are not consistent. An increased bronchoconstriction response to allergen is seen with NO_2 , similar to O_3 .

Young asthmatics may be particularly susceptible to inhaled environmental exposures. Data from a 12-year follow-up in the Six City Study of air pollution have shown that exacerbations of symptoms in asthmatic children (but not a decrease in pulmonary function levels) are associated with levels of exposure to particulates at or below the current United States ambient standards. The occurrence of new cases of asthma did not appear to be related to ambient levels of pollutants. In contrast, as a group, children do not have increased respiratory symptoms as pollutant exposures increase. The long-term consequences of modestly elevated ambient pollutant levels and increased symptom burden on asthmatic children are unknown at present.

Controlled exposure studies of adolescent asthmatics have shown increased sensitivity to inhaled sulfuric acid, a common atmospheric transformation product of SO_2 . Asthmatics are more sensitive to SO_2 and may experience exacerbations caused by brief exposures allowable under the National Ambient Air Quality Standards. The interactive effects of air pollutants may cause pulmonary toxicity that is not detected in single-exposure challenges. Very few studies have investigated the combined effects of pollutant exposures. There are no controlled human exposure studies evaluating the impact of PM on airways disease. There is some evidence in animals and humans that diesel exhaust increases local airways allergic responsiveness. PM

and diesel exhaust are currently intense areas of research in pollution health effects.

Overall, there are data to suggest that a number of inhaled pollutants may affect pulmonary function or respiratory symptoms, or both, of asthmatic children and adults.

Chronic obstructive pulmonary disease

Historical episodes of uncontrolled air pollution have demonstrated serious adverse health effects, particularly among those with pre-existing respiratory diseases. In the London fog incident of 1952, the maximal 24-hour concentration of SO_2 soared to levels estimated at 10 times the current maximum permissible level. Among the 4000 excess deaths attributed to pollution, the majority were ascribed to bronchitis, pneumonia, tuberculosis, and other respiratory diseases.

Chronic obstructive pulmonary disease (COPD) alters the structure and physiologic functioning of the lung, causing a loss of elastic recoil and a decrease in airway caliber, with a resulting increase in resistance to flow. These changes affect both the deposition and clearance of inhaled particles. Particle deposition occurs more centrally because terminal air units are not accessible. More particles are deposited at sites of obstruction. Thus, in diseased lungs, inhaled toxins may exert more pronounced and varied effects compared with healthy lungs. For example, there are some data to suggest that persons with COPD (and not normal elderly persons) experience considerable decrements in pulmonary function following acute NO_2 exposure. Persons with COPD, particularly those with increased bronchial reactivity, are probably also at greater risk of developing symptoms (and possibly deteriorating lung function) from inhaled toxins than are persons without lung disease. Persons with COPD have increased symptoms on days with high PM₁₀ levels in ambient air.⁴² Insufficient data preclude more specific conclusions about the risk of exacerbation or the effect on overall prognosis of various environmental exposures among persons with COPD.

Heart disease

Although there is epidemiologic evidence that patients with heart disease have increased susceptibility to inhaled pollutants, there are no controlled laboratory studies of exposure. In a small exercise study, patients with coronary artery disease were exposed to high ambient ozone concentrations; no changes in pulmonary or cardiovascular function were detected. However, the authors caution that the limited exercise tolerance of these patients may have resulted in inhalation of low concentrations of ozone. Persons with cardiorespiratory disease, which limits exercise performance, thus may have a protective mechanism restricting their total dose of inhaled pollutants.

Individuals with cardiovascular disease are considered to be at greatest risk for adverse effects from CO exposure. Low levels of CO can exacerbate myocardial ischemia during exercise. This was confirmed in a multicenter study of patients with coronary artery disease. Even small

decreases in the oxygen-carrying capacity of blood in persons with coronary artery disease can produce myocardial ischemia because coronary blood flow cannot be augmented appropriately.

There is some laboratory and anecdotal evidence to suggest that patients with cardiomyopathies and ventricular rhythm disorders may be at risk for dysrhythmia from exposure to organic solvents, especially fluorinated ones. This is discussed more fully in Chapter 24.

Diabetes

Diabetes mellitus is frequently complicated by symptoms and signs of peripheral neuropathy. A number of chemicals, including certain metals, solvents, gases, pesticides, and substances used in plastics, are known to be peripheral nervous system toxins. In theory, there is reason to suspect that additive or perhaps synergistic toxicity could result when a diabetic is exposed to these toxins. Thus, a diabetic theoretically may be more likely to develop peripheral neurotoxicity and the disease may be more extensive or produce more severe symptoms than in a non-diabetic following exposure to a neurotoxin. However, there are no empiric data nor a convincing laboratory model for any toxin to confirm this theoretical possibility.

Obesity

Extreme obesity is associated with a reduction in lung volumes. The clinical picture of restrictive lung disease can be found in very obese persons without intrinsic lung pathology.⁴³ Because baseline pulmonary function is altered, obese persons may be at greater risk for the development of further respiratory impairment following exposure to respiratory toxins such as tobacco smoking and pulmonary infections. However, this possibility has not been confirmed in human epidemiologic studies.

In addition, obese persons may be at risk for sudden increases in the concentration of lipophilic chemicals in the blood because these chemicals are stored mostly in adipose tissue. Examples include organochlorine pesticides and dioxins. Higher amounts of lipophilic toxins accumulate in fat in an obese person than in a lean, athletic individual. The concentration of the toxin in the target organ may be lowered by such storage, and thus, this toxin may produce less toxicity in an obese individual than in a lean individual. However, when rapid mobilization of fat occurs, an obese person may have a greater increase in the concentration of the lipophilic chemical in the blood and, therefore, suffer acute toxic effects. This hypothesis has been studied and confirmed in animals exposed to organochlorine insecticides followed by starvation periods. Clinical toxicity in this setting has not been proved in humans.

Prospective studies have found a strong association between body mass index (BMI) and the risk of adult-onset asthma. Asthma severity may also be related to BMI.⁴³ Inner city asthmatic obese children show evidence of more severe asthma than those who are not obese. This effect is

independent of age, gender, family income, allergy or mental health. The dramatic increase in asthma prevalence rates in the US may be related to obesity and western lifestyle and diet changes.³⁶

SUMMARY

In order to better protect vulnerable groups and the population as a whole, accurate data on susceptibility are needed and should be incorporated into risk assessment to improve health-based policy development. Research and public policy are intensely focused on understanding and reducing risks among susceptible populations, particularly children. More mechanistic information is needed to increase understanding of how different factors impact toxicity and how these factors vary with genetic profile, behavior and age. Estimation of risk is becoming increasingly sophisticated. A new layer of complexity has been added to our understanding of disease causation with evidence that host factors may determine the impact of exposure to a carcinogen or other toxin.

Host factors may play a particularly important role in outcomes with low-level exposures. The challenge for risk assessment is to account for the wide interindividual variation in susceptibility to environmental agents, including for example the spectrum of interaction between environmental carcinogens and host factors. Public policy is creating the need for rapid advancement of scientific knowledge in human susceptibility to disease impacted by environmental exposures.

Chapter 11

Occupational and Environmental Health and Safety in Developing Countries

Mark R Cullen, Linda Rosenstock, Tord Kjellstrom

Although there are substantive differences in occupational and environmental health practice among the developed countries because of differences in history, culture, political system, and professional practice, the principles of clinical practice described throughout this text are generally applicable in all. On the other hand, about 80% of the world's population lives in areas that are defined under the label 'developing countries'. In some, such as Mexico, Brazil, and most of Southeast Asia, transformation to patterns of health more typical of developed societies has occurred, but other features of underdevelopment, such as high rates of poverty and low educational attainment, persist. In others, such as most of those in sub-Saharan Africa, Central America, and many of the world's island nations, the major determinants of health remain poverty, poor sanitation, and malnutrition. There is compelling evidence that a disproportionate amount of the world's occupational and environmental injuries and disease occur in these societies as well. The clinical effects of the major environmental and occupational hazards may occur anywhere, but the likelihood is higher, the consequences often more profound, and the strategies for prevention and treatment more problematic in poor nations than rich. Some of the classic occupational diseases, such as silicosis, lead poisoning, and benzene poisoning, that have been virtually eradicated in most developed countries remain endemic in many developing countries.¹⁻³ Lack of foresight, lack of interest, and lack of resources combine to create health risks, which could be avoided, sometimes at very limited cost.

What happens now in many industries in poor countries is a replay of what occurred in the affluent countries 30 to 50 years ago. The difference is that then most practitioners, industrialists, and decision-makers were genuinely ignorant about the attendant health risks. Control technologies and access to information were far more limited than they are now. In the 21st century, information systems and the communication infrastructure are so well developed that ignorance is no excuse for inaction anywhere in the world. The workers of the developing countries deserve a better fate than those who were the guinea pigs of seminal epidemiologic studies in developed countries. However, experience shows that the demonstration of significant exposures and sentinel cases of health effects are not enough in themselves to trigger preventive action. Just as in developed countries, pressure from government, worker organizations, and the community

advocacy groups, in combination with locally conducted studies, are often necessary to initiate such action.

The continued industrialization of many developing countries without sufficient attention to occupational health and safety presents an increasing public health problem, despite the availability of preventive interventions. In the sections that follow, we estimate the magnitude of the problem, then review the major, generic factors that distinguish occupational and environmental medicine (OEM) practices in developing countries from those with which the reader is likely more familiar. These are summarized in Table 11.1, and reviewed in more detail later in the chapter. While there are myriad issues specific to each country, different regions within the same country, and even different workplaces or environmental settings within the same region, these factors are almost universally important and should serve as an overview to practice issues in the developing context.

THE MAGNITUDE OF THE PROBLEM

The overall picture that emerges from all parts of the developing world is one of increased health and safety risks in all occupations for which data are available. Similarly, in most of the developing world, attention to environmental hazards is a low, often non-existent priority, with the individual and community being vulnerable to increased levels of exposure to both workplace and non-workplace factors. Because of inadequate data and reporting systems, capturing the impact of this increased risk is daunting. Nonetheless, several recent efforts by international bodies have shed some light on the staggering burden although, in general, attempts to derive evidence-based estimates are likely to systematically and significantly under-represent the extent of the problem.

Worldwide, it is estimated that there are at least two million deaths per year due to occupational diseases and injuries.⁴ The World Health Organization (WHO) recently evaluated the contribution of five select occupational factors in relation to the overall burden of disease.⁵ These data provide a more in-depth yet still incomplete picture of the overall problem. Nonetheless, a picture emerges of the significant impact of largely preventable conditions associated with these factors, as described below.

Condition	Implication
Distribution of economic activity	High proportion of workers in high-risk occupations
Susceptibility of the populations	Greater co-morbidity Multiple hazards
Proximity of workplaces to residential communities	Additive exposures Risk of catastrophic accident Risk to family/children
Demographics of population	Risk to children High job turnover
Climactic factors	Problems with PPE* Interference with sampling New hazards, i.e. parasites and animals
Inadequate regulations and enforcement	Poorly controlled exposures Importation of hazardous materials, equipment and waste
Low educational level of managers/OEM professionals	Poor supervision Limited professional guidance
Low educational level of population	Training difficulty
Higher proportion of migrant work	Social instability STD risk
Extent of informal sector work	Undocumented, unregulated work
Resource limitations	Low investment in public and private sectors Substandard equipment, PPE,* source materials

* Personal protective equipment

Table 11.1 Work conditions differentiating developed and developing countries, and potential impacts on occupational health practice

WHO found that occupational injuries result in more than 300,000 deaths per year. Contrast this to the approximately 6000 lives lost each year in the US due to occupational injuries. As in the developed world, high injury fatality rates in the developing world are clustered in certain sectors, including agriculture, construction, and mining. Understanding the role of occupational injuries in relation to quality of life is accomplished by use of the 'common currency' called DALYs (disability-adjusted life years, with one DALY being equal to the loss of one healthy life year). Occupational injuries account for nearly 1% of all DALYs and 16% of the unintentional injuries in the working population aged 15 to 69 years.

The second occupational factor analyzed by WHO was the effect of exposure to workplace carcinogens. Estimating that globally about 20–30% of men and 5–20% of women of working age (15–64 years) are exposed to occupational lung carcinogens (such as asbestos, diesel exhaust, and silica), WHO concluded that these exposures account for about 10% of all cancers of the lung, trachea, and bronchus. They also attributed about 2.4% of all leukemia to occupational exposures. Overall, the worldwide burden of occupational cancers was estimated at 146,000 deaths per year (0.3% of all) and 1.4 million (0.1%) DALYs.

Estimates of the global burden of chronic lung disease demonstrate the significant contribution of occupational

exposures, which account for about 15% of all chronic obstructive pulmonary disease (COPD). In total, WHO found the annual worldwide burden of work-related COPD to be 243,000 deaths (0.4% of all) and 3 million (0.2%) DALYs.

WHO found that 37% of all back pain worldwide is attributable to work, resulting in an estimated 0.8 million DALYs, significant loss of time from work, and high economic loss. Worldwide, 16% of all hearing loss is attributable to workplace exposures, resulting in 4.2 million (0.3%) DALYs.

The WHO analyses also provide some important insights into the global burden of select environmental risks. Again, as in the case of occupational conditions, WHO estimates, because they assess only a limited range of factors and because of under-reporting and inadequate or non-existent data, are thought to under-represent the overall burden. Beyond the workplace, unsafe water, sanitation, and hygiene were found to account for 3.1% of deaths (1.7 million) and 3.7% of DALYs (54.2 million). Urban air pollution was attributed as causal in 5% of trachea, bronchus, and lung cancer cases, 2% of cardiorespiratory mortality and 1% of respiratory infections mortality, amounting worldwide each year to 0.8 million deaths (1.4%) and 7.9 million (0.8%) DALYs. Indoor smoke from solid fuels, a source of heat for cooking for half the world, is associated with respiratory infection and lung cancer, and accounts for 2.7% of DALYs worldwide. Lead exposure accounts for 234,000 deaths per year worldwide (0.4%) and 12.9 million (0.9%) DALYs. Climate change was considered by the WHO to account for increased risk for diarrhea, malaria, and dengue fever, with an attributable mortality of 154,000 (0.3%) and attributable burden of 5.5 million (0.4%) DALYs.

Despite the importance of using systematic and transparent methods to better grasp the global burden of select factors, these new analyses fail to capture a broad range of significant workplace and environmental exposures, likely under-representing even further the burden that falls on the developing world. For example, pesticide exposures (both intentional and unintentional) cause a disproportionately high global burden of mortality and morbidity in the developing world (see Chapter 48). In addition, the many millions of workers in developing countries are exposed to a combination of health hazards both in the workplace and outside that lead to poor health status overall. Estimates of adult (age 15 to 59 years) mortality have shown that in a highly developed country, about 10% of 15-year-old persons will die before age 60, whereas in a country such as Egypt, about 30% will die, and in rural India, about 50%. How much of this preventable mortality rate is related to occupational hazards or other environmental hazards is not known.

DISTRIBUTION OF ECONOMIC ACTIVITY

One important reason for differences in occupational and environmental health priorities between developed and

developing countries is the difference in the relative types of occupations and differences in the major sources of pollutants. The majority of people in the poorest developing countries (including India and China) work in subsistence agriculture. Health in the workplace is integrated into all aspects of daily life because the distinction between time at work and time at home is often blurred (see below). In societies where women work predominantly in the home, tasks such as cooking, gardening, water collection, firewood collection, and other chores may engender major risks, as has been established in relation to cooking and heating with biomass fuels (see Chapter 50). Beyond subsistence farming, formal sector agriculture is one of the largest occupational groups in many developing countries, entailing exposures to the entire spectrum of physical, biologic, and chemical hazards seen in developed countries (see Chapter 12) but often with exposures far less well controlled. In developed countries, by contrast, the proportion of the population involved in agriculture is rapidly dwindling, less than 2% currently in the US. Moreover, farm laboring is often a family affair in developing countries, with children exposed as well as pregnant women and the elderly.

One specific type of agriculture that is on an industrial scale is forestry, which has become a very important contributor to the economy of developing countries with rain forests. The destruction of the world's rain forests is, in itself, a well-known hazard to the global environment. Less well recognized is the high injury rate among forestry workers. Problems are similar in planted forests, and although there is better control of the environment in such forests, these workers often have to reside in poorly designed camps far from their families and the community support of village life, engendering an additional set of health risks (see below).

Another primary industry of greater importance in many developing countries is mining. Extraction of ore (or coal) for direct export is widespread, and refining of the ores is increasingly carried out in the country of origin. Mining in these settings often involves greater risks for injuries from falls, slips, and unexpected movements of ore or rocks than in more highly regulated settings (see Chapter 13). Mining still involves high risk of silicosis or coal-workers' pneumoconiosis (anthracosis and anthracosilicosis) in many countries.^{1,6} Coal mines are also prone to explosions and fires, which can trap workers and lead to multiple fatalities.

Closely linked to the mining industry is the metal refining industry, which also is of major importance in developing countries. The occupational hazards in this field depend on the product. Limestone and quarrying industries create risks of silicosis. A special case is the mining (quarrying) of asbestos or other asbestos fiber-containing minerals, which can give rise to asbestosis, lung cancer, and mesothelioma. Non-ferrous metal refining involves risks of poisoning by a number of agents, including lead, cadmium, arsenic, and sulfur dioxide (SO₂).

As part of the development process itself, employment in construction and transport industries increases.

Generally, developed countries have a larger proportion of such workers than developing countries. Although in many countries sophisticated and modern buildings are going up rapidly, construction is often accomplished without the benefit of comparably sophisticated safety programs; risk of falls and fatalities is very high. In Singapore, for example, there was a dramatic increase in the number of serious injuries reported in the construction industry during the transformation of the municipality in the 1970s. A report from China in the last decade underscores the seriousness of this pattern.⁷

The transport system and the hazards in the transport industry depend on geographic factors, with increased risks of injuries in traffic accidents among drivers in countries with difficult terrain and bad roads. Vehicles are frequently substandard, often lacking mirrors, seatbelts and other modern safety devices, and open vans and lorries are widely used to transport workers. Increasing motor traffic also leads to an increase in non-occupational traffic accident injuries, with young and elderly pedestrians at the highest risk. In many countries, the per capita rate of occupational and non-occupational fatalities exceeds levels in the US and Europe by 10-fold or more.⁸

Light industry emerges in developing countries at early stages of development. The textile industry, assembly and repair industry for imported machinery, and small chemical formulation (mixing) factories may be the first to appear. To support an increasing use of cars, lead battery factories often are established early and are found in almost every developing country. The hazards in these industries are well known; however, protection for the workers is typically insufficient. High prevalence rates of systemic poisonings, hearing loss, respiratory conditions such as byssinosis, and other occupational diseases largely eradicated in western industry have been reported. Moreover, as is true with a number of other manufacturing processes at early stages of development, lead battery remelting is often performed as a cottage industry to extract the lead for paints and glazes. These conditions create not only the occupational health risks but also health risks to the family and the community.² These small-scale enterprises, which often fall outside government administrative control, play an important role in grass roots industrial development, but the lack of local knowledge about health hazards and the varying involvement of family members and neighbors as workers make them very difficult to track for health consequences. The special problem of so-called informal sector work, the most primitive of these, is discussed further below.

SUSCEPTIBILITY OF THE POPULATION

Many of the occupational and environmental health hazards that occur in developing countries are similar to those in developed countries, albeit more frequent and often more severe. But others are features of poverty and early development that are scarcely, if ever, seen nowadays

in developed countries. For example, not only are injuries more common, but poor sanitation and inadequate surgical care and public health infrastructure result in far poorer outcomes and, sometimes, unheard-of complications such as tetanus. In the poorest countries, this totally preventable complication still ranks as an important cause of death; it has been estimated that a high proportion of tetanus cases in adults are caused by agricultural injuries.⁹

Poor sanitary conditions mean that for many workers in developing countries, the health problems of poverty overshadow the specific health effects of occupational hazards. Malaria and other tropical diseases, tuberculosis, diarrheal diseases, and other infectious diseases take a heavy toll not only among children, but also among people in the working age group. Such risks are often exacerbated by conditions of work – e.g., exposures in the field – as well as by associated living conditions such as overcrowding, inadequate potable water, and contamination of living space by chemicals and pollutants from the workplace.

Some occupational hazards combine with the diseases of poverty and make the exposed person more vulnerable. For instance, the problem of silicosis in Chinese mines is made worse by the relatively high incidence of tuberculosis, leading to silico-tuberculosis. In South Africa, miners face not only the same high risk of tuberculosis, but also the risk of HIV, to make all too common the devastating triad of AIDS, silicosis, and tuberculosis.¹⁰ Anemia is a common condition among workers in developing countries due to poor nutrition and parasite infections. Both the degree of anemia and the symptoms of such can be exacerbated in workers exposed to, for instance, arsenic, nitrites, lead or carbon monoxide. Child labor (see below) adds another dimension to these problems of vulnerability. Although data are still limited in this regard, it is widely believed that risk for many, if not all, occupational and environmental diseases may be enhanced by comorbidity, poor nutrition, and the coexistence of multiple health risk factors.

PROXIMITY OF THE WORKPLACE TO PLACES OF RESIDENCE

Because arable land, mines, and other large manufacturing complexes are most typically situated remote from sources of labor, the provision of residential housing at the workplace is commonplace throughout the developing world. Often, whole cities have sprung up, sometimes shockingly close to sources of pollution and dangerous activities, creating three major concerns. First is the blurring of the exposure context of work: workers are exposed to many of the same hazards on and off the job. Second, fires, explosions and toxic discharges may pose a direct threat to large populations. Third, industrial levels of exposure are often conferred on spouses, children, and other family members living in this often intrinsically overcrowded and undesirable housing stock. Contamination of residential air, water, food, and soil from this source is commonplace. A particularly gruesome and everyday example is the domestic use

of the large drums in which agricultural chemicals are typically supplied. Residues from these are sufficiently lethal to result in hundreds of thousands of cases of pesticide poisoning per year, inadvertent or intentional. This source likely exceeds the already vast toll in human health taken by occupational application of the chemicals. The special health problems of migrant workforces, where housing is typically provided for workers but not for their families, will be discussed further below.

The smelter town of La Oroya, Peru, illustrates the first concern. Rows of workers' huts line up in front of the main entrance to the smelter, which is situated in a narrow valley at an altitude of 3600 m (about 12,000 ft). The emissions of SO₂, lead, cadmium, arsenic, and other toxic metals create high concentrations in the air and contaminate house dust, leaving workers and their families exposed for essentially 24 hours each day.

Living close to the workplace was the major reason for the disaster in Bhopal, India. A cloud of methyl-isocyanate was released from a storage tank during a night in December 1984, owing to erroneous procedures, faulty equipment, and other factors. The highly toxic gas was heavier than air and spread throughout the densely populated neighborhood of the factory. An estimated 2000 persons died and as many as 250,000 were affected, mainly by lung and eye damage. In many, the effects have persisted for years in spite of the fact that the exposure lasted only a few hours.¹¹

DEMOGRAPHIC FACTORS

In addition to the blurring of the work and domestic environment, demographics in many developing countries strongly favor risk for children. In part this is due to the economic advantage for women in subsistence farming, cottage industries, and other activities paid by the 'piece' to bring young children to the workplace, often to work. Child labor laws are often either non-existent or unenforced. The complementary problem is the contamination of the home for the reasons discussed above, and because little attention is given to accidental transportation of work materials into the home.

Another demographic factor of importance to practice is the reality of an unskilled labor force that vastly exceeds the size of the formal workforce in most developing countries, resulting in wide-scale unemployment. Up to 70% of the population in the poorest nations exist outside the formal economic sector. The consequences are manifold, above and beyond the obvious issue of poverty. The replacement cost for sick and injured unskilled workers is effectively zero, sharply reducing economic incentives to prevent such turnover. For these workers, low job security results in a willingness to work in undesirable conditions, to continue working despite illness, to under-report injury for fear of job loss, and the like. Even multinational corporations, which in their home countries may adopt a cradle-to-grave ethic towards workers who typically devote careers to that single employer, may behave very differently in such divergent economic circumstances.

CLIMATE

Most, but by no means all, of the developing countries have climates very different from the developed countries of the temperate zones. In addition to the obvious issues of heat stress, there are a host of unexpected consequences. First, many extreme climates introduce a multitude of new hazards, including insects, reptiles, wild animals and hazardous terrain. Second, the chemistry of many commercial operations may be quite different in tropical climates, such that contaminants may evolve that are not a problem, or far less of one, in temperate climates. Volatile chemicals, or those reactive with water in densely saturated air, are the most obvious examples. Sampling equipment may function poorly in these climates, or give results divergent from the same operation sampled in a cooler climate. Personal protective equipment, often designed for ambient conditions in developed countries, may also fail more readily or may simply not be tolerated in warm climates.

INADEQUATE REGULATION AND ENFORCEMENT

There is reasonable evidence to support the proposition that for the largest employers in developed countries, social, legal, and public relations considerations may outweigh the importance of regulation as the primary driver to minimize occupational and environmental health risks. But the same cannot be readily said of smaller employers, for whom the regulatory framework and its enforcement provide incentives without which behavior would likely revert to what it was before the modern regulatory era. Unfortunately, in most developing countries, regulations are inadequate or inadequately enforced or both. There are many reasons for this, including lack of political will, compromises against the perceived need for rapid economic expansion, inadequate resources, few professionals to fill key technical responsibilities, corruption, etc. Whatever the reasons, lack of strong regulations for workplace and environmental standards, or poor enforcement of those standards that exist, results in greatly increased risk of injury or disease from environmental contaminants and work.

The consequences of a voluntary approach to occupational and environmental risk reduction, in the context of the other issues listed in Table 11.1, are not hard to imagine. Two are of the greatest overall importance. First is the export of hazardous industries and materials from developed to developing countries for the purpose of escaping strict health and safety regulations.¹² This is becoming increasingly attractive to some industrial sectors, for whom restrictions on the sale or requirements to divulge contents effectively preclude economic utility. For some materials, pressure builds to find a place to 'dump' it, as is the case with asbestos, which has limited marketability in the developed world. Likewise, older technologies, such as machines without baffling (to prevent noise) or guards (to

prevent injury), may find second homes in workplaces where such technical advances are not requisite. In other situations, products, although deemed harmful in some or all developed countries, are so cheaply produced relative to their value that companies are reluctant to dispense with them, and there is pressure for entrepreneurs in less regulated areas to adopt them. Export of hazardous waste, which can be very costly to dispose of in regulated environments, is a related practice. It leads to a few jobs, but brings health risks that may be almost impossible to predict or prevent. International agencies have managed, albeit slowly and incompletely, to induce agreements between governments in developed and developing countries which explicitly forbid the trans-boundary transport of hazardous waste and hazardous technologies without information about the hazards involved, which at least gives the recipient country an opportunity to take action. In an economic climate where developing countries are desperate for income, there is still a risk that hazardous technologies and materials end up where they are most difficult to control.

Far and away the most common consequence of inadequate regulation is uncontrolled exposure, widespread contamination, and poor preventive practice. Numerous investigations have documented very high exposures to hazards well controlled in the US and Europe, such as lead, silica, and benzene. Not surprisingly, higher prevalence of effects in developing countries is the rule.

The often inadequately controlled workplace environment is further worsened when coupled with an especially unregulated non-work environment. To individual and community, the result is quite simply greater exposure, whether to lead, diesel or injury risk.

LOW EDUCATIONAL LEVEL OF MANAGERS AND OEM PROFESSIONALS

Most developing countries have few OEM-trained physicians and industrial hygienists to provide expert guidance and policy for government, or to support practice by employers. In general, reliance is placed on physicians and engineers trained in other disciplines, with predictable suboptimal results. Sadly, for those who receive training – usually in developed countries – demand and opportunities for advancement are often greater in the developed context, resulting in a drain of these crucial resources from the societies that need them most. Even employers with the most extensive resources and motivation may be unable to develop optimal programs because of these manpower limitations.

Equally problematic is the low level of training and knowledge regarding occupational and environmental health and safety among managers and the personnel in the workplace charged with day-to-day protection of workers and the environment. Although the dearth of such training may be in part attributable to the lack of regulations mandating it, much is attributable to the historic inatten-

tion to such issues in all aspects of the educational system in many parts of the world. In addition to the traditional occupational diseases and injuries referred to above, industrialization leads to an increased risk of major hazard incidents caused by mismanagement of modern technologies, as occurred at Bhopal and other sites of industrial disaster.

LOW EDUCATIONAL LEVEL OF WORKERS AND THE POPULATION

Although training in occupational and environmental safety and health has not been widely adopted as part of public or technical education in most developed countries, there is nonetheless widespread public awareness of these issues, reinforced by media and employer efforts, in the US and Europe. An obvious example is the use of seatbelts in motor vehicles, in which the disparity between developed and developing countries is huge. Comparable societal awareness is not evident in many regions of the world – one of the factors underlying inappropriate exposure of children to industrial risks and chemicals, expropriation of industrial materials for domestic purposes, and failure to apply even ‘lay’ precautions such as natural ventilation or protective clothing. This puts a higher burden on employers to engineer out risk to the extent possible, and to train workers in matters including those of hygiene and safety that might otherwise be considered ‘common sense’ in developed countries.

MIGRANT WORKERS

As noted above, mining, agriculture, and many industrial activities in developing countries rely on large migrant workforces, in which workers typically live in provided housing separate from the family home for large portions of the year. Beyond the issues of poor living and working conditions, job insecurity, and the effects of low-wage, dangerous work, migrancy creates other serious concerns. First, the cultures that develop around migrant workforces may be extremely unhealthful, with prostitution, alcohol abuse, and violence commonplace. In many parts of the world, these are important sources of HIV spread, as they are to a far smaller extent in truck drivers and transportation workers in developed countries. A second consequence is lack of health services. Workers may be dependent on employer-provided service since community resources are typically not available in these remote regions. Finally, because the employment relationship is even more transitory in this setting than in high-turnover non-migrant workplaces, incentives for employers to provide training, health services and prevention may be weak or non-existent.

INFORMAL SECTOR WORK

In every society there are some economic activities which are ‘informal’, i.e., not documented through tax or other systems that, in theory, provide government with some

knowledge and control of conditions. For the most part in developed countries these are limited to less than 10% of the workforce and involve mobile selling of goods, illicit activities such as prostitution and drug trade, and domestic labor, including day care. In many developing countries, however, a far higher (upwards of 70%) and more diverse cross-section of economic activities are informal, including subsistence farming, transportation work, construction, vending and commerce, and even light manufacturing. Not only are these enterprises and the people they affect usually well outside the scope of possible government regulation or surveillance, but employers have little reason not to discharge anyone sick or injured as expeditiously as possible. Since so much of the workforce may be engaged in just such work in many developing countries, these enterprises form a particularly intractable problem for control of occupational and environmental health and safety risks.

RESOURCE LIMITATIONS

Although many of the issues raised above are themselves amenable to intervention, the absolute limitations on financial and technical resources cannot be underestimated. In many parts of the world, per capita expenditures for all health are less than a US employer spends for each employee for occupational and environmental services alone. Machinery and technologies proven to reduce exposures or safety risk are often unfeasible economically, as are substitutions from dangerous to safer chemicals. The cost of appropriate safety equipment may be prohibitive, as may be even its availability, for example in countries with limited foreign exchange capacity. At the government level, expenditures on environmental health and safety must be balanced against other health priorities, such as care for AIDS, or provision of community health services. In this context, locally performed studies documenting the extent of risk and cost to employers may be extremely important in driving resource allocation. Programs oriented towards outcomes with proven economic advantage are most likely to be implemented – for example, those that reduce neuro-intoxication or musculoskeletal injuries, whose impact on productivity can be demonstrated. One of the most valuable services highly trained OEM professionals can offer is demonstration of such links, to encourage investments that might otherwise be deemed as economically impossible or undesirable, whether for government or employers.

POTENTIAL SOLUTIONS

A rather bleak picture of the occupational health and safety situation in developing countries has been painted in the previous sections. The lack of published data makes it difficult to assess accurately whether the situation is getting worse or better. Based on the overall increase in the number of workers and the changes in occupational structure over time, increasing occupational health and safety problems can be expected; however, in some developing

countries, concerted efforts are being made to introduce effective prevention programs and some reports show that improvements are taking place.

In some ways, the increasing dependency of developing countries on foreign capital for investment in industry is an opportunity to introduce enlightened occupational health and safety practices into countries where legislation and practices lag behind. The World Bank, for example, has prepared guidelines for environmental and occupational health issues that should be taken into account when new investments are made.¹³ Such guidelines can be used by government agencies and community groups as a pointer to practices that should be adopted.

Recent environmental protection agreements at an international level will also provide opportunities to protect worker health and safety; for example, the Basel Convention on Export of Hazardous Waste, initiated by the United Nations Environment Program (UNEP). This convention aims at reducing the uncontrolled dumping of hazardous waste in countries that are not prepared to deal with the hazards. Another example is the voluntary code of practice between the pesticide-producing industries and the Food and Agriculture Organization of the United Nations (FAO) concerning the export to and use of pesticides in developing countries. This code of practice gives guidelines for information supply, labeling, training, and other preventive methods. These guidelines provide a means for local users of pesticides, local inspectors, and community groups to implement appropriate practices of import and use of pesticides.

There is no lack of information on occupational health and safety in the international arena. Several publications from WHO and the International Labour Organization (ILO) are identified in the reference section.^{4,5,14} A large amount of material on individual hazards is available, e.g., the Environmental Health Criteria, the Health and Safety Guides and the International Chemical Safety Cards from the WHO/ILO/UNEP International Program on Chemical Safety. Other international organizations, such as the international trade unions (e.g., the International Chemical and Energy Workers' Federation [ICEF] and the International Metal Workers' Federation [IMF]) and the international industry groups (e.g., Groupement International des Associations Nationales de Fabricants de Produit Agrochimiques [GIFAP] and the International Lead Zinc Research Organization [ILZRO]), produce review reports and information material on occupational health and safety hazards. National agencies in many developed countries also produce material that could be used in developing countries to attain local solutions.

The challenge lies in making all this information and knowledge available in developing countries and in translating the knowledge into practical actions in the workplace. Occupational health and safety professionals, government agencies, industry, trade unions, and community groups in developed countries can provide support, by

advising and assisting specific projects at a bilateral level or by contributing to broader growth of technical cooperation. WHO has developed an infrastructure for such activities via the collaborating centers in occupational health.

Experience shows that it is seldom enough to identify potential health risks from known occupational health and safety hazards. Local health effect studies can be powerful tools in bringing a sense of urgency into prevention work. Clearly, the results of health effect studies have to be interpreted in the context of other health risks in the country. The challenge for occupational health and safety professionals in all countries is to unite in an effort to rapidly reduce all the unnecessary suffering and death that uncontrolled occupational health hazards in developing countries are causing. More and better epidemiologic information is required, as well as improved access to information in the field. Clean technology and better control technology need to be used when industry is established. Local initiatives for self-reliance need support. We can all contribute in one way or another.

Chapter 12

Agricultural Workers

Stuart L Shalat, Mark G Robson, Sandra N Mohr

INTRODUCTION

Agricultural workers consist of individuals that range from owners of family farms to employees of large corporate enterprises. They may be full-time permanent employees of a single farm or they may be migrant or seasonal farm workers. The term farming includes a variety of enterprises encompassing the cultivation of row crops, fruit orchards, dairy farms and the raising of livestock and poultry. In the United States, the number of family farms has steadily decreased since the Second World War from 9 to 2.2 million in the period between 1940 and 1999.¹ The size of the average farm between 1953 and 1993 has almost doubled from 242 to 474 acres, reflecting the switch from small family to large corporate farms. In general these corporate enterprises are not only far larger in acreage, but employ more workers and are more highly mechanized.

Row crops

For those unfamiliar with farming in general, it is useful to consider the activities involved in each type of farming as a framework to understanding how health and safety problems arise in each category of farming. What most people think of in terms of farming is most likely to be the cultivation of row crops. These include the raising of grains (i.e., wheat, oats, rye, sorghum) and vegetables (i.e., carrots, corn, broccoli, peppers) to name just a few. It also can be used to describe vineyards, although these crops require different and unique activities and have occupational hazards of their own. The cultivation of row crops routinely employs the use of numerous farm chemicals including fertilizers, insecticides, herbicides, and fungicides. Additionally, row crops are highly amenable to mechanization in all stages of cultivation including tilling, irrigation, fertilizer and pesticide application, and harvesting. The cultivation of row crops employs the use of chemicals in a cyclical manner. Prior to planting, fertilizer and pre-emergent chemicals (herbicides and insecticides) are applied. This is followed by periodic re-applications during the growing season. Pesticides may be applied from once to several times as the crops mature. While in some climates there is only one growing season, others may be capable of two or more growing seasons.

Often different crops may be cultivated in the same field in different seasons. In the US, excellent sources of information of the types of crops grown locally and the types and quantities of pesticides employed can be obtained from county agricultural extension offices and extension specialists at the state land grant colleges and univer-

sities and state departments of agriculture. This is important in that pesticides are employed and applied in highly specific patterns dependent on the crop and the region. The county extension office is the primary source of information for the agricultural community and the main source of training for new application techniques, safety equipment, new chemicals and changes in state and federal regulations.

In terms of health and safety issues in the cultivation of row crops, two of the major acute sources of health problems arise from worker exposure to agricultural chemicals and heat stress. In warmer climates, these may be highly correlated, because the use of personnel protection equipment (PPE) may exacerbate the potential for heat exhaustion. Injuries can arise from the mechanized equipment employed or from the moving of irrigation equipment. Because of the widespread use of mechanized equipment in the US, the greatest risk of death in a farm setting is from trauma associated with farm equipment and in particular from tractor accidents. Farm vehicles account for approximately half of all fatal farm accidents, and the majority of these deaths are due to tractors. Farm equipment, and specifically tractors, are also the predominant cause of fatal injuries to children in agricultural settings. Deaths of children due to machinery are 80 times more likely to occur in a farm setting.² Pesticides may be applied on row crops by a variety of mechanized techniques including towed spray rigs as well as from aerial application. While most row crops in the US are amenable to mechanical harvesting, some – including celery, onions and strawberries (among others) – are still harvested by hand (Fig. 12.1). During the harvest, health concerns arise from the use of pre-harvesting pesticides (in particular insecticides and fungicides) and the resultant potential worker exposure.

Orchards

Orchards involve the year-round growing and maintenance of fruit and nut trees. By their very nature, orchards require a higher degree of manual labor and less mechanization. They require very different types of equipment and periodic maintenance of the trees, including pruning. This usually requires the use of ladders or mobile 'cherry picker' cranes, which introduce the potential for falls. As in row crops, the use of agricultural chemicals is highly crop and region specific. Depending upon the crop, the harvesting may also be highly labor intensive and utilize migrant and seasonal farm workers. Pesticide application is often mechanized, but may also be by hand, using backpack spray rigs. These can

Figure 12.1: (a) and (b) Workers harvesting fresh strawberries. Workers are in the fields 8–12 hours per day harvesting crops. Note that crops are also sorted and stacked by workers in the field.

pose particular problems from leakage and spillage on the worker. One unique method of pesticide application is employed in the growing of bananas. This method makes use of pesticide-impregnated polyethylene bags. These bags, which contain a small quantity of organophosphate pesticides, are placed over bunches of bananas as they grow on the tree. This method results in lower exposures to workers, compared to manual spraying of the bananas, but may transfer the hazard to the workers involved in the manufacturing and preparation of the bags.

Livestock and poultry

The raising of livestock and poultry, as well as dairy farming, is very different in nature from the previously described types of farming activities and thus very different in the types of hazards to workers. This type of farming involves the breeding and care of farm animals ranging from chickens and turkeys to pigs, sheep, and cattle. It may include large indoor facilities and/or outdoor holding pens and feed lots. Typically, the raising of poultry for either egg production or meat usually occurs indoors. Cattle, with the exception of veal and dairy cattle, typically spend all their time outdoors. Pigs and sheep may be raised either indoors or out. While a large variety of insecticides and herbicides are used in the cultivation of row crops and fruits, a relatively limited number of insecticides and biocides are usually employed in the raising of livestock and poultry. These chemicals are applied for insect pests on the animals, or biocides for disinfections. This is often performed by workers using either hand spray or dips. While crushing injuries are possible in the handling of large animals, greater risks may be present from infectious agents (zoonoses) and from the handling of silage and grains and the inherent confined spaces and explosion hazards in storage facilities (i.e. silos, grain elevators).

Occupational hazards

Occupational hazards in farm settings may arise from several different factors including physical, chemical, and

biologic factors, as well as structural and engineering practices. Physical hazards arise from lifting, climbing, heat and sunlight (ultraviolet radiation), and farm equipment (trauma). Lifting hazards can result from such diverse activities as lifting or handling irrigation pipes and equipment, and moving boxes of produce or bales of hay. While most people think of hay as something that is light, a bale of hay (depending upon type of equipment employed and moisture content) can weigh up to several hundred pounds.

Heat exhaustion can be a major problem in farming that employs manual and stoop labor for harvesting of crops, particularly in warmer climates. These workers are often paid by the quantity picked, so that workers may go from sunup to sunset with few to no work breaks. In addition, despite field sanitation laws, access to potable water may be limited. This may be compounded by requirements for the use of personal protective equipment (PPE) in the handling of pesticides (see appropriate sections below). In extreme heat, such as occurs in the southern US during the summer, as well as numerous tropical climates, the use of full PPE may be contraindicated by concerns for heat stress. In as little as 15 to 20 minutes, workers' lives can be endangered by respirators and impermeable jump suits.

Chemical hazards

In the agricultural setting, by far the most common method used to minimize dermal and/or respiratory exposures to farm chemicals is personal protective equipment (PPE). PPE may range from gloves and half-face respirators to full protective plastic suits and full-face respirators (Fig. 12.2). While PPE in agricultural settings is most commonly thought of in terms of the handling of pesticides, other chemicals used on the farm can require protection of the workers as well. For example the use of anhydrous ammonia as a farm fertilizer, requires PPE for both dermal and respiratory protection. The use of PPE in particular applies to pesticide mixers, loaders, sprayers, and flaggers. It is important to consider that mixers and loaders may

Figure 12.2: (a) and (b) A farmer wearing personal protective equipment (PPE) during a planting operation. Treated seed and granular insecticide are applied during the planting operation. Typical protection includes a respirator, gloves, goggles, and coveralls.

not even work on a farm, but rather may be employed at a small airfield where aircraft utilized for aerial spraying of pesticides and herbicides are maintained and serviced.

Mixers are involved in the preparation of the pesticide by mixing pesticides either in powder or liquid form from diluents. Diluents may be either water or organic solvents including kerosene. Additionally, surfactants such as nonyl-phenol may be added to improve the adherence of pesticides to the plants. Compounds such as nonyl-phenol and many others are viewed as 'inerts' in the technical terminology of pesticide formulation. This should not be construed to mean that these compounds may not also present some hazard. For example, in several studies nonyl-phenol has been found to be an estrogen disruptor.^{3,4}

Loaders are involved in transferring the mixed pesticide to containers for application. Particular hazards may arise during pouring of solutions. Fatalities have been documented when loaders have spilled organophosphate pesticide mixtures into boots which they then failed to remove, and subsequently failed to wash the affected area promptly. The US Environmental Protection Agency estimates that farm workers experience approximately 300,000 acute illnesses and injuries each year related to pesticides. This is likely to be an underestimate of the true number as adequate clinical tests for pesticide poisonings only exist for organophosphates. There are very few states that require mandatory reporting of pesticide illnesses. In California in 1990, almost 2000 pesticide-related illnesses caused by occupational exposure were reported. More than half of these involved exposure during mixing and loading and an additional one-quarter involved exposure of workers to residues on crops.² Sprayers may be involved in manual spraying of crops or the operation of spray rigs. Hand spraying may involve either hand-carried tanks or spray backpacks (Fig. 12.3).

A major hazard may arise when tanks are filled while the worker is wearing these backpacks, as spillage onto the worker often occurs. Again, as with loaders, particular problems can arise from spillage into gloves or boots. Failure to remove them and wash promptly may result in acute poisoning episodes or even death. The availability of water for washing of workers who accidentally come in direct dermal contact with pesticides is another reason that field sanitation rules are important to worker health and safety. Flagging involves the use of workers on the ground, to mark areas to be treated by aerial spraying. These workers are at risk of over flight by the aircraft applying the chemicals. For this reason, the use of PPE by these workers is also important.

Once the pesticides have been applied, it is important that workers are not allowed into the field for a prescribed amount of time, termed the 're-entry' period. This is particularly important prior to harvest as a large number of workers, far more than are usually involved in the pesticide application itself, may be exposed. Re-entry periods are well established for all pesticides utilized in the US. However, re-entry time may be modified by weather, as temperature and humidity can effect how long the pesticide may remain wet and thus more readily transferable to workers. Some of the largest pesticide poisoning episodes have been associated with premature re-entry to fields following the application of organophosphate pesticides.

Figure 12.3: A worker applying pesticide using a backpack, mist blower sprayer. This application is taking place in West Africa; the worker is applying an organophosphate insecticide. He is not using any personal protective equipment (PPE).

Another factor that is often not considered is the potential for exposure of families of pesticide mixers, loaders, flaggers and applicators. This can result from several factors: (1) proximity of the family residence to mixing areas, (2) storage of pesticides in homes, (3) and washing of work clothes with the family laundry.⁵ Workers may also reuse containers that previously held pesticides and employ these for carrying potable water. This practice has resulted in numerous poisonings and even fatalities. It is therefore important for the clinician not just to consider the potential for the exposure of pesticide workers, but the potential for exposure to their families as well.

Zoonoses

While hazards from zoonoses may most readily come to mind in the case of farms which raise livestock and poultry, they are certainly possible in other farm settings as a result of insect and arachnid bites arising from the handling of

fruits and vegetables. In the latter category, the rickettsials and arboviruses may be of concern. In addition, in the Southwestern part of the US storage of grains may lead to infestations of rodents, which may harbor fleas that carry Hanta virus. The focus of the clinician should be such that where locales are known to have problems with insect-borne viruses, zoonoses should certainly be part of the differential diagnosis and the determination of treatment of farm workers. With respect to zoonoses, animal handlers are clearly at a higher risk. With more and more farmers raising exotic livestock (i.e., alligators, llamas, emus, ostriches, etc), the possibility of non-traditional farm zoonoses must also be considered. The astute clinician needs to bear in mind these possibilities in the evaluation of infectious diseases in these workers. Despite recent concerns in Europe regarding bovine spongiform encephalopathy ('mad cow disease'), there is little evidence to suggest that farm workers are at specific risk from this agent.

Confined spaces

Though more common in grain elevators than farm silos, the hazards of confined space accidents and fatalities represent a small, but real health and safety factor on some farms. Workers who are employed at farms that store grain (either awaiting sale or for feed) are at particular risk. The hazards involved are three-fold: (1) oxygen-deficient atmospheres; (2) explosive dusts; (3) pneumoconiosis. Workers should be cautioned regarding these hazards. The hazards can be minimized either by the use of PPE or through ventilation of the spaces and testing of the atmosphere prior to entry.

Sunlight (ultraviolet radiation)

Separate from the health risks posed by heat from working in the hot sun are the risks from exposure to ultraviolet radiation during long days spent outdoors. Both acute problems such as severe sunburns, as well as chronic risks of skin cancer are associated with repeated long-term exposure to sunlight. Even though this might be perceived as being of greater concern in the warmer climates or high altitudes, these risks are quite real regardless of the locale. The preventive measures are relatively simple and include the use of sun blocks, long-sleeved shirts, and hats.

HEALTH AND SAFETY PRECAUTIONS

Personal protective equipment

The nature of farm work presents several health and safety hazards, which can be minimized by the use of proper personal protective equipment (PPE), as well as by proper engineering. Both of these methods may be employed with respect to workers' exposure to agricultural chemicals. As previously pointed out, while usually thought of in terms of pesticide application, other farm chemicals may also require PPE. The use of the correct and adequate PPE is a

common problem on the farm. Farmers and farm workers often perceive pesticides as beneficial substances. Among Mexican-American farm workers, insecticides and herbicides are commonly referred to as *medicinas*, medicines for the plants. What is not obvious is that these chemicals can present both acute and chronic health risks to workers. The level of risk these chemicals may represent to human health is often not apparent to the farmers and farm workers, because technical language warning labels are frequently difficult to understand. This can be further confounded by language problems, as many farm workers in the US are illiterate in English. These workers may also be at the greatest risk for not having access to proper equipment or adequate training in its proper use. Compounded by the fact that a large proportion of farm work is done during the warm growing season, it is not surprising that PPE is underutilized on farms. Detailed studies by Fenske et al. have demonstrated that limitations of the use of some types of personal protective equipment on farms is a significant and important source of excessive exposure of workers to agricultural chemicals.⁶

The appropriate PPE for mixing, loading, and spraying of pesticides varies between specific compounds; however, in general the hazard is greatest for those involved in mixing, since they handle the most concentrated form of the chemical. PPE for agricultural workers may include either half- or full-face respirator, rubber gloves, and either a protective suit or chemical-resistant apron. In addition to inhalation as a route of exposure, some compounds can be absorbed through intact skin. The soles of the feet can be a major area of concern from accidental chemical spills in rubber protective boots. One of the difficulties in minimizing dermal exposure is to convince workers of the necessity for protective clothing. The other problem is the previously mentioned issue of balancing the chemical hazards against the heat stress that wearing PPE may entail. Since most small farming operations lack the resources and ability to train workers, problems of excessive exposure and poisoning of farm workers will unfortunately continue. For this reason clinicians, and particularly emergency room workers, need to be familiar with the recognition and treatment of acute organophosphate poisoning.

Controlled-environment cabs

Due to the increased mechanization of the application of agricultural chemicals, the use and desirability of controlled-environment cabs has increased in farm equipment. While the move to controlled-environment cabs has been driven by driver comfort (air conditioning), these cabins are increasingly being engineered into farm equipment for the increased protection they offer operators to inhalation exposure to agricultural chemicals. These systems may include the use of both high efficiency particulate filters (HEPA), as well as those for organic vapors. There may also be pre-filters to trap large dust particles. If manufacturer's recommendations are followed including appropriate routine replacement of filters; these cabs can reduce or eliminate major sources of worker exposure to

agricultural chemicals. This has a two-fold benefit in eliminating the direct health effects of the exposure to the worker, as well as the additional protection from the potential of some chemicals to impair the ability of the operator to safely operate farm equipment.

Rollover protection

Injury data on farm accidents that result in serious injuries or death indicate that single greatest risk for farmers and farm workers results from rollover accidents of tractors and farm equipment. Tractor accidents account for an estimated 600 fatalities per year. Rollovers account for more than half of these deaths. Tractors made more than 40 years ago are still in operation today. It is estimated that fewer than one-third of the 4.4 million tractors used for agricultural purposes have rollover protection. Older tractors often are used in situations typically associated with tractor rollover accidents, such as mowing the road ditch area, using a front-end loader, and hauling fallen trees.^{7,8} Because many tractors are based on a tripod like structure with two closely spaced wheels in the front (Fig. 12.4), they are prone to tip and roll over. While some tractors have adopted a wider spacing of the front wheels (Fig. 12.5) to decrease the risk of rollover, this does not totally eliminate the problem. In the US, tractors have been required to be fitted with seat belts and rollover protection since 1976. When used properly, this combination has been shown to significantly reduce the risk of injury from tractor rollover accidents.⁷ Unfortunately, many older tractors still in use do not have these safety devices; however, retrofitting kits are available at reasonable costs. Given the high rate of injuries from tractors without rollover protection and seatbelts, the cost/risk benefit for these devices cannot be overstated.

Equipment guards

Another significant source of farm-related injuries is limb crushing and amputations from power take-off attach-

Figure 12.4: An older model tractor with narrow front end and no rollover protection system (ROPS), with only a shade used to reduce exposure to the sun.

Figure 12.5: (a) and (b) Modern tractors with rollover protection system (ROPS). Note the tractors have a wide front end and front-end weights to counterbalance any equipment attached to the drawbar at the rear.

ments to farm equipment. While most modern farm equipment includes appropriate guards for pulleys and power take-offs, this equipment may be removed or not properly re-installed when the equipment undergoes repair or maintenance. It is important that farmers and farm workers appreciate the severity of injuries that may result from failure to employ these important safety devices.

CHRONIC DISEASE AND INJURY

Cancer

Numerous studies of farmers and farm workers have observed an increased risk of cancer. In particular, studies have found elevated risks for the development of hematopoietic malignancies including leukemias and non-Hodgkin's lymphomas.⁹ These studies examined a broad range of farm activities as potential risk factors, including a variety of agricultural chemicals and possible zoonoses associated with livestock and poultry production. Most of the studies have focused on specific herbicides and pesticides used on farms. This has proven to be a difficult task for several reasons. First, a large variety of pesticides are applied on many farms. Second, changes have taken place both in the types of pesticides applied, as well as the method of application. Finally, a large group of agricultural workers, who are employed as migrant and seasonal employees, have been difficult to track with respect to health endpoints. However, despite these limitations, several chemicals have been implicated in epidemiologic studies including 2,4-D (2,4-dichlorophenoxyacetic acid). While no firm conclusions have been reached with respect to these pesticides and the apparent increased risks of cancer, it would appear to be prudent for farmers and farm workers to minimize their exposure to farm chemicals.

Clearly it is important for farmers and farm workers to make use of protective measures (as previously described) in handling farm chemicals. In addition, it is important for them to follow manufacturer's guidelines with respect

to proper use of PPE for mixing, application, and field re-entry. By following these procedures exposure and cancer risks should be minimized.

Even though the source of the increased risk of hematopoietic cancers in agricultural workers is not fully understood, one well-understood cancer risk is ultraviolet radiation from sunlight. Agricultural workers are thus at increased risk for skin cancers including squamous and basal cell carcinomas and malignant melanoma. While skin pigment (level of melanin) is important in the actual level of risk, even dark-complexioned farm workers are at elevated risk. As was previously discussed, the use of sun block, hats and long-sleeved shirts can help minimize these risks.

Dermatologic conditions

Besides the risk of skin cancer, other dermatologic conditions are also associated with work on farms. These may arise from a variety of different types of exposures. These include, but are not limited to, the maintenance of farm equipment, handling of farm chemicals and certain farm produce. Irritant contact dermatitis from the maintenance of farm equipment results from the handling of gasoline, diesel, and oil. Allergic contact dermatitis may also result from handling the crops or livestock. Skin problems associated with insecticides and herbicides can arise from the use of organic solvent diluents acting as defatting agents, as well as from the chemicals themselves. Some of the earliest dermatologic problems documented in the medical literature, pertaining to agricultural workers, were keratoses associated with the use of arsenical compounds in vintners.¹⁰

Clearly those individuals who are involved in mixing of pesticides may be at greatest risk due to their handling of the concentrated chemicals. It is also important to point out that the risk of dermatitis may not just arise from the handling of chemicals, but also from improper hygiene in the use of rubber gloves. If the protective rubber gloves are

not thoroughly cleaned and dried inside and out, bacterial growth can lead to secondary infection, e.g. cellulitis. Therefore the availability and use of clean, dry gloves for PPE is essential. This can be aided by the use of disposable cotton liners for rubber gloves.

Musculoskeletal disorders

Musculoskeletal problems on the farm arise at least to some extent from the combination of light activities such as running farm equipment, in conjunction with other tasks requiring heavy lifting. Even though increased mechanization has made many tasks easier, lifting is still required for numerous farming activities. Lifting tasks on farms can range from replacement of tires on farm equipment to lifting bales of hay or boxes of produce. In addition, repetitive trauma to the wrist and elbow joints may arise from activities relating to hand picking of crops and/or trimming of vines. Migrant or seasonal farm workers are at particular risk for this type of injury. While the repetitive nature of hand milking has mostly disappeared from dairy farms in the US, musculoskeletal problems are still present from the bending and/or kneeling involved in attaching the automatic milking equipment in some dairy farm settings. This can be minimized by ergonomic design of the milking area, including the use of different elevations that allow workers to attach the equipment while in a standing position. There are also risks to workers of being stepped on or kicked, resulting in either crushing injuries or fractures in the handling of large animals.

Neurologic disorders

The use of pesticides, in particular organophosphates (OPs) and carbamates, has long been associated with acute neurologic conditions (see Chapters 28.1 and 48) but relatively little research has been conducted on possible chronic health effects of these compounds. Many of the older OPs were highly lipophilic and so long-term effects are possible. Future research is clearly called for in this area.

Reproductive disorders

Another area which has been of concern with respect to agricultural workers is the possibility of adverse reproductive effects. Areas that have been studied include both effects to males (i.e. azoospermia, oligospermia), female infertility and effects to the developing fetus (i.e. spontaneous abortion, low birth weight, stillbirth, and congenital malformations).¹¹⁻¹⁹ An increasing number of human epidemiologic studies have examined this issue. Clearly the majority of studies have examined the potential for health effects to the fetus (see Endocrine & Reproductive Disorder).¹¹⁻¹⁷ The evidence for significant adverse health effects to the fetus from pesticides and herbicides used on farms is increasing. In comparison to the volume of work on direct effects to the fetus, relatively little is known about effects on male gamete production (i.e. sperm abnormalities, oligospermia, azoospermia).

Perhaps the best documented effects on males involved farm workers using the pesticide dibromo-chloropropane (DBCP) in Rio Frio, Costa Rica.¹⁸ In this study, male workers who were exposed to DBCP experienced sharp reductions in sperm production. While in most individuals this was found to be reversible, some men experienced permanent azoospermia. Arsenical compounds have been utilized both as pesticides and as defoliants on cotton. Based primarily upon a large number of animal studies, but also on studies of workers in production facilities, concern has been raised about arsenic compounds and a variety of reproductive endpoints.¹⁷ These include increased rates of spontaneous abortion, stillbirths, and congenital malformations. Unfortunately, for many agricultural chemicals the issue of reproductive toxicity has been largely overlooked.

Respiratory diseases

Upper and lower respiratory symptoms among farm workers can result from non-specific mucous membrane irritation due to the fumes and dusts associated with crops, animal waste, and farm chemicals. Asthma and allergies are common from exposure and sensitivity to plant and animal allergens. 'Farmer's lung' is an illustrative term used to describe hypersensitivity pneumonitis among farmers. Although historically described as due to thermophilic actinomycetes contamination of hay, sugar cane, and mushrooms, hypersensitivity pneumonitis has now been ascribed to numerous bacterial, mold, and animal antigens found in various farming processes. In its acute form, hypersensitivity pneumonitis may mimic influenza, presenting with fever, chills, malaise, cough and shortness of breath, which usually resolves within a few days after removal from exposure. Chronic hypersensitivity pneumonitis may develop after repeated acute episodes and continued antigen exposure or rarely after a single severe attack. This can lead to irreversible progressive airflow limitation and parenchymal changes (see Chapter 19.6). While corticosteroids may be used to treat acute episodes, prevention either by removal of the exposure or avoidance of the exposure by the affected worker remains the mainstay of treatment.

CHILD LABOR

Perhaps no area is of greater concern with regard to the health and safety of agricultural workers than the plight of children as farm workers. This takes two forms: first, children who work on the family farm, and second, those children whose families are employed as migrant and seasonal farm workers. With regard to the former group, the major concern is the operation of farm equipment, where a disproportional number of tractor accidents involve young drivers. In respect to the latter group, the effect may be far less obvious, but no less serious. These children, some less than one year of age, are exposed to long days in the field. Those only slightly older (age 3) may be actively involved in the harvesting of row crops. This brings up not just the issue of repetitive trauma, but

possible health effects of pesticides on infants and young children.

Unfortunately, little research has been conducted to determine the full range of health hazards these chemicals may represent to young children. It is also essential to keep in mind that personal hygiene is usually poorer in young children and infants. This, coupled with the high frequency of hand/mouth and object/mouth activities, results in a high risk for pesticide ingestion. For these reasons, it should be clear these children represent a high-risk population. Unfortunately, neither state nor federal laws in the US appear to adequately address this problem. Pediatricians in agricultural communities need to be cognizant of pesticide-related health effects and well educated in recognition and treatment of acute poisoning.

While many people view the farm environment as a safe place for children, the truth is that many children who work on farms suffer serious injuries and death. The National Agricultural Worker's Survey indicated that between 1993 and 1996 there were approximately 128,000 farm workers aged 14 to 17.²⁰ In the US in 1998, approximately 33,000 agricultural injuries occurred to children or adolescents under the age of 20. Injuries occur annually at a rate of 17 per 1000 farms. Boys were almost four times as likely as girls to suffer an injury. Approximately a third of all youth injuries occurred in children age 10 to 15, resulting in almost 300 deaths per year. Sixty-four percent of the work-related fatalities in children under age 16 occur on family-owned farms. Farm machinery, in particular tractors, is the leading cause of fatal farm accidents, accounting for 36% of deaths in workers under the age of 20. Perhaps most tragically, 30% of farm equipment accidents take the life of children under the age of 5. This same age group also falls victim to drowning, which is the second leading cause of farm deaths.²¹

Chapter 13

Mining

Jeffrey L Kohler

INTRODUCTION

Mining is a basic industry, providing modern society with the energy and material resources required for everyday life as we have come to enjoy it. The role of our mineral wealth is apparent when we see copper plumbing, a concrete sidewalk, or a piece of gold jewelry. Although the use of electricity is ubiquitous, many are unaware that over 50% of it is generated in coal-fired plants. Even less obvious dependencies include carpets (whose components include five mined products), plastic pipe (with a pulverized stone content of 50%), computers that contain more than 30 mined products, and paint and many medicines that depend upon mined constituents for their prized properties, to name but a few. Agriculture is heavily dependent on mined products in the form of fertilizers, and other industries utilize mined products even when those mineral commodities do not show up in the manufactured article. Indeed, it is difficult to find any corner of the economy that is not tied to the availability of quality minerals or mineral resources.

Mineral resources come from the Earth's crust, and their extraction is seldom easy. Even after extraction, considerable effort may be expended to separate, refine, and concentrate the valuable minerals that are often mixed or bound with waste materials. Minerals production can be divided into two general phases: the *extraction phase* is concerned with removing the material from the Earth; the *processing phase* separates the valuable component from the less valuable or waste material. In practice the distinction between the two phases is often blurred. Commonly, the term mining is used to describe the extraction phase, while processing is used to describe the phase of preparing the product for human use. Usually, the people involved in both are called miners or mineworkers, although in some quarters other terms are used.

In its simplest definition, mining includes all of the job processes required to produce a mineral commodity in saleable form. A simple example would be the mining of a limestone deposit and the subsequent processing to a crushed stone for sale to a concrete producer. A more complex example would be the mining of an iron ore deposit and the subsequent processing to concentrated taconite pellets for sale to a smelter. An increasing number of mining operations are becoming vertically integrated – that is, an end product for direct sale to the consumer is produced and processed on the mine site.

Economics and globalization of mining

Mining occurs where the deposit is found, of course, and where the mined commodity can be converted economically to the desired product. Transportation costs are often a limiting factor, and accordingly coal will be mined for the use of a nearby power plant or perhaps a plant that is hundreds of miles away but readily served by rail. Stone, on the other hand, has a lower value with respect to its transportation cost, so a stone mine will typically serve customers within only several miles. The transportation factor and the geographic linkage between mining and manufacturing have become more evident in recent years as metal mines employing hundreds of workers (e.g., copper mines) have closed and moved operations to other countries. Shortly thereafter, the associated manufacturing plants (e.g., copper rod and wire), also employing several hundred workers, close and move operations nearer to other mines. Of course, certain rare and precious commodities are completely decoupled from the transportation cost constraint – e.g., gold and diamonds.

Mined products had a value of 60 billion dollars in 2002, and added nearly one-half trillion dollars in value to the US economy. Approximately 300,000 people were directly involved in mining, and another 3 million people were employed downstream in the support, processing, and conversion of these mineral resources. Figure 13.1 illustrates the location of mines, by sector, within the United States – as the data reveal, mining occurs in almost every part of the country. (The sectors in common use are coal, metal, stone, and non-metal. Non-metal includes such commodities as boron, potash, sulfur, salt, and vermiculite. The US Geological Survey¹ provides an excellent discussion of all US mineral commodities.)

Mining has always been a global endeavor, but over the past decade the globalization of the industry has accelerated. Large multinational corporations now conduct extensive metal, non-metal, and coal mining in the United States and in South America, Africa, Europe, Asia, and Australia. Mining methods and equipment have become similar throughout much of the developed world, as have occupational health and safety hazards to which mineworkers are exposed. At the same time, this globalization has presented significant parallel opportunities to improve conditions on a global basis. For example, successful health and safety interventions are developed in one country and then applied to similar mines throughout the world. While many of the examples used in this chapter are drawn from

a. Coal mines (2144 operations)

b. Metal mines (281 operations)

c. Non-metal mines (785 operations)

d. Stone mines (4282 operations)

e. Sand and gravel mines (7131 operations)

f. Distribution of mineworkers by mining sector

Figure 13.1: Location of mines and distribution of mineworker employees by mining sector in the United States. Parts (a)–(e) from MSHA 2001,²¹ part (f) from NIOSH 2003.²²

the US mining industry, the mining methods, descriptions and associated health and safety issues apply to mining throughout most of the world.

Human costs of mining

In the course of meeting society's direct and multifaceted needs for mineral commodities, mineworkers have been killed, others have suffered lost-time injuries, and still others have endured the silent progression of occupational

illnesses brought on by excess exposures to noise, dust, or other potentially harmful substances. Similar injuries and illnesses occur throughout the mining industry. At the most severe levels are traumatic injuries, cumulative trauma disorders, respiratory diseases, and hearing impairment or loss. Certain injuries and illnesses are far worse for certain commodities or mining methods, and a few are particular to a specific commodity or method.

Mines are 'built' directly within the crust of the Earth and therefore are made of whatever geologic materials exist at

the site. Thus, the geologic setting can be inhospitable, containing dangerous gases, and the associated rock can be weak and prone to failure. This creates special health and safety challenges well beyond those of a factory setting, where the construction is entirely man-made materials and the factory operations are comparatively routine and predictable. Moreover, the dimensions of the working spaces within the mine are generally limited by the deposit dimensions, and in many cases this results in confined space working conditions.

A more detailed discussion of health and safety issues is presented later in the chapter.

MINING METHODS

The classification of mining methods for engineering purposes is complex, with many individual methods and sub-methods in use. However, in the interest of focusing on health and safety issues, a number of simplifications can be made. First, all mines can be classified as one of three types: *surface*, *underground*, or *solution*. Deposits that are close to the surface can be accessed by removing the relatively shallow cover or overburden materials, thereby exposing the deposit that can then be recovered. Copper, coal, and stone are examples of materials that are commonly mined by surface mining methods. Deposits buried deeper within the Earth's crust cannot be accessed simply by removing the overlying materials, so access to the deposit is gained by sinking shafts or driving other openings from the surface down one hundred to a few thousand meters deep to the deposit. Then an extensive network of 'tunnels' is driven into the deposit itself and/or within the host rock surrounding the deposit. This network of openings both facilitates the extraction of the ore and provides a way for the services infrastructure to get the ore from the solid ore body to the surface. Underground mining is much more difficult, expensive, and dangerous than surface mining, so it is primarily used for commodities that are otherwise unavailable from surface mines. Examples of underground mines include coal, gold, salt, and stone.

Occasionally a deep deposit can be mined with a solution method, in which 'wells' are drilled into the deposit, a dissolution agent is pumped down the well, and the solution is pumped back out for removal of the desired metal or mineral. This type of mining is used for commodities such as sulfur, trona, salt, and uranium, and is sometimes known as borehole mining. A modification of this is heap leaching, in which low-grade ores are mined, typically by surface methods, and placed into engineered piles where the lixiviant percolates through the pile. The resulting solution is then treated to recover the mineral product of interest. Heap leaching remains an important method for recovering gold.

The mining engineer chooses the mining method based on several technical and market factors. While it may be significantly cheaper to surface mine 100-foot-thick coal seams in Wyoming than to underground mine five-foot-thick seams in West Virginia, the cost of transporting the Powder River Basin coal to the East Coast tips the balance in favor of the more expensively mined coal in West Virginia.

Mine type	Class	Method	Commodities
Surface	–	Strip (open cast) Quarry Open pit	Coal Stone Metal
Underground	Stoping	Dredging	Metal, non-metal
		Room and pillar mining	Coal, non-metal
		Stope and pillar mining	Metal, non-metal
		Sublevel stoping	Metal, non-metal
		Cut and fill stoping	Metal
Solution	Caving	Longwall mining	Coal
		Block caving	Metal
		Leaching	Metal
		Borehole	Non-metal

Table 13.1 Important methods used to mine coal, metal, and non-metal commodities

Another example described earlier is stone. As a very low-cost commodity, it would appear that surface mining would be the only economic choice. However, some limestones are of very high purity, often called 'pharmaceutical grade', and because of this they fetch higher prices.

Major mining methods are summarized in Table 13.1. These methods will be described in more detail for each of the major mining sectors of coal, metal, and non-metal. For each sector the more important underground and surface methods will be summarized. The presentation of the mining methods is then followed with an overview of mineral processing operations. A complete treatment of mining methods is given by Hartman and Mutmansky.²

Underground coal mining

Deep coal deposits are tabular in nature (i.e., they lie in horizontal layers), and those being mined range from under a meter to several meters in thickness, with a thickness of a few meters accounting for the majority of underground mines. Within the coal seam, rooms are mined and pillars are left behind to support the overlying strata or roof of the mine. This is known as room and pillar mining, and is conducted usually with continuous mining equipment, and rarely today with the older conventional mining equipment. Continuous mining involves equipment that both cuts and removes material without the more conventional use of drills or explosives.

As the rooms are mined a vast network of 'tunnels' is created, stretching for many miles in larger mines. These mined openings are known as 'entries' and 'cross-cuts'. As these are developed they serve as conduits for ventilating air, travel and haulage ways for people, machines, conveyor belts, and even a mine-size railway system. Indeed, the underground mine is like a small city, complete with an electricity distribution system, as well as fresh and contaminated water distribution systems. While it is protected from the weather by virtue of being underground, parts of the mine closer to the intake air portals reflect the outside air temperature due to the high volumes of air drawn into the mine, whereas parts more distant from the fresh air

Figure 13.2: Schematic view of an underground coal mine showing the longwall panel and the ‘rooms and pillars’ comprising the network of underground openings.

intakes more closely reflect the temperature of the deposit. During the winter, for example, the temperature of the intake air may be well below freezing and remain near freezing through much of the main entryways of the mine, although it would be warmed by the underground rock, which may be close to 15 degrees C. By the time this air reaches the working face, the air temperature may approach 25 degrees C. Such significant temperature differentials are not uncommon in other locations and mining types. The air in some parts is further warmed by the equipment, but throughout the mine the air tends to be very humid. Some mine operations cut through or break into the water table, and in these situations it may even seem to be raining in parts of the mine with generally wet conditions throughout.

Room and pillar mining is practiced by itself in smaller mines, whereas in larger mines room and pillar mining is used to facilitate a more productive method known as longwall mining. In this method, room and pillar mining is used to create the main infrastructure – in a sense the major highways and secondary roadways of the mine ‘city’ – and to delineate large blocks of coal. These large blocks

are then longwall mined at great efficiency and with additional safety over the room and pillar method. A brief overview of continuous and conventional mining methods is presented in Chapter 19.10. Figure 13.2 illustrates an underground coal mine with room and pillar workings and longwall panels. A longwall face is shown in Figure 13.3.

The primary hazards of underground coal mining fall into four general categories, each of which is discussed in greater detail below and in subsequent chapters:

- *traumatic injuries* – these are caused by rock falls or the consequence of large machines and people working in close proximity in a confined space;
- *cumulative stress disorders* – these disorders arise from working in a confined space in which the distance between the floor and roof may be well under a meter, necessitating extensive crawling, kneeling, and ‘duck walking,’ or from operating equipment mechanisms, such as remote control consoles that require repetitive motions;
- *respiratory disease* – respirable coal dust is liberated during the mining process, and silica dust is generated during different phases of mining, especially during drilling to

Figure 13.3: Coal mine longwall face, showing the shearer operator with the remote control pendant for the shearer. An important engineering control, the dust suppression water sprays, is visible, as is the personal protective equipment used by the operator. Note the confined conditions under which the operator performs the job over a period of 8–12 hours. (Photograph courtesy of Joy Mining Machinery, 2003.)

install roof bolts and from the action of longwall shields;

- *hearing loss* – the act of ripping tons of rock per minute from the deposit, rock drilling, and the many associated operations are inherently noisy, and harmful noise levels may result.

Surface coal mining

When the deposit lies close enough to the surface, it may be economically feasible to remove all of the overlying materials to expose and then mine the coal. Various methods used to do this make up surface mining, also known as open cast mining. Regardless of the specific method employed, surface coal mines follow a typical sequence of operations.

1. Vegetation is removed and soil layers are removed and stored for subsequent use.
2. The rock layers overlying the coal seam – referred to as ‘overburden’ – are removed and stored. Generally this overburden removal involves the drilling of holes for explosives, then blasting, loading, and hauling the overburden.
3. The exposed coal seam is mined, which may involve some additional drilling and blasting prior to loading and hauling.
4. After the coal has been harvested, the overlying materials are then returned in an exact sequence, which may involve the addition of materials such as stone or lime to neutralize acid-bearing layers and to facilitate the reclamation of the disturbed area.

Often the terrain overlying the coal is not flat but mountainous, and as mining advances the depth of the overburden

will increase until it is no longer economically wise to remove it. At this point, surface mining stops, leaving an exposed highwall. Sometimes an underground coal mine will be developed, gaining access through the exposed coal seam in the highwall, and other times mining is terminated. An alternative to both of these is to engage in some form of highwall mining, in which a mining machine, such as a thin seam miner or an auger, is set up and operated on the bench – a horizontal working surface created during mining – at the highwall face. This allows some coal to be retrieved at a low cost without the expense or risk of developing an underground mine. The distance to which these machines can ‘burrow’ under the mountain top is of the order of 300 meters or less. While the mining operations are obviously vastly different for the surface mining of a 30-meter-thick seam in the wide open spaces of Wyoming versus a 1-meter-thick seam on a mountainside of West Virginia, similar health and safety issues exist for both.

By definition, the health and safety hazards are somewhat less in surface than underground mining. Many of the confined space issues of underground mining disappear, as do many of the respiratory hazards. The open spaces of surface mining also permit the use of cabs on equipment to protect workers from excessive noise levels, which cannot be done as practicably in an underground mine. Generally, all of these facts are also reflected in surveillance data. Nevertheless, some surface coal mineworkers are exposed to hazardous levels of respirable coal dust, and drillers have the potential to be exposed to silica dust when the overburden contains crystalline quartz. Traumatic injuries still occur, and cumulative stress disorders are as prevalent as in underground mining, although slightly different in cause.

Underground metal mining

Underground mining of deposits containing metal – called ‘metaliferous’ – is dramatically declining in the United States, due to the high cost of recovering relatively low-grade ores, although many new metal mines are being developed in South America, Australia, and Asia. Within the US, there are some remaining underground mines, primarily in the western part of the country, principally for mining gold, silver, lead, zinc, molybdenum, and platinum. Of course, if a high-grade deposit were discovered, it is likely that new operations would open. Metaliferous deposits tend to be complex in shape when compared to the relatively tabular coal deposits, and accordingly, the mines tend to be more complex as their workings access different parts of the deposit. These mines are typically developed at many different depths or levels, and there may be extensive development within the host rock as well as in the ore body itself.

Access into the mine is usually by way of a vertical or inclined shaft (called a ‘winze’), although ramps may wind between levels as well. Various openings are mined to access the ore body, and various levels are interconnected by raises and winzes. The term ‘stopes’ refers to working areas where ore is being removed. Depending on the method, openings are mined to provide chutes and funneling

channels to drawpoints, where the broken material is concentrated and removed. Given the complex three-dimensional nature of the mine and the varying combination of properties between the deposit and surrounding rock, a variety of caving and stoping methods have evolved. In the *caving method*, the relatively weak ore is undercut in some fashion, and the ore then ‘caves’ under its own weight, with or without some blasting, into areas from which it will be loaded and removed. In the *stopping method*, openings are driven into the ore body and the material is drilled, blasted, loaded, and removed. As caving methods are less costly than stoping, they can be used to recover lower-grade ores economically. As with the underground coal mine, underground metal mines usually have a significant infrastructure of utilities and materials handling systems. From an occupational health and safety perspective, however, the complex mining nuances are less important than the commonalities of health and safety risks inherent in all mining processes.

Drilling and blasting

Drilling – which utilizes large rubber-tired equipment such as jumbo drills or portable drills such as drifters or stoppers – is a major unit operation in underground metal mining. This drilling is done to provide a cavity to accept explosives and the holes are drilled to exact, calculated depths and in carefully controlled patterns. Care is taken to ensure safe and efficient rock breakage without undue overbreakage of the surrounding rock, proper size distribution of the fragments, and appropriate positioning of the blasted material. In any drilling operation, respiratory hazards are associated with generated dust and air-borne lubricants in the drill exhaust. Repetitive stress trauma and noise exposure are also common health issues associated with drilling. Cumulative stress and vibration problems are especially worrisome with portable drills.

Established blasting practices ensure that the substantial hazards of handling explosives result in very few injuries. As personnel are evacuated prior to blasting, the potential hazards of toxic fumes, dust, and noise are drastically reduced. However, it is possible for fumes to remain in a pile of blasted rock until the pile is disturbed by loading operations, with the fumes then liberated. A more common worry is the possibility of a ‘bootleg’ hole that failed to ‘fire’, leaving open the possibility of an inadvertent explosive discharge during loading with potentially serious consequences to workers in the area.

Loading and haulage

Loading of the ore, or waste rock, is likely to be done using diesel-powered vehicles in the form of separate loaders and trucks, or using a hybrid vehicle known as a load-haul-dump (LHD). The hazards associated with loading include excessive noise, diesel exhaust, and repetitive stress trauma. In some operations, electrically powered trucks may be used with a significant reduction in the respiratory hazards to the miner. Electrically powered slushers – machines that employ scraper blades to move material – are still used in some mining methods to move the ore from a drawpoint

to a point where it is either loaded or flows by gravity to a collection point.

Mining support workers

In all types of mining, a large number of workers who are not involved directly in the extraction or processing nevertheless perform essential support services. Ground control, ventilation, electrical power, compressed air, and materials handling are but a few examples. In addition to being at risk for traumatic injuries, these workers also undergo health and safety risks due to their exposure to high-noise environments and from repetitive stress trauma. A significant health hazard present in many underground metal mines, but absent from most coal mines, is heat stress. Often there are significant geothermal gradients in proximity to the metaliferous deposits, and it is not unusual for the wall rock to exceed temperatures of 35 degrees C.

Surface metal mines

Open pit mining is a common method used to extract metaliferous ore bodies lying close to the surface. Unlike coal deposits, these can be a thousand meters or more in thickness, and as a result mining develops and continues downward until an economic limit is reached. In the case of an especially large deposit, this can take many years or several decades. The need to gradually spiral down through the deposit – and to facilitate the movement of equipment and ore in and out of the pit – gives rise to the characteristic shape of open pit mines. The ‘steps’ or benches are built to provide a working surface, and the combination of benches reduces the chance of a slope failure – when sections of the pit walls break free and fall downward with potentially disastrous results for workers below.

The general sequence of mining in open pit operations is as follows. Large drills are used to drill blastholes, which are then filled with explosives. Periodically these explosives are ‘shot’, resulting in a large pile of broken material, which is then loaded using front end loaders, shovels, or hydraulic excavators, and finally placed in large haul trucks. The trucks then travel out of the pit to a dump where the ore is often crushed and transported by belt to a plant for processing. Sometimes the trucks only travel part-way out of the pit and then dump onto an in-pit crusher. This crusher feeds a conveyor belt that transports the ore more economically out of the pit and directly to the nearby processing plant.

The health and safety hazards are again less in surface metal mines as compared to underground mines, but still include traumatic injury, repetitive stress trauma, noise exposure, and dust. Drillers and blasters have the greatest exposure to dust and noise, and jarring and jolting can be particularly problematic for truck drivers.

Underground non-metal mining

The primary non-metallic materials mined underground include salt, trona (a mineral used as a source of sodium

carbonate), and stone. Trona mining is concentrated in Wyoming, while underground salt mines are dotted in a few locations of the East and Midwest. Underground stone mines are primarily located in the East, and their numbers are increasing. Methods similar to the room and pillar used in coal mining are frequently used in these tabular stone deposits, although a more irregular spacing of the pillars is necessary in both salt and stone, and thus the method is often termed stope and pillar rather than room and pillar mining.

Trona mines utilize mining machinery similar to coal mines, whereas salt and stone mines utilize equipment more characteristic of underground metal mining. Thus continuous mining machines, full-face boring machines, and roadheaders (boom-type tunneling machines) are found in underground non-metal operations such as trona, while diesel-powered drills, front end loaders, and haul trucks are found in stone and salt mines.

Surface non-metal mining

The surface mining of non-metals ranges over several important materials, but such mining constitutes a small portion of overall mining activity with the exception of aggregates – the mineral materials used in making concrete – including stone, sand, gravel, and dimension stone. Aggregate operations occur in large numbers throughout the country. Dimension stone is a localized but important industry in certain parts of the country, where granite, marble, and slate are carefully mined for a variety of architectural uses.

The surface mining of stone is known as quarrying, and the open pit mine is called a quarry. The unit operations and sequence of quarrying are nearly identical to those of open pit metal mining – i.e., drilling, blasting, loading, and hauling – as are the health and safety hazards.

A few different methods are used to surface mine sand and gravel. Sometimes a pit is created and the material is simply dug out with an excavator. Other times the pit is flooded and a dredge is used to recover the material. Occasionally water cannons, which generate high-powered water-jet impulses, or hydraulic monitors, devices that employ large flows of water under high pressure, are used to break the material away from a bank where it is then recovered, although this is more likely to be used in placer deposits to access precious metals. Dredging is often utilized on lakes, rivers, and harbors to recover gravel. The primary risks with sand and gravel operations are traumatic injury and noise exposure.

Dimension stone mines have remained relatively unchanged over the years. Everything in these operations centers on cutting large blocks of material, such as granite or marble, from the solid deposit, with minimal damage to either the cut block or the remaining material. Blocks of material are removed by the careful use of explosives or a high-powered mechanical saw, and then they are hoisted intact or toppled and broken into smaller blocks. The use of ever larger and more powerful mining machines has no place here. Consequently, it is still a difficult and tedious

process to carefully cut sections off the solid. Many of the cutting operations are deafeningly loud, and noise exposure is a high risk. Repetitive stress trauma is also a risk, and at a lower level, so is traumatic injury. Respirable dust risks have not appeared as a significant problem in this setting.

Solution mining

Solution mining methods are limited in application, but are becoming increasingly important especially for certain commodities. Consider, for example, that approximately 35% of gold, 50% of common salt, and 100% of lithium are derived from one of the solution mining methods. Sulfur is recovered using a solution mining process known as the Frasch method, in which superheated water is pumped down holes that have been drilled into the sulfur dome to melt the sulfur. The molten mixture is then recovered through other holes, or parts of the same borehole, and the sulfur is separated from the water and other impurities. The solution mining of uranium in particular offers a much safer method than the underground room and pillar method once used in uranium mines in the US, and like the solution mining of other commodities, it offers improved health and safety benefits as well as economic ones.

A modification of the solution mining method is heap leaching, discussed earlier in 'Mining methods'. Heap leaching remains an important method for recovering gold from low-grade deposits because it is unprofitable to run the low-grade ore through the traditional circuit of a mineral processing plant. Another similar application is the leaching of copper from waste piles created from material too low in grade to be sent to the mill, or from mill tailings that may still contain small percentages of copper. Vat leaching is a similar process that is conducted in large vats rather than heaps. Evaporation operations are an important method of solution mining, in which the liquid part of the solution is evaporated, typically with solar energy, leaving the desired component.

There are no documented health problems associated with solution mining, although the hazards associated with the use of solvents containing cyanide and acids, among other chemicals, are clear. In the past, some leaching sites have created serious environmental contamination, but modern environmental regulations and engineering practices are believed to be adequate to prevent future contamination of the environment from solution mining.

Mineral processing

Mineral processing plants are part of most mining operations. Their purpose is to convert the mined ore into a product for sale or subsequent use. A sand and gravel operation typically has a plant to wash the product and separate it by size. A stone plant typically includes several circuits to crush and separate the rock into a variety of sizes. In some cases this crushing includes pulverizing the stone down to micron sizes.

Coal preparation plants are somewhat more complex. While some crushing and sizing occur to meet customer requirements, most of the processing is concerned with separating the coal from impurities to reduce the ash and sulfur content. Thus, in addition to screen sizing, gravity separations are usually performed – where specialized machinery uses gravity to separate heavier and lighter materials. Moreover, as more sulfur can be released through crushing coal to increasingly smaller sizes, there is a significant fine coal component that must be recovered through sink-float processes that are heavily dependent upon organic chemicals. The plants associated with metal mines can be the most complex, with crushing and screening circuits and significant chemical circuits to isolate and concentrate the desired and undesirable constituents. These plants may include circuits for the beneficiation of metals associated with the primary metal, e.g., bismuth from a gold operation.

The health and safety hazards related to processing depend to some extent on the type of plant. Most plants have large machinery and are multileveled with numerous potential slipping hazards, and the processes are intrinsically noisy. Respirable dust can be a problem in certain locations of these plants, particularly near crushers. Traumatic injury problems and the problems associated with excess levels of noise or respirable dust are well known and well understood in mineral processing plants. The use of toxic chemicals such as cyanide has been studied extensively, whereas the risks associated with the use of neurotoxic chemicals in coal preparation plants, for example, is understood less well. Acids and other caustic materials used in these plants present safety hazards, if proper precautions are not applied.

MINING SAFETY AND HEALTH PROBLEMS

At the end of the 19th century, mining fatalities within the US numbered greater than 2000 a year; today the figure is less than 100 per year. Similar reductions have occurred for many injury classes and occupational illnesses. In some parts of the world these metrics are slightly better than in the US and in other parts are far worse. Efforts within the US by organized labor and progressive companies, research in university and government labs, and increasingly stringent regulations by state and federal agencies have all had a positive impact on mineworkers. Nonetheless, mining occurs under extremely difficult, and sometimes unpredictable, physical and environmental conditions. The Mine Safety and Health Administration (MSHA) has a mandatory reporting system for mine injuries and fatalities, and therefore good data are available to study the number and type of fatalities and injuries by commodity, work location, geographic region, and other variables.

Occupational illnesses in mining do not occur as discrete events, and as a result they are not reported with the same degree of certainty as fatalities or lost-time injuries. In fact, it is commonly believed that occupational illnesses among mineworkers are grossly under-reported, although this has not been substantiated through study.

Non-fatal lost-time injuries

Lost-workday injuries have declined over the past decade for mine operators in all commodities. Still, the rate in 2001 was 4.4 cases per 100 full-time coal mineworkers, as compared to a rate of 2.6 for general industry. Table 13.2 summarizes the number and annual average rate of lost-workday cases associated with various types of employers and commodities by work location. Note that the order and approximate magnitude of the injuries have changed little over the past few decades. During the period 1988 to 1997, for example, the five leading types of injuries were associated with materials handling (34%), slips or falls (21%), powered haulage (11%), machinery (11%), and hand tools (9.5%). The five most severe injuries, as reflected in the median number of days lost per injury between 1996 and 2000, were falling or caving rock (20 days for underground mining and 21 days for surface mining), slips or falls (25 days for underground and 17 days for surface), powered haulage (23 days for underground and 16 days for surface), stepping/kneeling on an object (22.5 days for underground and 9 days for surface), and materials handling (19 days for underground and 12 days for surface). Sprains to the back region due to overexertion accounted for the largest proportion of lost workdays. On a positive note, the number of back injuries has decreased over the years from nearly 5500 in 1992 to approximately 3500 in 2001.³

Many of these injuries are attributable to the natural conditions under which mining is conducted. Small slabs of rock may peel off the roof or back of the underground mine, striking a worker and causing a serious non-fatal injury. The presence of water and clay materials in the floor can cause a dangerously slippery condition. The close proximity of large machines and workers is always hazardous, but even more so in the confined spaces of underground mines. Visibility is often limited, further exacerbating the confined space hazard.

Despite extensive research over the years, significant improvements can still be made to reduce injuries resulting from these factors. Slips and falls have been a particularly difficult injury to reduce, because they occur in diverse settings and from many causes. Materials handling injuries have been reduced through improved workplace design. The increasing practice of palletizing supplies and providing vehicles with lifting forks has dramatically reduced the lifting and manual handling of supplies and materials that must be done each day in the mine. The development of stronger yet lighter materials for roof supports and stoppings has led to a reduction in materials handling injuries. A few mines have even installed exercise facilities at the mine site and encouraged employee fitness programs, and they report anecdotal evidence of reduced back injuries.

Work-related musculoskeletal disorders (WMSDs)

The leading illnesses among mine workers reported to MSHA in 2001 (excluding hearing loss) were repetitive trauma, accounting for 45.7% of illnesses. Numerous tasks

within mining require repetitive actions, and many of these are physically demanding. Often, especially in underground mining, these actions must be performed in awkward postures. Many underground coal miners perform tasks where the total vertical clearance available to them is less than their body height. Over the past two decades, more attention, primarily through research, has been focused on WMSDs, and on the design of mining equipment, supplies, and processes (see Chapter 23). However, during this same time, equipment innovations to achieve higher levels of efficiency and productivity have at times placed even more demands on the human body. A comprehensive treatment of ergonomic issues in mining is presented by Gallagher.⁴

Lower back problems make up a significant proportion of the WMSDs in mining. Upper body problems of the shoulder and hands are not as severe, and carpal tunnel syndrome is relatively rare in mining.⁵ The increased use of remote controls, as well as other changes to mining machinery, may contribute to an increase in upper-body WMSDs.

A final WMSD of note is miner's knee. This problem occurs in workers mining in thin seams, which requires extensive walking on the hands and knees. The resulting constant pressure leads to bursitis in the knee. The combination of pressure and frequently wet conditions also leads to infected hair follicles and thickened macerating skin that is easily infected. Miner's knee is confined primarily to the low coal fields, and in the United States, predominantly appears in mineworkers from Pennsylvania, West Virginia, and Virginia. Knee pads are provided to workers, but in many cases the design of the knee pads may worsen

the problem by trapping moisture under the pad, or concentrating stresses behind the knee.⁶

Hearing loss

Unlike many occupational illnesses in mining, noise-induced hearing loss (NIHL) is of epidemic proportion. NIHL and noise exposures are discussed in Chapters 20.2 and 35 respectively. Despite 30 years of regulation, research, and intervention, 91% of coal miners and 64% of metal/non-metal miners have a hearing impairment greater than 25 dB by age 50, as compared to 9% of non-exposed males of the same age.^{7,8} The resulting problems of hearing-impaired mineworkers go beyond quality of life issues, and include difficulties in communication or understanding speech, along with an increased accident risk on the job when normal safety cues cannot be discerned. MSHA's enactment of more protective rules combined with significant research efforts should help stem the tide of new cases in the future. However, mining is an inherently noisy endeavor, and even if engineering controls were 100% effective and applied diligently throughout the industry, it is estimated that only 20% of future cases would be prevented. Reduction of the remaining cases will depend heavily on the use of recommended hearing protectors. While engineering or administrative controls are the preferred approach, the proper use of individual hearing protective devices must be part of the solution to address the problem effectively.

Mineworkers, like those in other occupations, do not fully appreciate the risks to their hearing, nor do they fully understand the consequences of noise-induced hearing loss. For example, a common belief is that it will simply

become quieter as hearing is lost – miners are often completely unaware of tinnitus and the fact that it often accompanies NIHL. Mineworker understanding of the risks posed by excessive noise levels is essential to gaining their co-operation in maintaining noise controls, as well as getting them to take steps to protect their hearing, such as wearing hearing protectors. New training approaches are being explored to more effectively educate miners on the causes of NIHL and the actions they can take to prevent it. Low-cost personal dosimeters have been developed to empower individual mineworkers to measure their noise exposure and take protective actions as their dose accumulates during the shift.

Most noise sources found in mining cause a temporary threshold shift, and given sufficient exposures over time, the temporary shifts will become permanent. There are a few noise sources, however, which are loud enough to cause damage over relatively short time periods, so-called “impulse” noise. These include air arc welding, channel jet drilling, and the impulse noise from the detonation of some explosives. For workers exposed to these tasks in particular, it is imperative that adequate hearing protection be worn and that exposure to these sources is limited.

Work-related lung diseases

Coal worker pneumoconiosis (CWP) and silicosis are the two lung diseases most relevant to mining, discussed in greater detail in Chapters 19.10 and 19.9, respectively. CWP is more commonly referred to as black lung. CWP primarily affects underground coal workers, although cases in surface mine and coal preparation plant workers do occur infrequently. Silicosis, while affecting fewer miners, occurs across all sectors. Among the illnesses reported to MSHA in 2001, dust-related diseases made up 13.4%. Fiber-related dust diseases associated with the mining and processing of asbestos or vermiculite are rare among US mineworkers, but might be seen in areas where these commodities are actively mined.

Coal worker pneumoconiosis

Over the past three decades, average shift production levels have increased by an order of magnitude while respirable coal dust concentrations have been cut nearly in half. This is a remarkable testament to the development and application of engineering controls during this period. Despite these gains, however, CWP remains a large problem of the coal mining industry, and while there has been a steady decline in the number of cases reported per year, there is still a significant problem.

Respirable coal dust generation is largely a function of cutting rates, and therefore respirable dust increases with production. Longwall mining is the most productive coal mining method, and it is not surprising that the two highest exposure occupations are stationed at the longwall. Advances in control technology in recent years have just been able to keep up with the increasing production levels. Of course, there is less margin of error as well. If one of several control parameters is set incorrectly or a part of the

dust control system malfunctions even briefly, significant concentrations of respirable dust can become air-borne. The coursing of ventilating air throughout the working face is a primary means of diluting and carrying away excess dust. However, in many cases limiting factors that could negatively affect mineworkers prevent further increases in this quantity of ventilating air.⁹

Full-shift sampling using the traditional gravimetric sampler – which employs quartz filters to collect particulate matter – captures the mineworker’s exposure, but this information is not available until the sample has been weighed at the MSHA lab and the results are reported back to the mine – a process that takes weeks. Thus, the use of a real-time dust dosimeter is a crucial step towards the elimination of black lung. After years of development, prototypes of a new personal dust monitor (PDM) have been successfully tested in underground coal mines, and they are expected to be commercially available in 2005. These devices will allow mineworkers to make nearreal-time changes to the dust control system to reduce respirable dust levels. MSHA is also developing more stringent regulations, which include provisions requiring operators to utilize the PDM, to aid in the fight against CWP.

Silicosis

A chronic overexposure to respirable crystalline silica causes the progressive lung disease known as silicosis (see Chapter 19.9). The respirable crystalline silica is released by silica-bearing minerals as they are fragmented during mining processes. The strata surrounding many coal seams contain these quartz minerals. Three common sources of silica exposures in underground coal mines are:

1. cutting by the continuous miner into the roof for additional clearance or to construct overcasts;
2. drilling by the roof bolter into the roof to install bolts;
3. advancing longwall shields, which crush the immediate roof and distribute this dust as the shields move forward.

Dust exposure in coal mines

Water sprays and fan-powered dust collectors are commonly used on continuous miners to limit respirable coal dust, and are effective for reducing silica. The dry dust collection systems on roof bolters also capture much of the generated silica. A water misting system to reduce noise levels during the drilling cycle of roof bolting is undergoing field trials, and air-borne silica reduction may be an important side benefit from this noise control technology.

Despite these engineering controls, roof bolter operators are often careless when they empty and dispose of dust from the dust collection system, spilling the contents. In addition to the immediate air-borne exposure they suffer, significant amounts of respirable silica dust remain on the miner’s clothes, which become a source of additional exposure for the remainder of the shift. Although this is smaller than the exposure from the actual drilling, it is not insignificant.

Dust exposure during surface coal mining occurs primarily during the drilling or handling of the silica-bearing overburden materials. Blasthole drillers can be exposed, particularly if the dust collection system around the drill-hole collar is functioning poorly, which many do. Dozer operators can have a significant exposure as they move and further break silica-bearing overburden. Front end loader operators can be overexposed as they handle these materials. Workers in the vicinity of drilling and materials handling operations can receive an overexposure as well.

To address these issues, better dust collection technology is needed for surface drills, and existing systems need to be better maintained. Part of the problem is that workers underestimate the hazard, so better worker training is needed. The widespread adoption of environmentally controlled cabs has been a boon to reducing dust as well as noise exposures, and fortunately most equipment in the surface mining industry now has cabs. Surprisingly, respirable dust concentrations within these cabs can be high. The obvious case occurs with older equipment in which cabs have holes and are poorly sealed to the outside. Many of these older cabs have poor air-conditioning systems that are unable to filter out much of the dust. These deficiencies are being addressed through the development of retrofit kits and training materials on cab sealing.

An unexpected but significant source of respirable silica is tracked into the cab on the operator's boots, and then recirculated within the cab. Some effective means of reducing this hazard are operator training, the sprinkling of a natural canola oil-base sweeping compound onto the cab floor, and improvements to the cab filtration system.¹⁰

Dust exposure in other mines

The generation and exposure mechanisms in metal/non-metal surface and underground mining are similar to those described for coal. In underground mining, exposure occurs primarily from drilling operations and materials handling by loaders, load-haul-dump vehicles, trucks, and slushers. Surface mining exposures come from drills, dozers, and loaders. One important difference, however, is that the crystalline silica is part of the ore itself, rather than only being present in the surrounding rock, as is the case for coal. Accordingly, a significant dust source in metal/non-metal mining occurs around crushers. For underground crushers, the problem is amplified because of the confined space and the limited ventilation. For surface crushers, dust generation is generally less of a problem because of the open-air nature of the application. Sometimes an operator is stationed at the primary crusher, but is normally inside an environmentally controlled booth and well protected from the noise and dust of the crushing operation. If the crusher is fed by trucks dumping into it, the truck driver can be overexposed depending on the site arrangements.¹¹

Air quality regulations by the Environmental Protection Agency to control visible or fugitive dust help reduce the respirable dust concentrations in the vicinity of the crusher. Dust reduction in surface plants – e.g., at transfer points and stock piles – is accomplished through the use of

water sprays and to a lesser extent shrouds and mechanical efforts to limit dust generation. As with coal, training of metal/non-metal mineworkers is important to ensure that available control technologies are maintained and used effectively.

Many of the silica hazards present in mining also occur in other industries where surface drilling is an integral activity. Two large populations are water well drillers and heavy construction workers. Efforts are under way to apply the lessons learned in mining to these workers as well.

Heat stress

Heat stress can occur from mining in hot environments, further discussed in Chapter 34. The temperature of virgin rock in a mine is dependent on several factors including the depth of the deposit, the proximity to geothermal gradients, and the thermal conductivity of rock overlying the deposit. As an example, the temperature may be 25 degrees C at 250 m of depth and rise to 45 degrees C at 2000 m. Heat is released into the mine environment as mining progresses, and then ventilating air passing over the hot rock is warmed, increasing the ambient air temperature. The common use of water to control dust contributes to very high humidity levels in addition to elevated temperatures. The high temperature alone, and especially in combination with the additional high wet bulb temperature, creates significant health hazards to miners. Chilling of the air used to ventilate the mine can reduce the temperature and humidity levels to uncomfortable but safe values. Heat acclimatization regimens have been developed and have been shown to reduce heat stroke among miners.¹²

The problems of mining in hot environments have not been as severe in the US as in some other mining countries, due to the nature of the deposits. This may change as deeper deposits are mined in the future. Two fatalities from heat stroke occurred in the Nevada gold mines in 2003, after several years with none reported. In addition to adverse health effects of heat stress, the adverse impact on safety is also well documented. Accident rates are decidedly higher for persons working in hot humid conditions,¹³ likely due to the resulting fatigue.

Toxic fumes from blasting

Gases, including some that are toxic, are produced during the chemical reaction process of explosive detonation and deflagration. Generally these are well understood, and proper material selection and blasting techniques are used to minimize any risk to workers. A relatively new problem has shown up with increasing frequency over the past several years, and that is carbon monoxide poisoning in structures and manholes at some distance from the blast site. The problem has been observed in trench blasting for construction purposes – e.g., municipal sewer projects – and in surface coal mining. Significant quantities of CO are produced during a normal blast, but this and other gases may not be vented to the atmosphere; rather the gas

is confined beneath the surface, where it then travels along a path of least resistance. This path may be fractures in the bedrock, a gas or water line path into a residential basement, and so forth.

CO is a very stable gas and may persist for days. CO poisonings (discussed further in Chapters 19.5 and 47) have been documented in both the US and Canada. Ironically, practices designed to minimize ground vibration and flyrock (rocks being propelled from the blast area), both of which are undesirable at blast sites near population centers, may contribute to excess entrapment of gas. Techniques to minimize the presence of gas and to provide relief to the atmosphere are under investigation. Until they are in practice, however, blasters are being encouraged to deploy CO detectors in nearby buildings and to recommend CO checks before workers enter any confined space, such as a manhole, near a blast site.^{14,15}

Other toxic substances

A variety of toxic or potentially toxic substances are used or encountered in mining, and they range from chemicals used in mineral processing to the byproducts of operations. There are no proven adverse effects from the presence of these agents in the mining workplace. However, studies that would detect adverse health effects have not been conducted for many of these substances, or in some cases studies have been conducted but were inconclusive. Four such agents of note are diesel particulate matter, froth flotation chemicals (where chemicals are used to separate minerals from one another), solcenic (a hydraulic fluid similar in formulation to emulsifiable metalworking fluids), and molds.

Diesel particulate matter (DPM) in diesel exhaust is considered carcinogenic and DPM levels are regulated in mining (see Chapter 44). DPM emissions into the mine environment can be reduced by fuel selection, through the use of filters and catalytic converters, or with newer engine designs. However, there are significant gaps in the current understanding of these control technologies. For example, the reduction of DPM by certain converters can result in dangerously elevated levels of nitrogen oxide or the release of potentially harmful heavy metals in respirable particles.¹⁶

Direct worker exposure to chemicals used in modern coal preparation plants has been reduced through changes to the delivery, mixing, and application phases. Nonetheless, some exposure during maintenance and operation does occur. A link between Parkinson's disease and exposure to neurotoxic chemicals used in coal preparation has been postulated, but remains unproven.¹⁷

Solcenic, a non-flammable hydraulic fluid commonly used in underground coal mining, was suspected of causing respiratory disorders, work-related asthma, and allergic and irritant skin disorders among longwall coal miners, but studies have failed to establish any relationship.¹⁸ Reasonable precautions to minimize exposure, for example from leaks in the hydraulic lines, will prevent adverse effects in susceptible individuals. Large spills may result in atmospheric formaldehyde concentrations at or above

the NIOSH-recommended REL, and precautions should be taken during these atypical events to protect workers. Notwithstanding, chemical exposures in the mining industry are poorly understood, and any unexplained symptoms presented in mineworkers should be investigated with chemical exposure in mind.

Humidity and temperature conditions in mines are particularly well suited to the growth of molds. There has been increasing interest in the health effects of these molds, but no investigations have been performed to date. Special precautions are necessary for underground lead miners to ensure that lead ore is not ingested or tracked out of the workplace. Strict rules regarding showering and changing clothes before eating or leaving the mine site, among others, are successfully applied.

Work-related stress and fatigue

Work schedules in mining have changed over the years. Work-related stress and fatigue (see Chapter 28.3) are increasingly being recognized in the mining industry. Many modern operations are in production 24 hours per day or in some combination of maintenance and production round the clock. Some operations stay open on the weekends, and some work almost every day of the year. Thus, workforce scheduling is obviously a challenge in these operations, and has resulted in various shift schedules in relation to consecutive days of work, i.e., a worker might be on the job 10 consecutive days, followed by a smaller block of days off, e.g., 4. Sometimes a more extended off-period is given after several of these cycles to help reduce work-related stress and fatigue.

Rotations from first to second and then to third shift still occur, but are not as common as they once were. Mining has become increasingly capital intensive, and as such, idle time of the expensive equipment involved is less acceptable. In underground coal mining, for example, it used to be common for one crew to leave the working face and travel to the outside portal for arrival at the end of the 8-hour shift. Then the next crew departed from the portal and traveled to the working face, where it restarted the production cycle. Travel times of 30 minutes or more on each end of the shift, along with the lost-time of cycling down and then restarting production, meant that less than 60% of the total shift time was spent in production. As mining became more competitive, the practice of changing crews directly at the working face, sometimes called a hot-seat change at the face, became common. This significantly improved productivity and effectively increased the shift length by as much as 2 hours because a full 8 hours of production time per crew was established. Two 10-hour production shifts with a 4-hour maintenance period evolved as one popular schedule. Some companies even went to 12-hour shifts.

Studies have been conducted primarily on the effect of these work schedules on safety, and as expected worker fatigue and disorientation from shift rotations is a factor in accidents, although the findings are not as dramatic or definitive as might be expected. Long-term health effects

on workers are less understood, although significant interest in examining stress-related health effects on cardiovascular disease and worker depression is developing in the research community, and work schedules would likely be an important focus.¹⁹

There was significant research interest in the effects of work organization in mining several years ago, as the changes described previously began to evolve. More recently, a new complication has developed. Deposits located far from established communities are being mined. In the US, workers are now being transported by bus for up to 2 hours each way, each day, to work a 10- or 12-hour shift as part of an extended workweek schedule. This is common in the coal fields of the Powder River Basin in Wyoming and the gold fields of Nevada, and less common elsewhere. In Australia, even more remote locations are being mined, and workers are flown in, stay for several weeks, and are then flown back out. Concern over the health effects of these practices on workers in Australia has spawned several research studies, which are now in progress.²⁰

Informational resources on mining health and safety

The understanding of mining safety and health problems is increasing, as are prevention and intervention measures. The clinician is ideally positioned to detect heretofore unknown adverse health effects from occupational exposures. A detailed occupational history of the patient may provide key clues, and unexplained or otherwise worrisome relationships should be reported. NIOSH scientists can conduct targeted health hazard evaluations to investigate such concerns.

Several sources can provide timely information to supplement the technical literature. The NIOSH and MSHA websites (<http://www.cdc.gov/niosh/homepage.html> and <http://www.msha.gov/>) are good places to start. Labor unions such as the United Mineworkers of America (coal), the United Steelworkers of America (metal), and the International Union of Operating Engineers (stone) have active health and safety departments. Finally, trade associations such as the Bituminous Coal Operators' Association (coal), the National Mining Association (metal/non-metal and coal), and the National Stone, Sand, and Gravel Association also aggressively promote health and safety for mineworkers. Labor and trade organizations have partnered to solve a number of important health and safety problems, and they provide a valuable source of information and training materials, in addition to the government agencies. States with significant mining interests often have their own mining agencies as well, which provide yet another source of information.

Chapter 14

Construction Industry Hazards

Laura S Welch

INTRODUCTION

Construction workers build, repair, renovate, modify, and demolish structures: houses, office buildings, temples, factories, hospitals, roads, bridges, tunnels, stadiums, docks, airports, and more. In industrialized nations, construction is consistently ranked among the most dangerous occupations. In the United States, 19% of all fatal on-the-job injuries occur in construction, about three times its 6% share of the total employment;¹ half of all fatal falls occur in construction. High fatality rates occur around the globe as well.² Construction also has a high rate of non-fatal injuries. In 2000 there were four lost workday cases per 100 full-time equivalent construction workers compared to a rate of 3/100 full-time equivalent workers in all private industry; the rate in construction exceeded all other sectors.³

Construction work is composed of many different tasks undertaken by many different trades. To understand the risk for injury and illness, one must understand the work of specific trades and their characteristic tasks. In the United States, the unionized industry consists of 15 distinct trades, with specific tasks defined by the jurisdiction of each trade. In other countries, and on non-union job sites in the United States, the tasks of these trades may vary. A description of the work of each trade as defined by the US Bureau of Labor Statistics (BLS) is helpful in describing the variety of work in construction (Table 14.1).

Occupational diseases are also an important cause of morbidity in construction workers. Table 14.2 summarizes sentinel health events that may occur in construction workers and specific exposures that can lead to these diseases. This list was developed to identify diseases that, if they occur, point to an opportunity for intervention and prevention of future cases. These diseases do not represent an exhaustive list of occupational disease in construction, but illustrate the extent of the possible problem.

The costs of injuries in the construction trades are substantial. Estimates in the US range from \$10 billion to \$40 billion annually.⁴ Assuming a cost of \$20 billion, the cost per construction worker would be \$3500 yearly. One cost indicator, worker's compensation premiums for three trades (carpenters, masons, and structural iron workers), averaged 28.6% of payroll. In addition to worker's compensation, there are liability insurance premiums and other indirect costs, including reduced work crew efficiency, clean-up (from a cave-in or collapse, for instance), or overtime necessitated by an injury. These indirect costs can exceed the worker's compensation claim for an injury by several multiples.

Construction work entails a number of physical hazards and psychophysiologic stressors, including extreme temperatures, shift work, and unpredictable work (discussed in Chapters 34, 38). Construction often must be done in extreme heat or cold, in windy, rainy, snowy, or foggy weather. Night-shift work is common in highway and bridge construction. On-again, off-again work adds to the health risks, including the emotional toll of uncertainty regarding job security and seasonal work.⁵ In the US, where there is no universal health insurance, intermittent employment and the high cost of health insurance can leave construction workers and their families without healthcare coverage. Even when construction workers work the 30 or 60 days frequently needed to qualify for insurance coverage on a job (if coverage is available), they often cannot afford to maintain coverage between jobs.

For workers who do have healthcare coverage, episodic employment, frequent changes of employer, and continuous changes in worksite exposures and ambient conditions limit the clinician's or the researcher's ability to trace the individual's work history or exposures to hazards. Because of these factors, many of which are unique to construction, data on the extent or effect of toxic exposures in the construction industry are limited.

Construction work is demanding, both physically and socially. Data from the United States suggest that construction workers retire at an earlier age than does the average US worker. Construction workers who work in production jobs, as contrasted with management jobs, retire earlier than the general workforce; the average of age retirement is 54 for production jobs in construction, and 56 for the general workforce.⁶ Tuomi characterized risk factors for early retirement or disability retirement in a follow-up study of over 6000 Finnish workers aged 45–58.⁷ Specific aspects of the job that increased the likelihood of disability included static muscular work, diminished muscular strength, lifting and carrying, sudden peak loads, repetitive movement, and simultaneously bent and twisted work postures.

Most of these risk factors for early retirement are common in construction work. A study in Ireland found that 30% of construction workers who retired early because of a medical problem retired because of a musculoskeletal condition.⁸ Arthritis was responsible for 70% of these musculoskeletal conditions, and degenerative disk disease for another 20%. An analysis of the medical conditions leading to retirement among unionized sheet metal workers in the United States reported that musculoskeletal conditions made up 70%.

Boilermakers

Construct, assemble, maintain, and repair stationary steam boilers and boiler house auxiliaries. Work involves use of hand and power tools, plumb bobs, levels, wedges, dogs, or turnbuckles. Assist in testing assembled vessels. Direct cleaning of boilers and boiler furnaces. Inspect and repair boiler fittings, such as safety valves, regulators, automatic-control mechanisms, water columns, and auxiliary machines.

Brick masons

Lay and bind building materials, such as brick, structural tile, concrete block, cinder block, glass block, and terracotta block, with mortar and other substances to construct or repair walls, partitions, arches, sewers, and other structures.

Carpenters

Construct, erect, install, or repair structures and fixtures made of wood, such as concrete forms; building frameworks, including partitions, joists, studding, and rafters; wood stairways, window and door frames, and hardwood floors. May also install cabinets, siding, drywall and batt or roll insulation.

Carpet installers

Lay and install carpet from rolls or blocks on floors. Install padding and trim flooring materials.

Cement masons and concrete finishers

Smooth and finish surfaces of poured concrete, such as floors, walks, sidewalks, roads, or curbs using a variety of hand and power tools. Align forms for sidewalks, curbs, or gutters; patch voids; use saws to cut expansion joints.

Construction laborers

Perform tasks involving physical labor at building, highway, and heavy construction projects, tunnel and shaft excavations, and demolition sites. May operate hand and power tools of all types: air hammers, earth tampers, cement mixers, small mechanical hoists, surveying and measuring equipment, and a variety of other equipment and instruments. May clean and prepare sites, dig trenches, set braces to support the sides of excavations, erect scaffolding, clean up rubble and debris, and remove asbestos, lead, and other hazardous waste materials.

Drywall and ceiling tile installers

Apply plasterboard or other wallboard to ceilings or interior walls of buildings. Apply or mount acoustical tiles or blocks, strips, or sheets of shock-absorbing materials to ceilings and walls of buildings to reduce or reflect sound. Materials may be of decorative quality. Include lathers who fasten wooden, metal, or rockboard lath to walls, ceilings or partitions of buildings to provide support base for plaster, fire-proofing, or acoustical material.

Electricians

Install, maintain, and repair electrical wiring, equipment, and fixtures. Ensure that work is in accordance with relevant codes. May install or service street lights, intercom systems, or electrical control systems.

Insulation workers

Apply insulating materials to pipes or ductwork, or other mechanical systems in order to help control and maintain temperature. Also line and cover structures with insulating materials. May work with batt, roll, or blown insulation materials.

Operating engineers

Operate one or several types of power construction equipment, such as motor graders, bulldozers, scrapers, compressors, pumps,

derricks, shovels, tractors, or front-end loaders to excavate, move, and grade earth, erect structures, or pour concrete or other hard surface pavement. May repair and maintain equipment in addition to other duties.

Painters

Paint walls, equipment, buildings, bridges, and other structural surfaces, using brushes, rollers, and spray guns. May remove old paint to prepare surface prior to painting. May mix colors or oils to obtain desired color or consistency.

Paperhangers

Cover interior walls and ceilings of rooms with decorative wallpaper or fabric, or attach advertising posters on surfaces, such as walls and billboards. Duties include removing old materials from surface to be papered.

Plumbers, pipefitters, and steamfitters

Assemble, install, alter, and repair pipelines or pipe systems that carry water, steam, air, or other liquids or gases. May install heating and cooling equipment and mechanical control systems.

Plasterers and stucco masons

Apply interior or exterior plaster, cement, stucco, or similar materials. May also set ornamental plaster.

Reinforcing iron and rebar workers

Position and secure steel bars or mesh in concrete forms in order to reinforce concrete. Use a variety of fasteners, rod-bending machines, blowtorches, and hand tools. Include rod busters.

Roofers

Cover roofs of structures with shingles, slate, asphalt, aluminum, wood, and related materials. May spray roofs, sidings, and walls with material to bind, seal, insulate, or soundproof sections of structures.

Sheet-metal workers

Fabricate, assemble, install, and repair sheet-metal products and equipment, such as ducts, control boxes, drainpipes, and furnace casings. Work may involve any of the following: setting up and operating fabricating machines to cut, bend, and straighten sheet metal; shaping metal over anvils, blocks, or forms using hammer; operating soldering and welding equipment to join sheet-metal parts; inspecting, assembling, and smoothing seams and joints of burred surfaces. Include sheet-metal duct installers who install prefabricated sheet-metal ducts used for heating, air conditioning, or other purposes.

Stonemasons

Build stone structures, such as piers, walls, and abutments. Lay walks, curbstones, or special types of masonry for vats, tanks, and floors.

Structural iron and steel workers

Raise, place, and unite iron or steel girders, columns, and other structural members to form completed structures or structural frameworks. May erect metal storage tanks and assemble prefabricated metal buildings.

Terrazzo workers and finishers

Apply a mixture of cement, sand, pigment, or marble chips to floors, stairways, and cabinet fixtures to fashion durable and decorative surfaces.

Tile and marble setters

Apply hard tile, marble, and wood tile to walls, floors, ceilings, and roof decks.

From Bureau of Labor Statistics, Standard Occupational Classification Manual, 1998 revision. <http://stats.bls.gov/soc/socguide.htm>

Table 14.1 Construction occupations

The remainder of this chapter will highlight exposures and occupational diseases that are prevalent in construction, or those for which unique characteristics of the construction industry warrant attention. More extensive discussion of specific occupational disorders or exposures can be found in subsequent chapters.

WORK-RELATED MUSCULOSKELETAL DISORDERS

Musculoskeletal injuries make up a high proportion of all work-related injuries in construction. Key musculoskeletal disorders and associated construction trade or risk factors

Condition	Industry/process/occupation	Agent
Asbestosis Bronchitis (acute), pneumonitis, and pulmonary edema due to fumes and vapors Chronic or acute renal failure Contact and allergic dermatitis	Asbestos industries and utilizers Arc welders, boilermakers Plumbers Cement masons and finishers, carpenters, floorlayers†	Asbestos Nitrogen oxides Inorganic lead* Adhesives and sealants, irritants (e.g., cutting oils, phenol, solvents, acids, alkalis, detergents); allergens (e.g., nickel, chromates, formaldehyde, dyes, rubber products) Red cedar (plicatic acid) and other wood dusts <i>Histoplasma capsulatum</i> Hexane Mineral oil, pitch, tar Hardwood and softwood† dusts Chlorophenols Asbestos
Extrinsic asthma Histoplasmosis Inflammatory and toxic neuropathy Malignant neoplasm of scrotum Malignant neoplasm of nasal cavities	Wood workers, furniture makers Bridge maintenance workers Furniture refinishers, degreasing operations Chimney sweeps Wood workers, cabinet and furniture makers, carpenters Asbestos industries and utilizers	Asbestos Asbestos Asbestos Excessive noise Whole body or segmental vibration Redwood sawdust Silica Silica + <i>Mycobacterium tuberculosis</i> Lead Methyl bromide
Malignant neoplasm of trachea, bronchus, and lung Malignant neoplasm of nasopharynx Malignant neoplasm of larynx Mesothelioma (malignancy of peritoneum and pleura) Noise effects on inner ear Raynaud's phenomenon (secondary) Sequoiosis Silicosis Silicotuberculosis Toxic encephalitis Toxic hepatitis	Carpenter, cabinet maker Asbestos industries and utilizers Asbestos industries and utilizers Occupations with exposure to excessive noise Jackhammer operator, riveter Red cedar mill workers, wood workers Sandblasters Sandblasters Lead paint removal Fumigators	Asbestos Asbestos Asbestos Excessive noise Whole body or segmental vibration Redwood sawdust Silica Silica + <i>Mycobacterium tuberculosis</i> Lead Methyl bromide

*Lead exposure occurs in at least 23 construction-related industrial/occupational groups; including painting contractors, bridge and highway construction, and demolition work. Extremely high levels of lead exposure have been documented for workers in these groups.

†Not included in original 1991 table.

Table 14.2 Sentinel health events in construction

are shown in Table 14.3. Strains and sprains were second in frequency only to lacerations among construction workers treated in a large emergency department.^{9,10} Data from workers' compensation claims indicate that strains and sprains are the leading compensable injury for construction workers. In a study of carpenters,¹¹ 45% of all compensation claims were for musculoskeletal injuries and disorders. Cross-sectional studies also reveal a high prevalence of chronic musculoskeletal complaints (pain, ache, and discomfort) among construction workers.¹²

A survey of electricians showed that 51% had back symptoms, and 47% had hand or wrist symptoms;¹³ 82% had symptoms to at least one body location in the prior year that lasted more than a week or recurred at least three times, while 63% reported symptoms to two or more locations. In a Swedish study, early retirements due to these disorders were more common among construction workers than other men. During 1988-1989, 72% of all sick leaves longer than 4 weeks in the construction industry in Sweden were due to musculoskeletal disorders.¹²

In the United States 33% of all worker compensation costs were due to low back pain, based on an analysis from a large workers' compensation insurance carrier.¹⁴ The median cost of a low back claim in construction was 150% that of the reference group, and the cost of the 90th

percentile cases was over 200% of the reference group. Clearly musculoskeletal problems in construction are frequent and more severe than in other industrial sectors.

Epidemiological studies of construction workers have found an increased risk of various musculoskeletal disorders, summarized in Table 14.3. Interview surveys in Finland and Sweden studied the relationship between work and musculoskeletal disorders in construction workers. Carpenters, bricklayers, concrete workers, plumbers, and machine and crane operators had a significantly increased standardized morbidity ratio for musculoskeletal diseases compared with Swedish men.¹⁵ In Finland neck and shoulder symptoms, low back pain, and sciatica were more prevalent among machine operators and carpenters than sedentary workers,^{16,17} indicating that construction work is a risk factor.

Several studies have looked at the occurrence of specific medical disorders of the knee, back and shoulders in construction workers (Table 14.3). A Finnish work analysis of carpet and floor laying and painting showed that carpet and floor layers kneeled, on average, 42% of the time in the observed work tasks. Among painters, kneeling was rare.¹⁸ Bursitis in the front of the knee was more frequent among carpet and floor layers than painters,¹⁸⁻²⁰ suggesting kneeling and squatting as contributory factors. Ultrasonography

Disorder	Work posture, psychosocial factor, or trade	Reference
Neck, shoulder symptoms	Machine operators, carpenters	Tola 1988 ¹⁶
Neck, shoulder pain	Hand-held machines, hands above shoulder level, reported high psychological stress	Homstrom 1992 ¹²

	Carpet and floor layers	Jensen 2000 ¹¹⁹
		Kivimaki 1992 ^{18,19}
	Carpet and floor layers	Kivimaki 1992 ^{18,19} Thun 1987 ²⁰

Table 14.3 Key disorders and associated work postures, psychosocial factors, or trades

showed thickening of the prepatellar or superficial infrapatellar bursa in 49% of the carpet and floor layers and in 7% of the painters. In addition, radiographic changes of the patella were more common among carpet and floor layers than among painters.

A study of bricklayers and rock blasters found that physical workload contributed to the development of radiographic osteoarthritis of the acromioclavicular joint, and exposure to vibration contributed to the development of shoulder tendonitis.²¹ An association between severe low back disorders such as sciatica and herniated disk and heavy work has been shown in prospective studies, where heavy work was defined as construction work of some kind. An association between less severe non-specific back pain and workload is less well established in construction workers.^{17,22}

NOISE-INDUCED HEARING LOSS AND OTHER PHYSICAL HAZARDS

Excess noise exposures among construction workers and high rates of noise-induced hearing loss among these workers are well documented.^{23,24} More than 500,000 construction workers are exposed to potentially hazardous levels of noise. The United States has separate noise regulations for

construction and general industry; in the construction standard there is no action level above which a hearing conservation program is required, and no detailed requirements for training or recordkeeping. Yet the work is very noisy. For example, a laborer using a heavy duty bulldozer is exposed to 91–107 dBA, with a mean of 99 dBA. Exposure from other heavy equipment ranges from a mean of 81 dBA in a crane with an insulated cab to 97 dBA without insulation. Studies of hearing thresholds show damage from these exposures. The Workers' Compensation Board in British Columbia has developed a successful program to prevent hearing loss in construction workers, and the 'Blue Angel' program in Germany can also be a model for the future. The article by Suter²³ provides an excellent review of noise control programs for construction.

HAZARDOUS MATERIALS IN CONSTRUCTION

Construction workers use a wide range of hazardous materials. Carcinogens that may be found on construction sites are shown in Table 14.4. Selected dermally absorbed and sensitizing agents found in the industry^{25,26} are listed in Table 14.5. Construction exposures that can result in non-malignant respiratory effects are listed in Table 14.6. Effects

Uses or where encountered	
C1: Established human carcinogens	
Beech wood dust	Joinery, circular saw on building sites
Benzene	Gasoline
Nickel compounds	Welding electrode
Oak wood dust	Joinery, circular saw on building sites
Tar, pitch	Road works
Zinc chromates	Old coatings
C2: Probable human carcinogens	
Benzo[a]pyrene	Road works, diesel engine emission, chimney sweeping
Cadmium compounds	Old coatings
Chromium(VI) compounds	Wood protection
Diesel engine emissions	Diesel engines
Hydrazine	Water treatment
C3: Suspected human carcinogens	
Dichloromethane	Stripper, solvent
Diphenylmethane-4,4' diisocyanate	Polyurethane
Formaldehyde	Conservation of dispersion products
Lead chromate	Old coatings
Wood dust (besides beech wood and oak wood dust)	Joinery, circular saw on building sites

Table 14.5 Areas of use of transdermal and sensitizing materials in construction

of these exposures on respiratory health are summarized below. More detailed descriptions of the health effects of specific compounds can be found in subsequent chapters.

Lead (see Chapter 39.8)

Lead exposure and lead toxicity are particularly important problems in the construction industry. Nearly 1 million US construction workers are exposed to lead on the job;²⁷ more than 80% of these workers are involved in commercial or residential remodeling. Despite this risk in construction, the OSHA lead standard applied only to general industry before 1993. In 1992, NIOSH published an alert

for preventing lead poisoning in construction workers and reported on blood lead levels in bridge construction workers; levels ranged from 51 to 160 µg/dL whole blood with 62% of elevated blood lead levels involving work in a containment structure.^{28,29} This publication identified high-risk activities associated with lead dust and fumes among bridge and structural steel workers including: abrasive blasting, sanding, burning, cutting or welding on steel structures coated with lead paint, and the use of containment enclosures. In 1993 OSHA promulgated a lead standard for construction.

In addition to setting a Permissible Exposure Level (PEL) for lead, the standard incorporates a presumption of expo-

Lung cancer

Arsenic, inorganic (measured as AS)	Coal tar pitch volatiles
Asbestos	Formaldehyde
Beryllium	Zinc chromates
Chromic acid and chromates	

Non-malignant respiratory effects

Aluminum (pyro powders)	Mica, respirable dust containing <1% quartz
Asphalt fumes	Mineral wool fiber
Bismuth telluride (Se-doped)	Nickel (soluble compounds)
Carbon black	Nitrogen oxide
Chlorine dioxide	Oxygen difluoride
Chromium (II) compounds (as Cr)	Ozone
Chromium metal (as Cr)	Paraquat, respirable dust
Coal dust	Silica
Cotton dust	Soapstone
Ethyl acrylate	Sulfur dioxide
Ferrovandium dust	Sulfur tetrafluoride
Fibrous glass	Talc (containing no asbestos)
Grain dust (oat, wheat, barley)	Tin oxide
Graphite, natural, respirable <1% quartz	Trimellitic anhydride
Indium and compounds	Wood dust
Iron oxide (dust and fumes)	Yttrium
Methylene bis (4-cyclohexylisocyanate)

Health and safety in construction: state of the art reviews in occupational medicine, vol. 10. Philadelphia: Hanley and Belfus, 1995; 269–84.

Table 14.6 Construction exposures identified by OSHA as potentially resulting in respiratory effects

sure during specific high-risk tasks, and requires specific protections during these tasks, unless air monitoring demonstrates exposure below the PEL. Levin demonstrated that implementation of the standard can reduce blood lead levels in construction workers.^{30,31} However, the OSHA standard may not fully protect construction workers from lead toxicity.³¹ Although the OSHA standard requires monitoring every 2 months, some tasks such as burning lead-coated steel can cause a rapid rise in lead levels in the blood. Thus more frequent monitoring and a lower threshold for industrial hygiene inspection or medical removal have been recommended in some circumstances.

Occupational lung diseases

Construction workers are exposed to a variety of hazardous agents that may pose risks to the respiratory system, including asbestos, silica, dust, synthetic vitreous fibers, cadmium, chromates, formaldehyde, resin adhesives, cobalt, metal fumes, creosote, gasoline, oils, diesel fumes, paint fumes and dusts, pitch, sealers, solvents, wood dusts and wood preservatives, and excessive cold. Selected construction exposures that can cause chronic non-malignant respiratory effects are shown in Table 14.6. Potential lung carcinogens are also included in Table 14.6

Lung cancer (see Chapter 30.1)

Studies from several countries, using a variety of study designs, have documented an increased risk of lung cancer

among construction workers,³² even after controlling for smoking.^{33–38} Studies of specific construction trades have also shown an increased risk of lung cancer. Painters and plasterers appear to be at increased risk of lung cancer.^{39–41} One factor may be cadmium, used as a pigment in paint. NIOSH has also documented an excess risk of lung cancer associated with cadmium exposure and identified the construction industry as an area where OSHA standards are needed to better protect workers.

High exposures may occur during unventilated renovation work. In addition, painters and plasterers may be exposed to acetone, acids, alkalis, benzene, chlorinated hydrocarbons, chromates, drying agents, paint strippers, oil base and resin paints, pigments, silica, solvents, thinners, and turpentine, as well as asbestos from spackling compounds and building restoration. Selikoff and Seidman documented a significant increase in lung cancer mortality among 17,800 asbestos insulation workers in the United States and Canada.⁴² Finkelstein also documented an increased risk of lung cancer among insulators.⁴³ Sheet metal workers, who may be exposed to asbestos when working near insulators, are at increased risk of lung cancer.⁴⁴

Construction welders may be exposed to filler metals containing cadmium, fluxes containing fluorine compounds, and metal fumes including nickel and chromium. Several studies have found increased risk of lung cancer among welders in a variety of work settings.^{45–47} Masons have an excess of lung cancer^{48,49} and are exposed to lung carcinogens such as asbestos, silica,⁵⁰ nickel, and hexavalent chromium. Other construction trades in which increased risk of lung cancer has been observed include electricians,^{51–53} carpenters and woodworkers,⁵⁴ plumbers and pipefitters,^{53,57–58} and roofers and mastic asphalt workers.^{59,60} Roofers are exposed to volatile materials vaporizing from heated asphalt, including polycyclic aromatic hydrocarbons from coal tar pitch and bitumen fumes.

Nasal cancer (see Chapter 30.1)

Woodworkers, cabinetmakers, and furniture makers have an increased risk of nasal cancer.^{61–63} Carpenters and joiners also appear to be at increased risk of developing nasal cancer.^{64,65} Carpenters and cabinetmakers may be exposed to wood dust, formaldehyde, solvents, toluene, wood preservative, shellac, stains, bleaches, resin and casein glues, oils, polishes, and insulation agents including asbestos. Given the rarity of nasal cancer, the evidence for a relationship between nasal cancer and occupational exposure to wood dust is compelling. Several studies have also found an increased risk of nasal cancer among general construction workers.^{33,62,65–67}

Mesothelioma (see Chapter 30.1)

Reports of mesothelioma among construction workers come from several countries.^{34,44,66,69,70} Mesothelioma has been observed among construction workers who worked as insulators,^{42,71} shipyard construction workers,^{70–72} carpenters,⁷³ sheet-metal workers,⁴⁴ construction/maintenance workers,⁷¹ and electricians.⁷²

Respiratory condition	Prevalence rate per 1000 workers	Rate ratio
Lung cancer	1.7	1.31
Asbestosis	2.8	2.15
Asthma	19.6	0.82
Emphysema	25.8	1.34
Chronic bronchitis	24.1	1.30

Note: The rate ratio is the ratio of the rate in construction workers compared to the rate among other workers who participated in the survey. Reprinted with permission from: Sullivan P, Moon Bank K, Hearl F, Wagner G. Respiratory risk in the construction industry. In: Ringen K, Englund A, Welch LS, Weeks JL, Seegal J, eds. Health and safety in construction: state of the art reviews in occupational medicine, vol. 10. Philadelphia: Hanley and Belfus, 1995; 269–84.

Table 14.7 Prevalence rate and rate ratio of self-reported respiratory conditions among 1785 white male construction workers age 15 and older

Respiratory morbidity

Surveillance data on respiratory disease incidence or prevalence among construction workers are limited. Respiratory conditions accounted for 14.3% of approximately 7000 reported occupational illness cases among construction workers, based on the US BLS. NIOSH estimated the prevalence rate of reported respiratory conditions based on a national probability sample of construction workers. Prevalence rates ranged from 1.7 to 25.8 per 1000 white male construction workers for lung cancer and emphysema, respectively (Table 14.7). Construction workers reported asthma less frequently than in the general population, but since sensitized individuals may voluntarily leave the construction workforce, the reported prevalence may be low due to a healthy worker effect. Table 14.8 shows proposed exposure limits based on avoidance of respiratory effects for substances common in construction.

Asbestosis (see Chapter 19.8)

Asbestos has been recognized as a respiratory health risk for a number of construction trades.^{75,76} Occupational exposure to asbestos, and a diagnosis of asbestosis, can occur in many construction trades, particularly among those working as insulators, plumbers and pipefitters,⁷⁶ electricians and sheet-metal workers,⁷⁷ and several studies have suggested that all construction workers may be at risk for asbestos-induced disease resulting from exposure associated with working adjacent to insulation workers.^{77,78} Although asbestos is no longer used in new residential or heavy construction, workers may continue to be exposed to previously installed asbestos material during maintenance, renovation, addition, or demolition activities. For example, asbestos-containing fireproofing was sprayed on structural steel and other components of many US high-rise buildings before it was banned in 1973.

Silicosis (see Chapter 19.9)

Occupational exposure to silica can occur among various types of construction workers including those employed in concrete removal and demolition work, bridge and road

construction, tunnel construction, and concrete or granite cutting, sanding, and grinding.^{79,80} Sandblasters are at increased risk from exposure to crystalline silica. Those working nearby on the same construction site may also be at risk from silica-related disease. In the United States, sand containing crystalline silica is still used in abrasive blasting operations for maintenance of structures, preparing surfaces for painting, and in forming decorative patterns during installation of building materials. OSHA compliance monitoring data suggest that silica exposures within the construction industry continue to exceed recommended limits, and data in the US and in other countries show evidence of silicosis risk among construction workers.^{50,80,81}

Bronchitis and chronic obstructive pulmonary disease (see Chapter 19.4)

Bronchitis has been reported among construction workers exposed to asbestos⁸² and man-made mineral fibers,^{83,84} spray painters,⁸⁵ and arc welders.⁸⁶ COPD has been reported among tunnel construction workers, construction painters,^{85,87} sheet-metal workers,⁸⁴ and construction arc welders.⁸⁸ Chronic non-specific lung disease symptoms have been found among construction workers, wood workers, and painters,⁸⁹ even after adjusting for smoking and age. Specific exposures associated with excess risk of chronic non-specific lung disease included heavy metals, mineral dust, and adhesives.⁹⁰

Occupational asthma (see Chapter 19.2)

Construction workers can be exposed to a number of agents that can cause asthma or exacerbate underlying asthma. Chan-Yeung reviewed agents and trades at risk for occupational asthma, including construction.⁹¹ Possible causal exposures include wood dust and welding flux. Welders are at increased risk of occupational asthma; Kilburn and Warshaw found that 11% of male arc welders who had worked at construction sites reported a history of asthma.⁸⁶ Karjalainen confirmed the risk among welders, but also found an increased risk for asthma in almost all construction occupations.⁹² Numerous exposures common among construction workers can exacerbate underlying asthma including exposure to cold, various particulates, dusts, fumes, and irritants.

Respiratory irritation (see Chapter 19.5)

Such exposures can also cause respiratory tract irritation in various construction workers. Painters may experience irritation of the respiratory system following exposure to solvents such as acetone, methyl ethyl ketone, and n-butyl lactate used in paints, varnishes, or lacquers.⁹³ Cement workers are at risk of respiratory irritation from components of cement, including amyl acetate and methyl ethyl ketone. Welders are exposed to several respiratory irritants, including ammonium chloride and boron trifluoride in soldering flux. Metal fume fever has been reported with exposure to nickel, chromates, copper, beryllium, cadmium, and other metal fumes which may be present during welding operations.

Chemical name	NIOSH recommended exposure limits*	OSHA permissible exposure limits	1994–95 ACGIH threshold limit values	Species	Comments
Asphalt fumes	5 mg/m ³ ceiling (15-min) (total particulate) 0.5 mg/m ³ TWA		5 mg/m ³ TWA*

Silica C crystalline tridymite (as respirable quartz dust)	50 g/m ³ TWA	250/% SiO ₂ +5 (as mppcf)	0.05 mg/m ³ TWA	Rats	Most active form of free silica when administered by intratracheal injection
Silica C crystalline tripoli (as respirable quartz dust)	50 g/m ³ TWA	250/% SiO ₂ +5 (as mppcf)	0.1 mg/m ³ TWA	Lab animals	Progressive nodular fibrosis
Silica, fused		250/% SiO ₂ +5 +5 (as mppcf) 20 mppcf TWA	0.1 mg/m ³ TWA (respirable dust) 6 mg/m ³ TWA 3 mg/m ³ TWA		
Soapstone C total dust		5 ppm TWA	2 ppm TWA, 5 ppm STEL	Humans	Accelerated loss of pulmonary function
Soapstone C respirable dust				Rats	Emphysema, marked clinical signs of respiratory impairment
Sulfur dioxide	0.5 ppm TWA				
Sulfur tetrafluoride					

Table 14.8 Substances common in construction for which proposed limits are based on avoidance of respiratory effects

Chemical name	NIOSH recommended exposure limits*	OSHA permissible exposure limits	1994-95 ACGIH threshold limit values	Species	Comments
Talc (containing no asbestos)		20 mppcf TWA	2 mg/m ³ TWA (respirable dust)		
Tin oxide			2 mg/m ³ TWA		
Trimellitic anhydride			0.04 mg/m ³ ceiling	Rats	Intra-alveolar hemorrhage (no exposure duration indicated)
Wood dust, hard			1 mg/m ³ TWA		
Wood dust, soft			5 mg/m ³ TWA 10 mg/m ³ STEL	STEL	

*NIOSH time-weighted-average (TWA) limits are for 10 hour/day, 40 hour/week exposures unless otherwise specified, and its ceilings are peaks not to be exceeded for any period of time unless a duration is specified in parentheses; OSHA's TWA are for 8-hour exposures; its short-term exposure limits (STELs) are for 15 minutes, unless otherwise specified, and its ceilings are peaks not to be exceeded for any period of time. The American Conference of Government Industrial Hygienists (ACGIH) sets threshold limit values (TLVs). The TLV-TWA is for an 8-hour exposure; the 'ceilings' are peaks not to be exceeded for any period of time during a working shift.

Table 14.8 (Cont'd) Substances common in construction for which proposed limits are based on avoidance of respiratory effects

Respiratory infection (see Chapter 22)

Construction workers can be at increased risk of several infectious processes. For example, workers involved in excavation in tropical or subtropical areas may be at risk for nocardiosis, especially if they have another risk factor for the disease (such as lymphoma or deficient cell-mediated immunity). Road and bridge work and other construction activities which involve clearing of bird and bat roosts in river valleys in the eastern and central US can result in histoplasmosis, a pneumonitis caused by respiratory infection occurring after inhalation of air-borne fungal spores. The disease may be acute, inactive, or chronic, and can result in disability and death if untreated.⁹⁴⁻⁹⁷ Elevated tuberculosis risk is found among silicotics. Legionnaire's disease has occasionally been reported in construction activities involving excavation or in the vicinity of cooling towers.⁹⁸

Construction is a complex industry, involving many trades and employers on any single project. Because of that complexity, research and prevention activities have targeted construction less frequently than general industry, even though the need is great. These circumstances leave the industry with much room for improvement. The next decade should bring great improvement in health and safety in this industry.

Chapter 15

Office and Service Workers

Sandra N Mohr, Stuart L Shalat

INTRODUCTION

Office workers employed in traditional 'white collar' jobs are found in almost every industry. While some segments of industry employ office workers almost exclusively (e.g. insurance and finance), others such as manufacturing, construction, and transportation have some clerical, bookkeeping, personnel management, and other work performed in an office setting. Service work refers to activities that provide ancillary support to individuals, businesses, or industrial processes. Service work typically addresses needs other than manufacturing or fabrication. Examples include transportation, computer, hotel, personal service work (i.e. laundry, dry cleaning, barbers and beauticians, etc), business, entertainment, legal, social, and other services.

Historically, clinical and research aspects relating to occupational illness and injury have focused primarily on workers in the manufacturing and industrial sector. As job growth in the US migrated from manufacturing to office and service work, the nature of occupational health problems in this sector has become more important. Currently over 50 million workers are employed in service and office work in the US. The Bureau of Labor Statistics projects that service-related jobs will represent 95% of the total employment growth in the US over the next decade, with growth approaching 20%.¹ The development of the non-manufacturing workforce presents challenges to occupational medicine, with unique health issues not encountered in the traditional industrial sector.

The nature of the workplace environment has changed dramatically over the last 40 years, including workplace equipment, and office buildings themselves. Office workers may work in large buildings, with closed ventilation systems, or with limited make-up air. Ubiquitous use of computers has resulted in office workers spending longer periods of time in static postures at their workstation, at risk for repetitive motion from keying activities and challenges with ambient lighting, as well as video displays. Currently it is estimated that there are over 100 million computers in workplaces in the US.

As in other types of work, it is important to understand the nature of the workplace and the activities these tasks involve. Service jobs cover a broad range of occupational requirements ranging from sedentary activities at office workstations to physically demanding jobs such as postal carriers, and sales clerks standing all day in retail stores.

THE NEW WORKPLACE

Over the last 20 years, the number of individuals employed at computer-related occupations has grown exponentially. A broad array of occupations were created, and many that had previously existed have been significantly modified by an ever-increasing reliance on technology. The ergonomic problems associated with secretarial office work have expanded with the use of computers to involve numerous occupations and professions. While the computer keyboard is similar to that of a typewriter, several factors distinguish the computer operator. First, the worker at a computer faces a keyboard with more variable wrist postures and use of a mouse. Second, the nature of the work is often more continuous. For example, former use of typewriters would allow workers to replace paper at every page. The advent of the computer terminal meant that a worker could literally spend hour after hour performing the same repetitive task. Finally, in addition to working on the keyboard, the individual faces a computer screen with many of its own unique postural and ocular problems, as well as substantial productivity demands.

Service work in many different industries also makes broad use of computers. Workers may be located in large telephone and computer banks, consisting of many small cubicles. This type of organization is found in catalog and online retail sales, the insurance industry, transportation (reservations and dispatchers), and a variety of companies serving businesses. The common factor is the repetitive and sedentary nature of the workplace, with workers often at their workstation for long durations.

Office workers and ergonomics

The Occupational Safety and Health Administration has been attempting to improve ergonomic conditions in the workplace. While this resulted in the OSHA Ergonomics Program Standard in November 2000, this was overturned by Congress in the winter of 2001. In April of 2002, OSHA announced its Comprehensive Plan on Ergonomics to address musculoskeletal disorders in the workplace, in an ongoing effort to reduce illness and injury rates that will directly impact on office workers.

In the last two decades, ergonomics has risen to become one of the most critical factors in workplace injuries. Poor ergonomic design of the workplace is a major cause of musculoskeletal problems. Despite numerous studies that have examined workplace injuries that result from poorly designed workstations, many office design issues

that contribute to worker health problems continue.²⁻⁵ Common clinical syndromes among office workers include neck and back pain from poor postural position at the workstation, upper extremity problems from keying motion and improper positioning of keyboards, chairs, and arm supports.⁶ In addition, many also complain of eye strain which can result from video display use.

Neck and back symptoms are among the most common experienced by office workers.⁴ In many offices, desks without any provision for keyboard adjustment are still employed. The worker is therefore left with the choice between raising their arms to an uncomfortable height, or having their chair so high that their legs may be left dangling with no proper support. The use of adjustable keyboards and footrests can alleviate many of these problems. Customer service workers required to talk on the telephone and operate a computer simultaneously will often cradle the telephone receiver between their head and shoulders, leading to neck and shoulder strain. The use of headsets can alleviate this problem, as well as rotating tasks.

However, in many jobs in the service sector, such as phone bank workers or other telephone-based sales or customer assistance workers, there is likely to be little diversity in task. Constant repetition of tasks may also be exacerbated by productivity quotas, involving direct monitoring or surveillance of individual workers. Increasing task speed may increase short-term productivity, but may result in increased illness and injury rates. While having workers maintain high productivity is one measure of efficiency, it must be emphasized that a work force with fewer health complaints results in decreased lost time, as well as lower worker turnover. Research has suggested that frequent short rest breaks from computer work can have beneficial effects on workers' health and productivity.⁷

Prospective studies have been carried out to examine the role of workplace modifications in ameliorating musculoskeletal problems associated with visual display units (VDU). Key factors include the height of the display in relation to the operator, lighting of the room, and the adjustability of the keyboard and the operator's chair. Assessment of mechanical stressors in the office is reviewed in Chapter 32.

The development of functionally designed workstations for computers has helped to remedy some, but not all, problems associated with computer usage. The use of adjustable height and angle keyboards has significantly improved posture.² The use of footrests may assist in lower back problems. Chairs that tilt have been suggested to improve discomfort and lower extremity circulation.⁸ The ability to adjust VDUs for height as well as angle has also proven useful.^{9,10} Another ergonomic device that appears to be beneficial in reducing shoulder, neck, and back pain is the lower arm support on computer keyboards.¹¹

Workers with upper extremity problems associated with keyboard use have shown clinical response to multidisciplinary therapeutic approaches.¹² In a retrospective study, 25% of patients who presented with bilateral hand and forearm pain achieved complete resolution of most symptoms, with an additional 54% reporting moderate improvement. Treatment consisted of medical manage-

ment with pharmacologic interventions, occupational therapy, job-site evaluations, and psychological support with pain management and biofeedback training.

The efficacy of engineering modifications in computer keyboard and mouse shape and function, as well as wireless keyboards and mice, has not been well investigated. To the extent that these make an individual more comfortable, they may decrease the likelihood of injury and strain.

One workplace factor that has not been adequately studied is the recent introduction of the flat panel monitor into the workplace. The two primary types of flat panel monitors are light-emitting diode (LED) and plasma monitors. There are two factors in the design of these types of monitors which may make them more desirable for VDU operators. First, because they are truly flat, they are less likely to pick up reflections and create glare, as occurs with cathode ray tube (CRT) displays. Additionally, LED panels have a textured surface, which minimizes light reflection. Second, flicker rate has been blamed for many eye strain complaints associated with computer use in office spaces and fluorescent lighting. While the cost of plasma screens has limited their availability, the decreasing cost differential between CRTs and LED type displays make the latter an obvious choice for reducing visual fatigue.

A related issue in the use of VDU is eye strain that results when individuals change their plane of focus from computer display to paper copy. This is common both among office workers who are transcribing text from paper, and individuals reading from printed lists. The problem may also be exacerbated in older workers who require vision correction for presbyopia. If the distance from an operator's eyes to the VDU and to the paper copy is significantly different, it becomes difficult to maintain focus. It may therefore be useful to make use of copy holders that can be placed adjacent to display text at the same distance from the operator as the VDU.

Workplace lighting is another key factor in avoiding eye strain. Most office lighting is designed around standards that date back to the pre-Second World War era, for offices that used typewriters, not computers. The illuminated nature of the VDU screen and the potential for reflections from CRTs are a recognized problem for many VDU users. The use of glare-reducing screens can be of significant benefit, as can the use of light diffusers to soften lighting in offices. Many offices remain over-lit for current office needs. A re-evaluation of office lighting may have the dual benefit of reducing both eye strain and electricity costs.

Another area in which light is a problem is in electrostatic or dry copying. Workers who make copies, in particular when the document cannot be fed through a sheet feeder, often complain of the blinding light from the xenon flash tubes employed in many copiers. The primary recommendation for minimizing bright flashes from copier operation is use of engineering controls (i.e. covers).

Retail workers

One area of employment that is often overlooked in terms of occupational health problems is retail store clerks and

sales assistants. Tendonitis, tenosynovitis, and carpal tunnel syndrome are common complaints. While this was initially thought to be related to the use of cash registers, electronic price scanners continue to cause problems.¹³⁻¹⁵ Another problem in clothing sales is related to the folding of garments on display, and stacking activities. Complaints of carpal tunnel syndrome from this type of repetitive motion have been reported, that may be ameliorated by the use of folding templates.

Lifting during stocking and inventory activities results in risk for musculoskeletal injuries. Bulk packaging containers can be heavy, and when combined with twisting motions to place merchandise on display, may result in lower back injuries. Concern for low back injury in many retail businesses can be seen in frequent requirements to wear back braces. Unfortunately, numerous studies have not established the efficacy of these devices.¹⁶⁻¹⁸

INDOOR AIR QUALITY

One area frequently cited for health concerns among office workers is indoor air quality. Energy conservation measures since the 1970s have resulted in central heating, ventilation and air conditioning systems (HVAC) with closed windows, substantially reducing the amount of make-up air allowed into buildings. This overall decrease in air turnover rate means that any air pollutants within the workplace tend to remain in the ambient indoor environment. While the sources of air contaminants are not as obvious as those that may occur in manufacturing settings, there are a number of air contaminants that may affect workers' health.

Second-hand smoke

Among the most noxious indoor air pollutants, and the most likely to lead to long-term health effects, is second-hand (sidestream) tobacco smoke, also termed environmental tobacco smoke (ETS). Service workers in restaurants and bars in particular have health concerns associated with their exposure to second-hand tobacco smoke.¹⁹ Other studies have examined airline flight crews, concluding that they are exposed to a variety of air contaminants.²⁰⁻²³ Concern for cancer risk arises since flight attendants dating back to the 1950s were exposed to cigarette smoke for long periods of time in the close confines of the passenger cabins. Just as buildings have decreased make-up air to conserve heating and cooling costs, so airplanes have reduced make-up air to minimize jet fuel costs. Since the jet engines provide the energy for heating and cooling cabin air, decreasing the utilization of air handling units (termed 'packs') can lead to significant fuel savings. Studies have shown that such practices increase the levels of air contaminants including CO₂, and tobacco smoke in the cabin air.²²

Despite the banning of smoking on domestic flights within the US, smoking continues on many international flights by non-US flag carriers, and so remains a continuing problem for some flight attendants. Bartenders, waiters,

and waitresses continue to be at risk for smoking-related illnesses due to environmental tobacco smoke in their workplace. It must be emphasized that any service or office worker who is employed in a non-smoke-free workplace is placed at risk for complications of second-hand smoking.

Chemical contaminants

Other indoor air pollutants in the workplace may result from office equipment or furnishings. Copy machines and laser printers are often cited as sources; formaldehyde from composite wood products also causes respiratory effects.²⁴ Copy machines and laser printers rely on high voltage to generate an electrostatic charge, producing carbon black deposits on paper, as well as high-voltage xenon flash tubes. The paper then passes through a heating process to fix the pigment. This process results in two separate air pollutant streams, namely ozone, a well-recognized respiratory irritant, and vaporization of fuser oil. Workers may experience both eye irritation and respiratory symptoms from these exposures. Local ventilation with exhaust engineering can often eliminate these problems.

Office furnishings can contribute significantly to indoor air pollution. These can derive from carpets and carpet padding, as well as adhesives used to secure carpet and tiles to the floor.²⁵ While off-gassing from glues usually dissipates in a relatively short period of time after the carpet is put down, the carpet and padding may continue to off-gas formaldehyde for weeks or months after it has been laid. Similarly, office furniture, including fabric-covered office dividers, chairs, and wood furniture made of wood composites, can off-gas formaldehyde for long periods of time. In combination with the decreased make-up air in many office places, these contaminants can linger in office air for long periods of time.

The lack of make-up air from outdoors can often affect levels of air contaminants in buildings, contributing to mucous membrane and respiratory irritant effects and neurocognitive symptoms termed sick building syndrome (SBS).²⁶ Poor maintenance and under-utilization of air exchange from HVAC systems can further exacerbate indoor pollution problems. An example of problems in HVAC installations can be seen in the following case. Workers at a Federal Air Traffic Control facility experienced severe eye irritation and fatigue. Many of the workers smoked cigarettes on the job. The nature of the work required hyper-vigilance utilizing computers for hours at a time. Management thought these two factors might have been the primary source of the health complaints. However, an industrial hygiene inspection of the HVAC system determined that a recently installed HVAC system had never had the shipping blank plate removed from the make-up air inlet. This resulted in build-up in the indoor air of tobacco smoke and volatile compounds from electronic equipment components.

Certain service occupations have specific chemical exposures. Two examples are individuals who are employed in the dry cleaning industry and those involved in

personal care, including hair and nail stylists. Concerns in the dry-cleaning industry have focused primarily on the use of perchloroethylene, a chlorinated solvent with neurotoxicity, hepatotoxicity, and potential carcinogenicity.²⁷⁻²⁹ Inhalation is the primary route of exposure for most workers, although operators who remove the clothing from the washers (wet transfer processes) may have dermal exposure. While a variety of dermatologic problems exist, even greater health concerns have focused on inhalation exposures.³⁰ It is important to note that exposures are not limited to operators, but involve other dry-cleaning personnel (e.g. pressers, counter workers). Perchloroethylene may continue to off-gas from clothing for significant periods after cleaning.

In the case of hair and nail stylists, exposures include a variety of chemicals used for hair coloring, conditioning, and curling. Some of these chemicals can be highly irritating or sensitizing, resulting in contact dermatitis. Inhalation exposures to hair care products by stylists, and bonded acrylic nail components by manicurists, can lead to respiratory illness. While in the past most exposures were related to ketone mixtures, the advent of acrylic nail applications has resulted in an increase in exposure to a variety of epoxy glues and organic solvent systems. These include heat application processes resulting in increased volatilization. Hairdressers and manicurists often work from home or in small shops with inadequate ventilation, resulting in exposures above permissible short-term exposure limits (STEL). A number of studies have examined health issues in this population, which include dermatologic, respiratory, and neurologic problems, as well as increased risk of miscarriage.³¹⁻³⁶ Since these are small workplaces with small workforces, it is extremely difficult to fully examine less common outcomes such as cancer.³⁷

The problem of infectious agents in office and service workplaces has been recognized for over a quarter of a century. Since the well-publicized outbreak at an American Legion Convention at a hotel in Philadelphia, Pennsylvania, in the 1970s, the importance of design and maintenance of HVAC systems has been established as an important factor in controlling *Legionella pneumophila*. Over 15,000 cases of *Legionella* are estimated to occur in the US each year. This bacterium is known to grow in cooling towers which are part of many HVAC systems. When systems are designed so that intake air for the HVAC system can become entrained in cooling towers, a problem potentially exists. Periodic maintenance and use of biocides in cooling towers are methods that have been utilized to control this problem. However, some controversy exists over the effectiveness of chlorination, copper-silver ionization, monochloramine, and heat in controlling the bacterium.

Molds and mycotoxins

In recent years there has been increasing concern over health risks associated with mold in indoor air.^{38,39} The ability of various molds to trigger allergic and asthmatic responses in atopic individuals is well established.

Stachybotrys chartarum is a fastidious-growing mold associated with more severe mold contamination, and has generated substantial health concerns.⁴⁰⁻⁴² A wide range of symptoms including, but not limited to, respiratory difficulties, headache, body aches, fatigue, and neurocognitive symptoms have all been reported in association with *Stachybotrys*. In part, the origin of this concern centers on two reports of clusters of acute pulmonary hemorrhage in infants published by the CDC in 1994 and 1997. Even though the CDC later concluded that insufficient evidence existed to definitively link *Stachybotrys* to these serious respiratory problems, concern has continued. Clearly when dampness is present in office buildings, mold growth is possible, with potential allergenic or irritant responses in workers. The role of *Stachybotrys* in particular continues to be a source of concern and controversy.

VIOLENCE AND SERVICE WORKERS

An area of increasing concern in many workplaces is escalating violence in the workplace. In particular, service workers have become the target of violence with increasing frequency.⁴³ Police statistics have shown that personal assaults, including rape, serious injury, and death, represent the most serious acute health threat to service workers.^{44,45} The rate of assaults on employees of convenience stores is particularly high. In the year 2000 there were a total of 674 homicides committed in the workplace; over 65% of these occurred among service workers. Studies have shown that a disproportionate number of these crimes occur during evening and night-time work. Since these jobs are often held by young people and individuals of color, they experience a disproportionate burden as victims of crime in the workplace.⁴⁶ In addition, women are frequently victims of domestic violence, including homicide, in the workplace. The need for workplace security to prevent such violence represents an important public health concern.

STRESS

An area of increasing concern both to workers and employers is stress in the workplace. Stress has been shown to affect workers' performance and overall health.^{2,47} Although it is beyond the scope of this chapter to review all causes and implications of stress in service and office workers, several risk factors are notable in causing work-related stress among service and office workers.

Research has suggested that the amount of stress an individual experiences in the workplace is directly associated with the physical demands of their jobs and inversely associated with the amount of control a worker has over their daily tasks.⁴⁷ Since many service workers have relatively little control over their jobs, they may be at increased risk for stress. One aspect that may contribute to stress is electronic surveillance of productivity. This can take various forms, ranging from evaluation of the number of customers served, to direct video surveillance of work-

ers. Such surveillance impacts workers' sense of control and security and may be associated with stress.

The result of stress in the workplace may not be limited to psychologic symptoms, but may be manifest in an increase in physical symptoms. For example, a worker with musculoskeletal symptoms may experience greater severity or greater frequency of these symptoms due to stress.

Assisting workers in coping with stress in the workplace can be advantageous to both workers and employers, as a sense of job satisfaction and security is likely to result in lower rates of job turnover. There is also the potential for greater productivity with a more contented workforce. Such methods as worker empowerment, including quality control networks and workplace discussion groups, can provide workers with a greater sense of control, as well as providing management feedback on improvements that may increase productivity.

The attacks on the Alfred P. Murrah Building on April 19 1995 in Oklahoma City, and on the World Trade Center towers and Pentagon on September 11 2001 have resulted in heightened concern for terrorism in the workplace. It should be noted that most of the victims of these attacks were service and office workers. Anecdotal reports exist for employees working in high-rise buildings, as well as airline transportation workers, who have expressed concern for their safety following these incidents. These concerns may lead some employees to experience stress, with the potential for anxiety or depression.

Once thought to be a problem limited to healthcare, manufacturing, and transportation industries, shift work has become more prevalent in retail, food service, and customer service sectors moving towards a 24-hour economy. In numerous industrial settings, it has been demonstrated that workers on rotating shift work exhibit disrupted sleep patterns on both day and night shifts.⁴⁸ Shift work is also associated with gastrointestinal and cardiovascular diseases.⁴⁹ Studies on age and shift work seem to show an interactive effect^{50,51} and it is likely that office and service workers will experience a similar response.⁵²

Unlike shift work, there are very limited data on the health consequences of overtime in either voluntary or mandatory settings. Several studies have demonstrated psychological, cardiovascular and reproductive effects as well as impact on workplace performance.

CHILDREN IN SERVICE INDUSTRIES

The use of children and adolescents in service industries raises a variety of health and safety issues.⁵³ In addition to the traditional employment of children and adolescents in agriculture, the most common areas of employment are in the food service industry. In particular, the fast food industry in the US frequently relies on entry level workers. While not always apparent, a variety of health issues are present in these workplaces, including burns from stove top grills and open fry vats. The need for speed in food preparation and service of customers can result in slips and

falls, resulting in significant injury. In addition to illness and injury, the social impact of child labor includes potential adverse effects on school work due to fatigue and lack of study time.

Chapter 16

Manufacturing Sector

Tim K Takaro

INTRODUCTION

In characterizing the manufacturing sector, it is useful to consider the US Bureau of Labor Statistics definition for manufacturing, namely, any mechanical or chemical transformation of materials into new products. Manufacturing establishments are generally described as plants, factories, or mills where production may include fabrication, assembly, or blending of materials as finished products, or as raw material for subsequent manufacture. Manufacturing does not include facilities where the product is a structure or similar fixed improvement.

The products of the manufacturing sector are usually produced for the wholesale market, and are limited to orders for industrial uses as opposed to retail sale to the consumer. For example, food and associated products industries supply grocery stores, which are considered within the trade sector. The nature of manufacturing, requiring the mechanical transformation of materials into new products, presents numerous risk factors for illness and injury to workers.

Table 16.1 provides some examples of manufacturing establishments, along with average annual employment and injury and illness rates in 1994 and 1999 for the industries with the highest morbidity. Industry groups which are not on this list and have lower injury and illness rates include durable goods, electrical and other equipment and instruments; and non-durable goods such as tobacco, textile mill products, apparel, paper and allied products, printing and publishing, chemicals and allied products, and petroleum and coal products. Because the manufacturing sector is so large, diverse and complex, this chapter will focus mainly on the ten industries within the sector with the highest incidence of illness and injury in the United States.

The principal hazards associated with the manufacturing sector will be defined and the primary associated health

outcomes described, according to the most recent statistics from the United States Bureau of Labor and Statistics. In a few cases, a major industry has some industrial subgroupings with a higher injury and illness rate than the more general description provided in Table 16.1 (representing a two digit Standard Industrial Classification (SIC)). For example, household appliances (three digit SIC) and electron tubes (four digit SIC) within electronic industries, and coated fabrics and tire cord (four digit SIC) within the textile industry, have rates comparable to those higher risk industries described in Table 16.1. The reader must bear in the mind the specificity of the industrial classification when interpreting the data described.

Other chapters in this book will provide details regarding treatment and management of specific conditions associated with the hazards of the manufacturing sector such as musculoskeletal disorders (Chapter 23), diseases of the lung and pleura (Chapter 19), and dermatologic disease (Chapter 29). Specific hazards relevant to this industrial sector are described in detail in Section 4 of the text.

Manufacturing is the hallmark of the industrial era beginning in the 19th century. In most of the developed world, it is still the largest sector of employment in production. Factories employ more workers on average than non-manufacturing businesses. For example, in the United States, factories account for just over one-third of industrial establishments, but manufacturing employees outnumber workers in the next largest production sectors, construction and mining, by three to one.¹ In the US in 2000, the manufacturing employment level was 18.5 million, decreasing from 18.8 million in 1998, following a market-driven cyclical trough in the early 1990s (Fig. 16.1). Despite the shift of manufacturing jobs in the US and other developed nations to countries with lower wage rates, such as the emerging

Figure 16.1: The figures for employment and unemployment in the US manufacturing sector have converged in recent years as the number of US manufacturing jobs declined since 1998, concomitant with a national decline in unemployment. US manufacturing jobs are expected to further decline.

	Annual average employment 1999	Total injury and illness incidence 1999	Total injury and illness incidence 1994	Total illness incidence 1999	Skin diseases or disorders	Dust disease of the lungs	Respiratory condition due to toxicant	Poisoning	Disorder due to physical agent	Repetitive trauma disorder	All other occupational illnesses

Table 16.1 Occupational illness incidence for top ten manufacturing industries in 1999 per 10,000 FTEs

Figure 16.2: Non-fatal workplace illnesses by industry division, 1999. Manufacturing is defined as those establishments which are engaged in the mechanical transformation of materials into new products. This sector of the US economy accounted for three-fifths of all newly reported occupational illnesses for private industry in 1999. Source: Bureau of Labor Statistics, US Department of Labor, December 2000.

economies in Asia and Mexico, the unemployment rate in manufacturing dropped in the late 1990s in the US to 3.6% in 1998 and 1995, though this has increased during the recent recessionary cycle.¹

The fastest growing manufacturing zone in North America is in the US–Mexican border region, including foreign-owned factories with special tax status known as *maquiladoras*. Once assembly spots for multinational corporations, the *maquiladoras* have flourished and are now a manufacturing sector in their own right. Over 4000 *maquiladora* plants produce durable goods, including electronic equipment, household appliances, batteries, garments, furniture, and miscellaneous consumer products.^{2,3}

Chapter 10 in this book addresses some of the challenges of worker health and safety in the emerging economy and

manufacturing sectors such as the *maquiladoras* sector. These international manufacturing sectors are expected to cause a decline in employment in the United States manufacturing in the near future. Mining is the only other industrial sector expected to decline during this period.¹

According to the US Bureau of Labor Statistics (BLS) the manufacturing sector accounts for more illness and injury than any other sector of the US economy, with 9.5 cases of illness or injury per 100 workers in 1999. Despite a decline in this rate during the past 5 years in most industries (Table 16.1) this sector accounted for three-fifths of all newly reported occupational illnesses for private industry in 1999 (Fig. 16.2). The sector's distinction in this regard has been consistent throughout the past decade in the US. Since 1993, manufacturing has surpassed the construction industry in total injury and illness rates, though the construction trades' annual rates remain nearly as high during the past decade with 8.8 cases per 100 workers per year, and exceed manufacturing in days lost from work. As demonstrated in Figure 16.3, the manufacturing industries with the top ten injury and illness rates are all well above the manufacturing sector's average incidence of illness and injury of 125.5 per 10,000 full-time employees.

Manufacturing accounted for 11.3% of all work-related fatalities in the US in 2000. The manufacturing industries with the top ten injury and illness rates accounted for 80% of all the fatalities in this sector. Lumber and wood products had more than twice as many fatalities as any other industry group, with logging accounting for the vast majority of these (122 fatalities in 2000). Most of the industries have had a slow rate of decline in fatalities over the past decade, except for the industrial machinery and equipment sector, which has increased by 1% over the past five years.¹ The distribution of the 668 fatalities in the manufacturing sector is shown in Figure 16.4.

Data sources

Much of the current data for health and safety in the manufacturing sector comes from the Survey of Occupational Injuries and Illness of the United States BLS.

Figure 16.3: The top ten major US industries by injury and illness rate in 1999. These injury and illness rates are all well above the manufacturing division average incidence of illness and injury of 125.5 per 10,000 full-time workers.

Figure 16.4: Manufacturing accounted for 11.3% of all work-related fatalities in the US in 2000, with these industries in the top decile in 1999. Most of the industries have had a slow rate of decline in fatalities over the past decade except for the Industrial Machinery and Equipment, sector which has increased by 1% over the past five years.

This survey is collected annually on a state-by-state basis, from approximately 169,000 private industrial establishments. The survey measures non-fatal injuries and illnesses in private industry, with the exception of self-employed firms and those with fewer than 11 employees, private households, government agencies, or state and local governments. The survey is based upon logs kept by individual employees, which are subject to various incentives that may result in substantial under-reporting or over-reporting.

The survey probably underestimates the true occupational illness and injury rates. For example, in Washington State in 1997, the BLS indicated 4.4 cases of carpal tunnel syndrome per 10,000 full-time employees (FTEs) resulting in time loss. The rate for claims that were accepted for compensation through the state's workers' compensation program for this illness was 16.6 per 10,000 FTEs during the same period.⁴ The survey also likely under-measures long term chronic or latent illnesses.^{1,5} This latter deficiency is particularly important for cancers secondary to chemical exposures.

The estimates of occupational injury and illness are based upon a probability sample, with a standard error calculated around the estimate. For example, the 1998 incidence rate for all occupational illnesses of 6.7 per 100 full-time workers in the private industrial sector has an estimated relative standard error of 0.9%. Data are also subject to non-sampling error such as mistakes in recording and counting, misclassification due to imprecise definitions, which may not accurately describe the industry, and the inability to obtain information about all cases. These errors are not measured directly, though procedures have been implemented by the BLS to minimize non-sampling error. Industries are classified by the 1987 Standard Industrial Classification (SIC) Manual established by the Office of Management and Budget. This classification system will be replaced by the North American

Industrial Classification System beginning December 2004 in order to better represent new industries across North America.

Since the 1990s, restricted work activity, as opposed to days away from work, has become a much more common response by employers to workplace injury and illness. While the total number of injuries and illnesses requiring days away from work has continuously declined since 1992, the number of injuries and illnesses requiring work restriction has increased by over 70% during this same period.⁶ This trend is especially apparent in the manufacturing sector, where the rate of injury or illness requiring restricted work has been increasing since 1986.⁵ For injury or illness requiring restricted work, the manufacturing sector is 50% higher over the past decade than the next highest sectors, agriculture and transportation. This trend seems to indicate an effort on the part of employers to maintain employee productivity by restricting duty to accommodate an injury or illness. However, the trend also demands more scrutiny of the BLS data to include tracking of the outcomes of work restriction (follow-back analysis). Without such effort, the information needed for the design of future illness and injury prevention intervention strategies will be lacking.

In 1999, 76% of injuries and illness in the manufacturing sector could be attributed to the ten industrial groups with data shown in Table 16.1 (classified by two digit SIC code): Durable Goods: Lumber and Wood Products (24), Furniture and Fixtures (25), Stone, Clay and Glass Products (32), Primary Metal Industries (33), Fabricated Metal Products (34), Industrial Machinery Production (35), Transportation Equipment (37); and the Non-durable Goods: Food and Kindred Products (20), Rubber and Miscellaneous Plastics (30), and Leather Industries (31). In the US these industries all had rates of illness and injury greater than 850 per 10,000 workers in 1999, and have been the sector leaders for the past five years. Miscellaneous Manufacturing

Figure 16.5: The top ten major US industries by illness rates per 10,000 FTE in 1999. Though occupational illnesses are often more difficult to associate directly with work practices, they are particularly important in this industrial sector.

Industries (SIC code 39) has a comparable incidence of illness and injury, but is not addressed in the chapter due to the difficulty in defining specific industries and exposures of interest.

Disease outcomes associated with manufacturing

In 1999 (Figs. 16.2 and 16.5) it is important to note that the manufacturing sector accounted for fully three-fifths of all occupational illnesses reported by private industry. Although injuries account for more total cases and lost work days than illness in all manufacturing categories, they are more readily linked to work practice. Their prevention can thus be effectively addressed by standard industrial safety measures (described in Chapters 31 and 32). In contrast, illnesses are often more difficult to associate directly with work practices, and because of their importance in this industrial sector, this chapter will give special attention to these outcomes.

Common conditions experienced among manufacturing workers

Manufacturing accounts for over 70% of all repetitive trauma disorders in the US workforce,⁵ with industry specific rates described in Table 16.1. The proportions of illness due to repetitive trauma in each industrial group are similar to the total injury and illness rate proportions, except for textile mill production and apparel production, which have relatively low injury rates and high illness rates (69.2 cases per 10,000 full-time workers and 121.6 cases per 10,000 full-time workers, respectively) in 1999. For each of these industrial groups, repetitive trauma disorders are by far the largest contributor, frequently by an order of magnitude. The transportation equipment industries (e.g. autoworkers), food and associated products sectors, and leather workers have nearly three times the incidence

of repetitive strain injury than others in the manufacturing sector. This high incidence might be expected, based upon the repetitive job tasks of these workers, though the magnitude of difference is striking. Details of the hazardous exposures that are associated with musculoskeletal disorders, and the diagnosis and treatment of the associated disorders are described in Chapters 23 and 32.

Skin diseases are the next most common illness and are most prevalent in the transportation equipment sector, probably due to the heavy use of cutting fluids and other irritating lubricants.⁷ In 1998, the manufacturing sector accounted for more than half of the total number of permanent hearing loss cases reported by clinicians to the NIOSH Sentinel Event Notification System for Occupational Risks (SENSOR) program for hearing loss.⁵ Table 16.1 classifies this illness under Disorders due to Physical Agents. The NIOSH SENSOR program for silicosis, which covered seven states between 1993 and 1995, found that 75% of cases were from the manufacturing sector compared with 7% for mining and 9% for construction.⁵

INDUSTRY-SPECIFIC HEALTH CONCERNS IN THE MANUFACTURING SECTOR

Lumber and wood products

This industrial group includes the following industries: logging, saw and planing mills; fabricated wood products, ranging from cabinetry to prefabricated buildings, and wood composite manufacturing, representing in aggregate approximately 831,900 workers in the US in 1999. By far the largest fatality rate in this group is associated with logging, with 122 deaths in 2000 (65.6% of all deaths in this group). However, the illness and injury rates for workers manufacturing prefabricated buildings and wooden containers is much greater than that of loggers

(487.1 lost-work days per 10,000 full-time logging workers compared with 612.7 for prefabricated buildings and 661.7 for wooden containers, respectively in 1999).

Illnesses in lumber and wood products manufacturing are most common in mills and specialized production such as bowls, masts, poles and toothpicks. This latter category has the highest illness rate at 112.7 cases per 10,000 full-time workers. Ninety-six of these are associated with repetitive trauma, while the next highest illness in this category is dermatitis at 7.1 cases per 10,000 full-time workers. This relative proportion of repetitive trauma and dermatitis is seen throughout this group, and is consistent with the manual job tasks, exposures to irritants and allergens (such as allergenic wood dusts, preservatives, adhesives, lacquers and paints). The highest respiratory disease rate is seen in the hardwood and veneer industry, at 3.9 cases per 10,000 full-time workers. This rate is consistent with epidemiologic studies in wood workers that show symptoms of airway obstruction and decreases in lung function (FEV₁ and FVC),^{8,9} also consistent with a combination of irritant and allergic effects. Several hundred species of trees have been associated with dermatitis and some specifically with asthma (e.g., Western red cedar, mahogany, and rosewood).¹⁰⁻¹²

Carcinoma is also a significant problem for wood workers. Nasal cancers are clearly associated with wood dust exposures from various species, although the mechanism has not been well characterized.^{13,14} Leukemia and non-Hodgkin's lymphoma have also been elevated in mortality studies of wood workers,^{15,16} as has colon cancer, most frequently reported in wood pattern makers, though this risk has diminished substantially as car design has evolved to other methods.^{17,18} Elevations in lung cancer and pleural mesothelioma have been reported, though the data for these latter two cancer types are likely due to exposures to asbestos and other carcinogens found in the industry, rather than wood dust.^{19,20}

Furniture and fixtures

This industrial group includes the production of wood, metal, plastic and composite fabricated furniture, partitions, fixtures, drapery and blinds. This group employed approximately 547,000 workers in the US in 1999.¹ Some of the same hazards as seen in wood products, e.g. laceration, crush, and repetitive strain injury, as well as exposure to wood dust, paints, lacquers, and solvents are found in this group. The injury rate is comparable at 1030 per 10,000 full-time workers per year; however, the illness rate is more than double that of lumber and wood products (Table 16.1). The illness distribution is similar to lumber and wood products, with repetitive trauma and dermatitis accounting for nearly 90% of the reported US cases in 1999.

The subgroup of workers engaged in fabrication of seating and fixtures for public buildings (SIC 253) stand out in the furniture and fixtures group, with an illness rate of 301.1 per 10,000 full-time workers compared with the group average of 120.8 per 10,000 full-time workers annu-

ally. Eight-five percent of this illness is due to repetitive trauma and 9% due to dermatitis. It is not clear what hazards separate this group from workers in related industries such as office furniture workers (annual illness rate of 154.9 per 10,000 full-time workers), but it may be due to the increased exposures to metals and plastics used in furniture for public buildings, since the only comparable rate in this group is in the category of non-wood office furniture, with an illness rate of 191.5 per 10,000 full-time workers per year.

Respiratory effects are also more common in this subgroup, with an illness rate of 3.2 per 10,000 full-time workers per year. An analysis of Italian furniture workers showed that spray painters were more likely to have asthma-like symptoms (though not positive methacholine challenge) than assemblers or wood workers from the same factories.²¹ Isocyanate-containing paints are implicated as the etiologic agent in this study. The cancer epidemiology in the furniture and fixtures group is similar to that seen in the wood products industries, except for an additional increase in stomach cancer observed in white males working in metal furniture.¹⁶ This finding is consistent with other studies in metal workers.²²

Stone, clay, and glass products

This industrial group includes workers engaged in the manufacture of flat glass and other glass products, cement, concrete and gypsum products, pottery, cut stone, abrasives and some asbestos products. This group employed approximately 566,600 workers in the US in 1999.¹ The injury rate was 1010 full-time workers for 1999, with 60.4 illnesses per 10,000 full-time workers. While repetitive trauma accounts for 62% of this rate, the incidence of dermatitis is also relatively high at 16%. Dermatitis in porcelain workers is particularly high at 32.4 cases per 10,000 full-time workers per year, followed by concrete block and brick production at 25.9 per 10,000 full-time workers per year. Disorders associated with repetitive trauma were most problematic for china table and kitchenware workers, with 233.5 episodes per 10,000 full-time workers in 1999. Respiratory conditions are also high in this group at 6.0 per 10,000 full-time workers, though not as high as in abrasive products at 10.9 per 10,000 full-time workers per year. Abrasive products workers also show high levels of dermatitis, with 33.9 cases per 10,000 full-time workers.

Exposure hazards in this group are both physical (heat and infrared radiation) and chemical agents (silica, metal fumes, and vapors often found in colorants, hydrogen fluoride in etching processes, epoxies and polymer-based binders, noise, nitrogen oxide, other combustion products, and dusts). These hazards help explain the profile of illness in stone, clay, and glass products workers described above, since many of these agents can cause respiratory disease and/or dermatitis from either irritant (e.g. etching agents for glass) or allergic (e.g. chromates in cement) mechanisms. Pneumoconiosis remains a significant respiratory problem for this group (as shown for silicosis in Table 16.2).²³ The proportionate mortality ratios in stone, clay, and glass

Industry	Deaths	PMR	95% CI
Metal mining	105	81.30	66.10–98.91
Misc. non-metallic mineral and stone products	65	60.58	46.24–98.91
Non-metallic mining and quarrying	59	55.05	40.78–72.63
Iron and steel foundries	53	35.31	26.16–46.58
Pottery and related products	22	31.12	19.45–47.15
Structural clay products	22	30.15	18.84–45.68
Coal mining	68	9.41	7.18–12.11
Misc. fabricated metal products	21	7.93	4.90–12.13
Blast furnaces, steelworks, mills	68	6.29	4.80–8.10
Other primary metal industries	11	5.82	2.91–10.41
Cement, concrete, gypsum and plasters	6	4.63	1.70–10.09
Glass and glass products	10	3.54	1.70–6.51
Construction	114	1.86	1.51–2.26

Table 16.2 Proportionate mortality ratio for silicosis 1987–1996 in selected US states (adapted from Lewis⁴⁰)

products workers are comparable to those found in the mining industry, and represent an excellent opportunity for prevention of this potentially fatal lung condition.

Work in some sectors of this group have been associated with cancer, particularly lung cancer and to a lesser extent gastric cancer (IARC class 2A). Because flat glass manufacturing is largely automated, thereby reducing exposures in this subgroup, the main cancer risk in glass manufacturing currently is found in pressed glassware, art glass, and glass containers.²⁴

Primary metal industries

This group is composed of workers engaged in the smelting and refining of ferrous and non-ferrous metals from ore, pig iron, or scrap. Associated mills are involved in rolling, drawing, and alloying metals; in manufacturing castings and other basic metal products including nails, spikes, manufacturing of insulated wire and cable, and production of coke. In 1999, approximately 698,800 workers were engaged in these industries in the US. That year there were 1190 injuries per 10,000 full-time workers and 108.8 illnesses per 10,000 full-time workers.

Foundry workers have the highest illness rates in this group, with 183.5 cases per 10,000 full-time workers overall. These workers primarily fabricate castings, such as fittings, manhole covers, and railroad wheels. The illnesses are due to repetitive trauma (78%), dermatitis (6%), and physical agents such as heat and noise (5%). Aluminum foundry workers had the most cases of dermatitis, with 31.2 per 10,000 full-time workers per year. This accounted for 22% of all occupational illness in this group in 1999, and was twice the rate seen in 1998. Dermatitis is due in part to the heavy use of caustics (particularly with the Bayer process) and production of sulphuric acid during smelting, producing irritant skin effects and in some cases sensitization to alloys in metals such as nickel, chromium and zirconium. Chronic respiratory diseases including asthma, emphysema, and chronic bronchitis are also seen in aluminum and other foundry workers.²⁵ Respirating hazards specific to manufacturing of alloys include fluorides (aluminum), nickel carbonyl (nickel), arsenic (copper and lead), mercury and cyanide (gold). Some metals are directly toxic and are produced in pure forms (e.g. lead). Silica is also a significant

Figure 16.6: Foundry workers performing metal pour into a sand-filled form for steel manufacture. The worker on the left is controlling the rate of the pour by controlling the angle of dip of the crucible. The worker on the right uses the long pole with bar to prevent floating slag (waste products generated during the melting process) from getting into the form. There are several unsatisfactory safety practices that are occurring simultaneously during this pour, which include the absence of respiratory and hearing protection, face and body shielding, or proper elevation equipment for all workers present. Courtesy of Susan Swan.

hazard in the industry, as shown in Table 16.2. This exposure, along with coke oven and other furnace emissions, accounts for much of the relatively high respiratory disease rates seen in this group (Fig. 16.6).

A large prospective study of Finnish foundry workers from 1950 to 1987 found excess all-cause mortality (SMR 135 (95% CI 128–142)) and disease-specific mortality, including respiratory disease (SMR 153 (120–192)), lung cancer (SMR 143 (117–174)) and digestive organ cancers (SMR 150 (114–194)).²⁶ Polyaromatic hydrocarbon exposures are a significant hazard in the industry both for ferrous and non-ferrous metals utilizing coke, coal tar pitch, and related compounds, likely accounting for much of this increased risk.

Fabricated metal products

This manufacturing group covers the fabrication of metal products, such as cans, tinware, hand tools, cutlery,

radiators, fabricated structural metal products, hardware, stamped and forged metal, small ordnance, and a variety of metal and wire products. Machinery, precision scientific equipment, jewelry, silverware, and transportation equipment are classified in other SIC groups. In 1999, approximately 1,521,900 workers were employed in these industries. The injury rate is similar to the primary metal industries at 1260 per 10,000 full-time workers, and the illness rates are comparable at the general level described in Table 16.1 for 1999 (99.0 cases per 10,000 full-time workers compared with 108.8 for the primary metal industries). Repetitive trauma disorders are similar in each group. Dermatitis is a significantly greater problem for this group than primary metal industries, while lung disease is a greater problem for the latter group, due in part to the silica exposures noted above.

Fabricated metal products workers are often exposed to cutting oils, hard metal, and other particles from cutting, grinding, and polishing. The hazards of cutting fluids are described in detail in Chapter 43 and include a significant risk of irritant and allergic dermatitis, folliculitis, as well as acute and subacute respiratory effects.^{27,28} Particularly high rates of dermatitis are noted in the subgroup involved in metal forging and stamping (27.4 cases per 10,000 full-time workers) and other fabricated metal products (37.7 cases per 10,000 full-time workers). This latter subgroup also has a high rate of respiratory illness with 33.3 cases per 10,000 full-time workers in 1999, twice the group average in 1998 at 6.5 cases per 10,000 full-time workers.

Elevated cancer rates are reported in this group of industries. Cancer of the stomach, pancreas, larynx, and rectum were associated with metal-working fluids in a review by NIOSH in 1996.²⁹ Excesses in cancer of the digestive tract were also found in Finnish metal products workers in the large prospective study noted in the previous section,²⁶ and in several studies of workers involved in machining and grinding metals.³⁰⁻³²

Industrial machinery production

This group consists of workers manufacturing industrial and commercial machinery and equipment, including computers. Manufacture of engines and turbines; farm and garden machinery; construction, mining and oil field machinery; elevators and conveying equipment; hoists, cranes, monorails; industrial trucks and tractors; metal-working and other industrial machinery; power tools; computer and office equipment, and refrigeration and service industry machinery are included in this group. Machines powered by built-in or detachable motors ordinarily are included in this major group, with the exception of electrical household appliances. Workers who manufacture electrical equipment are classified elsewhere. This is the largest manufacturing group in the US, employing 2,207,800 full time workers in 1999. In that year there were 870 injuries per 10,000 full-time workers and 72.5 illnesses according to the BLS.¹ Disorders associated with repetitive trauma accounted for 50.5 cases per 10,000 full-

time workers, and dermatitis 11.8 per 10,000 full-time workers.

The highest repetitive trauma rates were found in the subgroups of carburetors, pistons, rings, and valves machining with 141.9 cases per 10,000 full-time workers (105.6 in 1998), lawn and garden equipment with 135.8 cases per 10,000 full-time workers (200.0 in 1998), and refrigeration equipment with 116.3 cases per 10,000 full-time workers (129.7 in 1998). Workers manufacturing carburetors, pistons, rings, and valves also have the highest subgroup rates of dermatitis, and their rate competes with pumps and pumping equipment (24.1 cases per 10,000 full-time workers) and industrial furnaces and ovens (12.5 cases per 10,000 full-time workers) for the highest respiratory disease rates due to toxic agents in 1999. While these other groups have lower rates of illness in 1998, workers manufacturing carburetors, pistons, rings, and valves had consistently elevated rates of respiratory illness. This is possibly related to the use of cutting fluids contributing both to acute and subacute respiratory illness.

The semiconductor industry is not encompassed by this group, though computer assembly is. The total injury and illness rate for computer and office equipment at 270 cases per 10,000 full-time workers per year is well below the group average of 850 cases per 10,000 full-time workers and consists primarily of injuries (210 cases per 10,000 full-time workers) and repetitive trauma (56.8 cases per 10,000 full-time workers).

Transportation equipment

This group includes workers engaged in manufacturing motor vehicles, aircraft, guided missiles and space vehicles, ships, boats, railroad equipment, motorcycles, bicycles, and snowmobiles. It does not include mobile home fabrication (see lumber and wood products above), or most off-highway farm, construction, or mining equipment (see Industrial machinery production, above). In 1999, 1,891,800 full-time workers were employed in the US in this group.¹

Transportation equipment manufacturing has the highest rate of injury and illness in the manufacturing sector. With 1370 cases per 10,000 full-time workers in 1999, it surpassed all other industrial groups in the US according to BLS statistics. This group's injury rate of 1050 cases per 10,000 full-time workers is also consistently higher than the manufacturing sector average of 800 cases per 10,000 full-time workers for 1999. The very high rate of illness in this group is of considerable public health concern. The illness rate of 326.6 cases per 10,000 full-time workers (343.3 in 1998) is considerably higher than any other group in the manufacturing division. The rate is contributed to primarily by the motor vehicles and car bodies subgroup with 789.7 cases per 10,000 full-time workers (818.2 in 1998). This group has a high rate of repetitive trauma disorders at 685.5 cases per 10,000 full-time workers, and also the highest rates of dermatitis (34.7 cases per 10,000 full-time workers), high respiratory

disease due to toxic agents (12.4 cases per 10,000 full-time workers), poisonings and disorders due to physical agents, particularly noise. The rate of carpal tunnel syndrome and tendonitis is 15.9 per 10,000 full-time workers per year.

In addition to the hazards and associated health effects described above for fabricated metal workers utilizing cutting fluids, occupational asthma and hypersensitivity pneumonitis (HP) has been associated with cutting fluid use in this industry.³³⁻³⁵ Although chemical constituents in fluids and their associated biocides and preservatives have been suggested as a cause for the immunologically mediated lung disease HP, a 1996 NIOSH workshop on the subject considered microbiological contaminants, including several disinfectant-resistant *Mycobacterium* species to be a more likely cause.³⁶ Endotoxin is often found in association with Gram-negative bacterial growth in these fluids, particularly when the reservoirs are not well maintained. This exposure may contribute to both HP and asthma in this group. In the case of HP, endotoxin is a proposed adjuvant to the antigenic response.³⁷ Elevated cancer rates for stomach, pancreas, lung, and bladder have all been associated with machining fluid use in this industry.^{38,39}

Food and associated products

The food and kindred products industrial group consists of food and beverage processing plants, including manufactured ice, chewing gum, vegetable and animal fats and oils, and prepared animal feeds. In 1999, 1,686,200 workers were employed in these industries in the US.¹ The injury and illness rate was 1270 total cases per 10,000 full-time workers per year. Eighty-two percent of these injuries were related to sprains and strains, often due to slips on wet surfaces (40%).¹ This mechanism of injury was highest in the dairy industry subgroup at 228.2 total cases per 10,000 full-time workers. Meat packers had the highest injury and illness rates of any subgroup with 2670 total cases per 10,000 full-time workers per year. In addition to sprains and strains, this group has the highest rates of lacerations and punctures, with 56.3 cases per 10,000 full-time workers per year.

As one might expect from the frequent repetitive motions performed by food preparation workers, illness from repetitive trauma is very common, with an overall rate of 189.5 cases per 10,000 full-time workers in 1999. With a rate of repetitive trauma disorder of 912.5 cases per 10,000 full-time workers, meat packers remain a group at risk for increased morbidity, with more than four times that of the next highest subgroup of workers, in cookies and cracker products (213.7 cases per 10,000 full-time workers). Tendonitis accounted for 15.0 cases per 10,000 full-time meat packers, and carpal tunnel 12.0 cases per 10,000 full-time workers in that year, with back pain the next highest category.

Dermatitis is another significant source of illness in this industrial group, with 17.4 cases per 10,000 full-time workers per year. Meat packers have the highest rates at 85.6 cases per 10,000 full-time workers, more than twice that of

chewing gum processing, the next highest subgroup. Respiratory conditions are also a problem with this group, particularly for cheese processing workers, with 29.5 cases per 10,000 full-time workers.

Rubber and plastics

This manufacturing group includes the production of products from plastics, resins, and from natural or reclaimed rubber. It includes tire manufacture, but not recapping. Some products made from these materials are included in other major groups, such as boats, toys, buckles, and buttons. Establishments primarily engaged in manufacturing synthetic rubber are classified within the group Chemicals and Allied Products. The US employed an estimated 1,008,600 workers in the rubber and plastics industries in 1999, with over 73% in plastics, 8% in tires and inner tubes, and the remainder in hose gasket and seal production.¹ The group's overall injury and illness rate was 1010 total cases per 10,000 full-time workers. Over 92% of this total is due to injuries, primarily sprains and strains (43%), lacerations and punctures (10%), and bruises (9%). Occupational illness rates for this group in 1999 were 84.2 cases per 10,000 full-time workers, with 70% of the illness attributable to repetitive trauma, 12% to dermatitis, and 5% due to respiratory conditions caused by toxic agents. The dermatitis is due to both irritant and allergic mechanisms. Many skin sensitizers exist in the industry, including latex, isocyanates, thirams, amines, and mercaptobenzothiol. In addition to allergic contact dermatitis, many of these agents have also been implicated in asthma and reactive airways dysfunction syndrome (RADS), particularly in workers exposed to curing fumes and epoxies.⁴⁰

Several carcinogenic hazards exist in the industry. These include benzene, 1,3-butadiene, and other polyaromatic hydrocarbons, nitros and aromatic amines, and asbestos. Elevations in standard mortality ratios have been described in several large studies of the industry and are reviewed by Roth.⁴¹ The most consistent findings are for leukemia, bladder, stomach, throat, lung, and pleura (mesothelioma). Several of these studies are limited due to the absence of control for the confounding effects of smoking, though the relationship to mesothelioma is not affected by this confounding exposure. The relationship between benzene and butadiene with leukemia is strong, with a consistent dose-response relationship shown.⁴² Benzene was the first chemical classified as a definite carcinogen by IARC (1A), and 1,3-butadiene is classified as a probable human carcinogen (2A).^{43,44}

Leather industries

These manufacturing industries are composed primarily of workers who are engaged in tanning, curing, and finishing hides, skins, leather converters, and artificial leather products, and other related products. The US employed 76,900 workers in this industry in 1999. The total injury and illness rate for that year was 1030 cases

per 10,000 full-time workers. Injuries accounted for 73% of these cases in 1999.

Most notable is the leather industry illness rate, which is the second highest in the manufacturing division, with 277.4 cases per 10,000 full-time workers per year, which has been stable for several years.¹ Repetitive trauma disorders are common in this industry, with 228.9 cases per 10,000 full-time workers per year. The industry has the highest rates of dermatitis found in the manufacturing division, with a rate of 29.1 cases per 10,000 full-time workers in 1999. Tanning is particularly hazardous in this regard, with 75.3 cases of dermatitis per 10,000 full-time workers. The likely sources of these dermatologic findings are trivalent chromium, potassium dichromate, glutaraldehyde, and formaldehyde. These agents are toxic by both allergic and irritant mechanisms.^{45,46} Many of these agents are also implicated in asthma, as demonstrated in a recent community-based survey in Spain among workers in the leather industry.⁴⁷ Another recent study from Spain utilizing a case-control design found an increase in oral cleft defects in children of mothers who worked in the leather industry (OR 6.18, 95% CI 1.48–25.69).⁴⁸ Other relationships to congenital malformations were also suggested by the data, but did not reach statistical significance.

SUMMARY

Manufacturing is the largest and most diverse sector of the goods producing economy of most developed countries. It employs over 18 million workers in the US, and accounts for the largest burden of illness and injury of any sector in the US economy, both in absolute terms as well as incidence. These incidence rates have steadily declined from 1994 to 1999, from an average of 1220 cases per 10,000 full-time workers to 920 cases per 10,000 full-time workers per year, but a significant opportunity for disease and injury prevention remains. An important decade-long trend which deserves scrutiny is the increasing rate of days with work restrictions, as opposed to lost work days, which have been in decline. Follow-back evaluations of specific manufacturing industries could provide valuable insights for illness and injury preventive strategies within these industries.

In the year 2000, manufacturing accounted for 11.3% of all worker fatalities, with nearly 20% of these related to logging. Although likely an underestimate, this sector accounts for over 60% of all occupational injury and illness among private industry in the US, with 8800 cases per 10,000 full-time workers per year. Injury, particularly sprains and strains, is the cause of most of this morbidity, but at least 10% is due to preventable occupational disease. The production of transportation equipment, processed foods, and leather goods are associated with the highest illness rates, more than twice that of other manufacturing subgroups. On average, repetitive trauma disorders account for approximately 80% of illnesses, with occupational dermatitis and lung disease the next most commonly diagnosed conditions. Repetitive motions, vibration, cutting fluids, metals, and dusts are common hazards in these

sectors. Control of these exposures offers an excellent opportunity for preventive intervention.

Chapter 17

Occupational Medicine in the Healthcare Industry

Mark B Russi, Marilyn V Howarth

The healthcare industry employs over 10 million workers in the US and encompasses an unusually broad spectrum of occupations and exposures. Job categories include physicians, non-MD clinicians, dentists, pharmacists, a range of clinical technicians, nurses, nurses' aides, house-keeping and maintenance personnel, engineers, security personnel, laboratory technicians, office and administrative personnel, and food service workers (Table 17.1). Work settings include hospitals, long-term care facilities, free-standing clinics, laboratories, and home care settings. Depending upon the specific work environment, health-care industry personnel are at risk for exposure to hazardous biologic, chemical and physical agents, as well as to repetitive strain, violence, and fatigue.

Biologic exposures include blood-borne pathogens, principally HIV, hepatitis B and hepatitis C; and air-borne pathogens such as tuberculosis and a wide variety of respiratory viruses. Many medical centers also contain animal laboratories which may expose personnel to animal allergens and zoonotic illnesses. Chemical exposures include antineoplastic drugs, anesthetic agents, sterilants and disinfectants, latex, and a variety of laboratory reagents and cleaning chemicals. Physical agents include radiation from external beams or radionuclides, lasers, and the substantial physical stresses entailed in patient care. This chapter considers the principal occupational exposures of

healthcare workers, addressing health effects, methods of exposure reduction, and applicable laws and guidelines.

BIOLOGIC HAZARDS

Blood-borne pathogens

A broad range of blood-borne infections can be transmitted to healthcare workers via needlesticks, splashes onto mucous membranes of the mouth, eyes, and nose or exposures to abraded skin. While an exact tally of such exposures is not at hand – due in part to the practical challenges of active surveillance – it has been estimated that well over 500,000 needlesticks occur annually in the US, of which at least 5000 involve HIV-contaminated blood.¹ Despite the hazard of percutaneous and mucocutaneous blood or body fluid exposures, a number of studies document substantial under-reporting of blood and body fluid contacts among healthcare workers, particularly in the operating room setting, where it is estimated that in as many as 15% of all procedures at least one person at the surgical table sustains a needlestick, and where blood contact may occur in as many as 50% of all surgical procedures.^{2,3} A study comparing incident reports of blood exposures with the actual frequency of such exposures observed at the operating table demonstrated that only approximately 2–11% were reported.⁴ Studies of percutaneous exposures with hollow-bore needles have also demonstrated significant differences between the frequency of needlesticks reported and that estimated through retrospective questionnaires. Since early prophylactic therapy is now indicated for exposures to HIV-infected blood or body fluids, under-reporting may place healthcare workers at unnecessary risk of infection.

Exposure prevention

A number of guidelines and regulations have been designed to reduce blood-borne exposures among health-care workers. Universal Precautions, developed by the Centers for Disease Control (CDC) in 1987, were incorporated into the OSHA Blood-borne Pathogen Standard of 1991, along with a requirement for annual training, exposure reduction plans, engineering controls, and provision of hepatitis B vaccine to potentially exposed healthcare workers. In 1995, Standard Precautions were introduced, combining Universal Precautions with body substance isolation, to establish a single set of procedures for patient

Clinical	Physicians Dentists Physician assistants Podiatrists Physical and occupational therapists

Clinical support	Pharmacists Laboratory technicians Diagnostic imaging technicians Operating room technicians
Facility support	Police/security personnel Engineering personnel Building maintenance staff Housekeeping staff
Office based	Food services staff Administrators Clerical support personnel

Table 17.1 Categories of healthcare workers

care and handling of blood and potentially infectious body fluids. Standard Precautions include use of barrier protections, such as gloves, gowns, and facial protection, where exposures to blood or body fluids may occur. They also include basic elements of infection control, such as hand-washing and proper sharps disposal. Fundamental to the concept of Standard Precautions is the assumption that all blood and body fluids, except sweat, are potentially infectious, regardless of the infectious status of the patient.

Substantial evidence has accumulated that needlestick injuries can be reduced through educational programs and replacement of standard instruments with safer devices. Significant reductions in injury rates have been demonstrated for phlebotomy devices with engineered safety features and for needleless intravenous delivery systems.⁵⁻⁸ Reductions in the rates of percutaneous injury among operating room staff following implementation of blunt needles for certain procedures have also been documented.^{2,9} Several studies show the value of educational programs addressing needle safety.¹¹⁻¹⁶ Based on the potential for safer devices to reduce blood-borne pathogen exposures among healthcare workers, the OSHA Blood-borne Pathogens Standard was amended in 2001 to require that employers document consideration and implementation of appropriate commercially available and effective safer medical devices designed to eliminate or minimize occupational exposure. Employers are also required to maintain a sharps injury log containing information regarding the type and brand of device involved in an exposure incident, and an explanation of how and where the incident occurred.¹⁷

Although a broad range of infections can be transmitted percutaneously or mucocutaneously, the blood-borne pathogens of greatest significance for healthcare workers are human immunodeficiency virus (HIV), hepatitis B virus (HBV) and hepatitis C virus (HCV).

HIV

In the US approximately 5% of individuals with AIDS for whom occupational information is known have been employed in healthcare. A very small number (<0.3%) of those healthcare workers were documented to have become HIV positive following occupational exposure, of whom most are nurses and laboratory workers. Among healthcare workers infected on the job, the majority suffered percutaneous exposure, and a few became infected following mucocutaneous exposure. Nearly all transmissions have been due to exposures to HIV-infected blood.

A 0.3% risk of HIV infection following needlestick exposures is commonly quoted. Characteristics which may be associated with higher risk of seroconversion include deep injury, visible contamination of the device with blood, needle placement directly into an artery or vein, or exposure to an individual with elevated viral titers.¹⁸ Risk of seroconversion following mucous membrane exposure has been estimated at 0.09%.¹ The risk of seroconversion following isolated skin exposure has not been quantified, but is likely to be of extremely low magnitude.

When percutaneous or mucocutaneous exposures to HIV-contaminated blood or body fluids occur, current US

Public Health Service recommendations call for prophylactic treatment of exposed individuals with antiretroviral medications.¹⁹ Several lines of evidence support use of prophylaxis. A case-control study has assessed risk factors for seroconversion in healthcare workers (HCWs) who became HIV positive following blood-borne occupational exposure to HIV.^{18,20} Compared to a control group who did not seroconvert, cases were significantly less likely to have used antiretroviral prophylactic medication (zidovudine) when adjusted for other HIV transmission risk factors. A study of HIV-positive pregnant women demonstrated that administration of zidovudine during pregnancy markedly lowered transmission of HIV to the fetus. Viral load testing revealed that a relatively small proportion of the difference could be attributed to reduction in maternal viral load, suggesting that zidovudine may have acted prophylactically in the fetus.²¹⁻²³ Subsequent studies utilizing alternate dosing regimens or other antiretrovirals have yielded similar results. Animal studies have shown mixed results, but demonstrate decreased drug efficacy if treatment is not begun until 48 or 72 hours following exposure, or if animals are treated for only 3 or 10 days.²⁴⁻²⁶

Despite convincing evidence that prophylaxis can prevent HIV infection, it clearly is not always effective. Several seroconversions have occurred despite prophylaxis with one or more antiretroviral medications, likely due to viral resistance, late initiation of therapy, inadequate length of therapy, or an overwhelming inoculum of virus. Clinicians prescribing combination antiretroviral therapy to exposed HCWs should consider probable patterns of viral resistance based on knowledge of source patient medication history. Drug toxicities also should be monitored closely in HCWs receiving prophylaxis. A broad range of side effects have been reported, including an individual who suffered fulminant hepatic failure following prophylactic treatment with a nevirapine-containing regimen.²⁷⁻²⁹

For HCWs exposed to HIV-infected blood or body fluids, mechanisms should be put into place to begin prophylaxis as soon as possible following exposure, to ascertain source patient infectious status, and to monitor side effects and serological results in the exposed. Mechanisms should also be put into place to provide prophylactic medications to HCWs working in HIV-endemic areas of the world where such medications may not be readily available.³⁰

Hepatitis B

The incidence of hepatitis B infection among HCWs in the US has declined dramatically since the 1980s to a rate below the current US population incidence. Although new infections among healthcare workers have fallen sharply in recent years due to widespread implementation of Standard Precautions and hepatitis B vaccine, prevalence figures among surgeons of 13–18% attest to the high risk of hepatitis B transmission in the past.³¹ Not surprisingly, hepatitis B prevalence rates are higher among physicians with frequent blood contact than among those who rarely performed invasive procedures.

Risk of HBV infection following exposure is dependent upon exposure characteristics, body fluid to which the

HCW is exposed, and whether or not the source patient has e-antigenemia. Percutaneous exposure to HBV-infected blood is associated with a risk of 1–6% if the source patient is e-antigen negative, but 22–31% if the source patient is e-antigen positive.¹⁹ The difference in risk results from higher rates of viral replication among e-antigen positive individuals. Viral titers may vary considerably, and may be as high as 1 billion virions per mL of blood or serous fluid. Titers are generally several orders of magnitude lower in saliva, semen, and vaginal secretions. In contrast to HIV and HCV, HBV is resistant to drying, ambient temperatures, simple detergents, and alcohol, and may survive on environmental surfaces for up to one week.³² Hence, contaminated sharp objects may pose a threat to HCWs for several days following last contact with a source patient.

The incubation period of the virus ranges from 7 to 23 weeks, and less than half of individuals who become infected with hepatitis B manifest acute symptoms. Acute illness generally consists of several weeks of malaise, jaundice, and anorexia, but fulminant hepatitis may develop in approximately 1% of patients. Chronic infection develops in approximately 5% of patients and is generally accompanied by persistent hepatitis B surface antigenemia. In individuals whose infections do not become chronic, hepatitis B surface antibody develops as surface antigen levels fall. IgM antibodies to hepatitis B core antigen indicate current infection, while IgG core antibodies are a marker of past infection. The core antigen itself is not found in blood, but e-antigen, which is separated from core antigen during intracellular processing, is a marker of core antigen production and viral replication. It has been estimated that cirrhosis develops in approximately 20–35% of individuals with chronic hepatitis B, 20% of whom will develop hepatocellular carcinoma.³³

Administration of hepatitis B vaccine, which contains recombinantly produced surface antigen, generates immunity in greater than 90% of individuals who receive three vaccine doses. Immunity lasts for at least 12 years following immunization, even if surface antibody titers fall or become undetectable, and there is currently no recommendation for periodic booster doses. Individuals who do not produce surface antibody following vaccination should have the three-vaccine series repeated. Those who do not mount a surface antibody response to the vaccine following repetition of the series should be counseled regarding their susceptibility to hepatitis B and should receive hepatitis B immune globulin and possibly additional vaccine if exposed percutaneously or mucocutaneously to hepatitis B-contaminated blood or body fluids. Hepatitis B immune globulin, which should be administered as soon as possible but which may be effective when administered as late as 7 days following exposure, is approximately 75% effective in preventing HBV infection in those without vaccine-induced protection.³⁴

The single most effective step to prevent hepatitis B infection among healthcare workers is vaccination. Despite an OSHA requirement that employers provide vaccine free of charge to healthcare workers, a surprising number of workers remain at risk. A survey of more than

100 hospitals revealed that approximately two-thirds of employees had completed the vaccine series.³⁵

Hepatitis C

An estimated 1.8% of the general US population is infected with hepatitis C virus.³⁶ Primary risk factors for the disease in the general population are intravenous drug abuse and receipt of contaminated blood transfusions. Among healthcare workers, several surveys show hepatitis C prevalence to be approximately equivalent to that of the general population. Needlestick exposures are independently associated with increased risk.

Following percutaneous exposure to infected blood, risk of hepatitis C seroconversion among exposed healthcare workers ranges from 0% to 10%, with an average risk of 1.8%.^{37,38} Infection following mucocutaneous exposure appears to be less common, though several case reports document its occurrence. HCV viral titers are low compared to HBV, and virus is generally not detected in urine, feces, or vaginal fluids.

Incubation period for hepatitis C varies from 2 to 24 weeks, and averages 6–7 weeks.³² Antibodies to HCV may be detected within 5–6 weeks of infection, and may persist regardless of whether virus is actively replicating. The vast majority of those who become infected with hepatitis C have no acute symptoms, and chronic hepatitis develops in approximately 85%.

There is no known neutralizing antibody to HCV, and no vaccine is available. Administration of immune globulin has not been shown to be effective and is not recommended following exposure. Several studies have demonstrated the efficacy of interferon alfa-2b as an effective treatment of chronic hepatitis C, and treatment early in the course of chronic disease may be associated with higher cure rates.^{39–41} To date, treatment efficacy has been demonstrated in individuals with liver enzyme elevations, but it is not known whether there is an advantage to treating prior to any liver enzyme elevation, or whether treating acute illness begets a more favorable prognosis than treating early chronic disease.³² One report has demonstrated high cure rates when interferon alfa-2b was begun during acute disease at an average of 90 days following infection.⁴²

Healthcare workers exposed percutaneously or mucocutaneously to hepatitis C-infected blood or body fluids should have hepatitis C antibody checked at baseline, and at 6, 12, and 24 weeks. Individuals who seroconvert should undergo PCR testing to detect viral replication, and should be referred to a liver specialist for consideration of early treatment with interferon and ribavirin.

Infected healthcare workers

Since the onset of the AIDS epidemic there have been two reported instances in which healthcare workers transmitted HIV to patients. The first was a case in which a dentist transmitted HIV to six patients in his practice.^{43–47} More recently, a French orthopedic surgeon transmitted HIV to a patient on whom he performed a 10-hour surgical procedure.⁴⁸ Of 982 other patients who underwent procedures

with the same surgeon, serological testing revealed no other transmissions.⁴⁹ Numerous serological surveys of patients treated by other HIV-positive healthcare workers, including dentists, surgeons, obstetricians, and other physicians, have revealed no other transmissions of HIV from healthcare workers to patients. Infection with hepatitis B following procedures by hepatitis B-infected healthcare workers is more common.^{50,51} Transmissions have taken place during dental procedures prior to widespread use of examining gloves, and during vaginal hysterectomies, major pelvic surgeries, and cardiac surgeries, and nearly all transmissions were linked to hepatitis B e-antigen-positive healthcare providers. Clusters in which hepatitis C was transmitted from healthcare providers to patients have been recently reported.^{52,53} The CDC has estimated that the risk for transmission of HIV or hepatitis B lies between 1/42,000 and 1/420,000.⁵⁴

On July 12 1991, the CDC issued guidelines addressing HIV and hepatitis B infection of healthcare workers, particularly among those who performed certain 'exposure-prone' procedures.⁵⁵ The guidelines stated that infected healthcare workers who adhere to universal precautions and who do not perform invasive procedures pose no risk for transmitting HIV or hepatitis B to patients, but that those who perform certain exposure prone procedures pose a small risk for transmitting hepatitis B or HIV. Exposure-prone procedures were characterized as those in which a needle tip was digitally palpated in a body cavity, or those in which a healthcare worker's fingers and a needle or other sharp instrument or object are simultaneously present in a poorly visualized or highly confined anatomic site.

The guidelines stated further that healthcare workers performing exposure-prone procedures should know their HIV antibody status, and if non-immune to hepatitis B, their hepatitis B surface antigen and hepatitis B e-antigen status. Healthcare workers infected with HIV or hepatitis B (and e-antigen positive) were further instructed not to perform exposure-prone procedures unless they had sought counsel from an expert review panel and been advised under what circumstances, if any, they might continue to perform these procedures. Such circumstances would include notifying prospective patients of the healthcare worker's seropositivity before they underwent exposure-prone invasive procedures. Mandatory testing of healthcare workers for HIV antibody, hepatitis B surface antigen or hepatitis B e-antigen was not recommended.

Several court decisions have rejected healthcare workers' discrimination claims regarding forced alterations of medical practice.⁵⁶ In contrast, a number of professional organizations including the Society for Healthcare Epidemiology of America have affirmed the ability of most physicians to continue to perform invasive procedures. This society also stated that patients should not be informed of a surgeon's serological status unless a clear exposure had taken place.⁵⁷ The American College of Physicians and the Infectious Disease Society of America generally reflected the CDC guidelines, but stressed the need for case-by-case evaluations of practice restrictions and the ethical obligations of individual physicians.⁵⁸ The

American College of Occupational and Environmental Medicine similarly reflected the guidelines, but stated that based on accumulated evidence, no invasive procedure had distinguished itself as 'exposure prone' with respect to transmission of HIV, and that HIV-positive healthcare workers performing invasive procedures with proper precautions, including double gloving, should not be otherwise restricted.⁵⁹

The American College of Surgeons distinguished between HIV and hepatitis B, stating that HIV-infected surgeons should be allowed to continue to practice and perform invasive procedures unless there were clear evidence that a significant risk of transmission existed, but that surgeons who were hepatitis B e-antigen positive should seek counsel from an unbiased expert review panel.^{60,61} In contrast, the American Academy of Orthopedic Surgeons stated that HIV-infected orthopedic surgeons should not perform invasive surgical procedures where there is substantial risk that the patient will come into contact with the surgeon's blood. The American Hospital Association stated that if an expert panel has already made a determination that a healthcare worker poses no reasonable risk to a patient, disclosure of the healthcare worker's infection status unnecessarily invades the healthcare worker's privacy. They stated further that providing patients with the HIV status of their caregivers is unacceptable.⁶²

Decisions regarding a healthcare worker's continued ability to perform invasive procedures should take into account the surgeon's adherence to appropriate precautions and nature of the specific invasive procedures performed. The higher frequency of transmission from hepatitis B e-antigen-positive surgeons, compared with the very low chance of transmission from HIV-positive or hepatitis C-positive surgeons should also be considered. While the accumulated evidence provides very little support for restricting surgical privileges among HIV-positive or hepatitis C-positive surgeons, greater hazard may exist among hepatitis B-infected surgeons with e-antigenemia. Suppression of hepatitis B viral replication with antiviral medications may influence transmission potential, and could play a role in future decision making for such cases.

Tuberculosis

Following an alarming rise in US incidence of tuberculosis (TB) through the 1980s and early 1990s, the incidence of TB in the United States has fallen in recent years. In 2000, 5.8 cases of TB were reported per 100,000 US population compared with 12.25 in 1980.^{63,64} Risk to healthcare workers increased substantially in the 1980s due to the emergence of multidrug-resistant TB and the need to hospitalize patients not responding to traditional outpatient antibiotic regimens. More recently, multidrug-resistant TB has also fallen, with approximately 1% of isolates collected during 2000 resistant to at least isoniazid and rifampin. Despite a currently decreasing population incidence, healthcare workers remain at risk without careful adherence to engineering and administrative controls.

The CDC has issued guidelines recommending that healthcare facilities at high risk for TB transmission develop and implement programs to prevent occupational exposure to TB.⁶⁵ The guidelines address early identification of potentially infectious patients, engineering controls to minimize spread of TB bacilli within a medical center, use of personal protective equipment, and medical surveillance among healthcare workers.

Strategies to identify potentially infectious patients before they expose healthcare workers in large numbers are integral to a successful tuberculosis prevention program. Tuberculosis is more prevalent among those infected with HIV, the homeless, prison inmates, persons from countries with high rates of TB, residents of long-term care facilities, and intravenous drug users. Use of epidemiologic indicators in addition to signs and symptoms of disease enhance early identification of potentially infectious patients. Once such patients are identified and isolated, the effectiveness of engineering controls is enhanced by keeping doors and windows closed, ensuring that room pressure is set properly, and performing regularly scheduled testing such as smoke-trail visualization.⁶⁶

Laboratory healthcare workers may also be exposed when clinical specimens are manipulated in a manner that generates respirable aerosols. Engineering controls in mycobacteriology laboratories include the use of class I or II biologic safety cabinets. Routine maintenance and effectiveness testing are essential and have been well described.⁶⁷

For the potentially infectious patient placed in negative pressure isolation, work practice controls include respiratory isolation signage, appropriate personal protective equipment, and restriction of diagnostic and therapeutic procedures to negative pressure isolation settings. Appropriate personal protective equipment, such as an N95 respirator, should be used by all individuals entering the isolation room of a patient with known or suspected TB, and while performing procedures with risk of aerosol production. OSHA requires that employers institute a respiratory protection program whenever respirators are in use. NIOSH has published guidelines to assist healthcare facilities implement respiratory protection programs for TB.⁶⁸ Appendices of the document include names and addresses of respirator manufacturers, respirator fit testing procedures, and checklists useful for program evaluation.

Medical surveillance of healthcare workers with tuberculin skin testing and symptom questionnaires may lead to the early detection of exposure and infection. Healthcare workers with negative tuberculin tests should be tested at time of hire. Those in whom testing has not been carried out within the preceding year should receive a two-step test to ensure adequate test sensitivity, as the tuberculin reaction may wane among infrequently tested individuals. Recommended frequency of ongoing testing is based on a risk assessment which considers community TB prevalence and frequency of inpatient TB admissions. Individuals with documented positive tuberculin tests should not be retested, and require only regular monitor-

ing of symptoms suggestive of active TB. Several investigators have shown that skin test conversion rates may be more substantially influenced by community tuberculosis prevalence and workforce demographic factors than by frequency of clinical exposure. Others have demonstrated elevated skin test conversion rates among highly exposed healthcare workers, such as emergency medicine residents and respiratory therapists.^{69,70} High rates of skin test conversion, as well as early progression to active disease, have also been demonstrated in hospital outbreak settings.

The Occupational Safety and Health Administration has made the decision not to proceed with a standard for TB, despite publishing a proposed standard in 1997.⁷¹ OSHA has used the CDC guidelines in issuing compliance directives and has cited hospitals based on such directives.

Infection control and immunizations

An effective infection control program is essential to minimize infectious disease spread within a medical center setting. Patients are at risk from infectious healthcare workers just as healthcare workers may be at risk for transmission from patients. Prompt assessments of patients and healthcare workers for signs or symptoms of infectious disease are necessary to ensure proper disease containment or use of personal protective equipment. Medical center facility design has also been shown to directly affect spread of infection. Primary design and renovation of medical centers should include consideration of modern techniques of engineering control (i.e., ventilation, selection of finishes for surfaces, flooring, privacy curtains, disposable versus re-usable medical equipment).^{66,72}

The Advisory Committee on Immunization Practice strongly recommends the following vaccines for healthcare workers who have not already received them or who can not document natural immunity: hepatitis B, influenza, measles, mumps, rubella, varicella, and tetanus.⁷³ Other pathogens commonly found in the hospital setting for which no vaccines are currently available include enteric pathogens, *Staphylococcus aureus*, CMV, cryptosporidium, scabies, and herpes simplex. Hepatitis A is a vaccine-preventable illnesses to which exposure may occur in medical centers, though hepatitis A vaccine is not currently recommended for healthcare workers.

Infection by varicella, CMV, and rubella can present teratogenic risk for pregnant medical center employees. Immunization for varicella and rubella prior to pregnancy reduces this risk. Though it was previously recommended that women refrain from becoming pregnant for 3 months after receiving live vaccines (i.e. rubeola, mumps, and rubella), recent recommendations have shortened the waiting period for rubella to 28 days.

Occupational health clinicians play an important role in the restriction of healthcare workers exposed to or infected with infectious diseases. State and local regulations may also restrict healthcare workers with infectious diseases. Table 17.2 lists work restrictions for healthcare workers with infectious diseases.⁷⁴

Diseases requiring no patient contact	Work restriction
Infectious conjunctivitis Acute diarrhea with symptoms* (i.e. fever, cramps, bloody stools) Group A streptococcal disease Hepatitis A* Herpes simplex infection on the hands Active measles infection Post-exposure to measles Active mumps Post-exposure to mumps Active pertussis Active rubella Post-exposure to rubella Scabies <i>Staphylococcus aureus</i> infection of skin Group A streptococcal infection* Active tuberculosis Active varicella (chicken pox) Post-exposure to varicella (chicken pox or shingles)	Until the discharge ceases Until symptoms resolve and infection with salmonella is ruled out, or if caused by salmonella (non-typhoidal), until stool is free of salmonella on 2 consecutive cultures not less than 24 hours apart Until 24 hours after adequate treatment begun Until 7 days after onset of jaundice Until lesions heal Until 7 days after the rash appears Susceptible personnel should remain out of the workplace from days 5–21 after exposure, and/or 7 days after rash appears Until 9 days after onset of parotitis Susceptible personnel should remain out of the workplace from days 12–26 after exposure, and/or 9 days after onset of parotitis From beginning of catarrhal stage through the 3rd week after onset of paroxysms or until 7 days after start of effective therapy Until 5 days after rash appears Susceptible personnel should remain out of the workplace from days 7–21 after exposure and/or 5 days after rash appears Until treated Until lesions have resolved Until 24 hours after starting adequate therapy Until proven non-infectious Until all lesions dry and crust Susceptible personnel should remain out of the workplace for days 10–21 after exposure and/or until all lesions dry and crust
Diseases requiring partial work restrictions	Work restriction
Acute febrile viral respiratory infection Diarrhea caused by enteroviral Infection Hepatitis B – e-antigen positive Orofacial herpes simplex Human immunodeficiency virus <i>Staphylococcus aureus</i> respiratory infections Active varicella zoster	During community outbreaks of influenza and respiratory syncytial virus consider excluding symptomatic personnel from caring for high-risk patients Personnel should not take care of infants and newborns until symptoms resolve Personnel should be excluded from invasive procedures until recommendations from an expert review panel are made based on the specific job tasks and their risk for exposing patients Personnel should not take care of high-risk patients until lesions heal Personnel should be excluded from invasive procedures until recommendations from an expert review panel are made based on the specific job tasks and their risk for exposing patients Personnel should not take care of high-risk patients until acute symptoms resolve Personnel should keep lesions covered and should not take care of high-risk patients until lesions dry and crust
Diseases not requiring work restriction	
Cytomegalovirus infection Mild diarrhea lasting less than 24 hours without other symptoms Hepatitis B – acute or chronic antigenemia: personnel who do not perform exposure-prone procedures should follow standard precautions Hepatitis C Genital herpes simplex Post-exposure pertussis (asymptomatic personnel)	

* Food handlers should also remain out of work with these infections

Table based on: Bolyard EA, Tablan OC, Williams WM, Pearson ML, Shapiro CN, Deitchman SD and the Hospital Infection Control Practices Advisory Committee. Guideline for infection control in healthcare personnel, 1998. Am J Infect Control 1998;26:289–354, with permission from the American Academy of Dermatology.

Table 17.2 Work restrictions for healthcare workers with infectious diseases

CHEMICAL HAZARDS

Anesthetic gases

Healthcare personnel working in operating rooms, labor and delivery areas, postanesthesia recovery units, and certain ambulatory settings are at risk for exposure to anesthetic gases. Exposure may occur to nitrous oxide alone, or nitrous oxide in combination with halogenated agents such as fluoroxene, methoxyflurane, enflurane, halothane, isoflurane, desflurane, or sevoflurane. Scavenging devices are capable of reducing exposures to below 25 ppm for nitrous oxide and below 0.5 ppm for halogenated agents, but may allow levels well in excess of this if functioning

improperly. Nitrous oxide levels as high as 300 ppm in hospital operating rooms and 1000 ppm in dental operating rooms using scavenging equipment have been documented.⁷⁵ Personnel working in postanesthesia care units may also be highly exposed to anesthetic gases due to exhalation by surgical patients of absorbed agents. Specific concern has been raised regarding exposures to desflurane and sevoflurane, due to the higher concentrations at which these two anesthetic agents are typically administered.⁷⁶ During inhaled induction with a rebreathing bag or a circle circuit system, sevoflurane concentrations as high as 20 ppm have been demonstrated, with nitrous oxide concentrations of approximately 100 ppm.⁷⁷

A number of epidemiologic studies have evaluated an association between anesthetic gas exposure and adverse reproductive outcomes (see Chapter 27.2). Although methodological flaws undermine the reliability of many studies, the data suggest an elevated spontaneous abortion rate among highly exposed women. Animal studies also suggest adverse reproductive effects. It is uncertain whether current reduced levels of anesthetic gas exposure in operating rooms using adequately maintained gas scavenging systems remain a source of excess risk. A recent meta-analysis revealed an overall relative risk for spontaneous abortion of 1.48 (95% CI 1.4–1.58).⁷⁸ However, nearly all data were collected prior to widespread use of gas scavenging systems.

Infertility has also been evaluated in a study of female dental assistants. Women with five or more hours of exposure to unscavenged nitrous oxide were 41% (95% CI 23–74%, $P < 0.003$) as likely as unexposed women to conceive during each menstrual cycle, adjusted for age, race, smoking habits, and reproductive/gynecologic history.⁷⁹ Among those exposed to scavenged nitrous oxide, there was no relation between the number of hours of exposure and fertility.

Elevated rates of congenital anomalies have been reported in women occupationally exposed to anesthetic gases. One survey found rates of congenital anomalies to be 25–50% higher among exposed women compared to unexposed controls, though no specific type of abnormality was predominant.⁸⁰ Another survey suggested elevated rates of musculoskeletal anomalies among children born to exposed dental assistants, while a third demonstrated increased anomalies when all defects were analyzed jointly, including minor malformations such as birth marks and nevi.^{81,82} It is uncertain how applicable the findings of these studies are to current operating room exposures, since the questionnaire-based data were collected prior to widespread use of gas scavenging systems.

Evidence for an elevated risk of cancer among healthcare workers exposed to anesthetic gases is limited, and pertinent studies, which were carried out prior to widespread use of scavenging equipment, suffer from selection biases, lack of information regarding confounders, and near absence of dose information. A large American Dental Association survey revealed no statistically significant increases in cancer risk among exposed men or women with the exception of highly exposed female chairside assistants, who had higher rates of cervical cancer.⁸³ A large survey of US operating room personnel was suggestive of increased leukemia and lymphoma risk among female but not male study participants. A survey of cancer mortality among physicians revealed no increase among anesthesiologists.⁸⁴

Although human epidemiological data do not exist to evaluate whether current exposure levels are associated with an excess risk of cancer, mutagenic activity has been associated with trace levels of anesthetic gases. Sister chromatid exchanges and micronuclei in peripheral blood lymphocytes of operating room personnel were shown to be elevated in personnel exposed to nitrous oxide and isoflurane.^{85,86} In contrast, an earlier study among dental

personnel exposed to nitrous oxide in excess of 100 ppm did not reveal elevated rates of sister chromatid exchange.⁸⁷

There is no OSHA standard for waste anesthetic gases in general or for specific agents in use today. The NIOSH recommended exposure limit (REL) is 25 ppm time-weighted (over the time of exposure) average. The REL for halogenated anesthetics is a ceiling level of 2 ppm. The ACGIH has set TLVs for nitrous oxide, halothane, and enflurane but not for other halogenated anesthetic gases.

Reduction of exposures is best accomplished through a multidisciplinary effort including regular maintenance and inspections of anesthesia delivery equipment and scavenging systems, maintenance of room ventilation rates, provision of training to staff members, and regular (at least every 3 months) measurement of nitrous oxide levels. In most situations, control of nitrous oxide to a time-weighted average concentration of 25 ppm during anesthetic administration will result in levels of approximately 0.5 ppm of the halogenated agent.⁸⁸

Hazardous drugs

The principal hazardous drugs of concern in medical centers are antineoplastic agents. Exposure to antineoplastic drugs may occur in a wide range of occupations. Pharmacists may be exposed if drugs are mixed outside a biologic safety cabinet, if inadequate personal protective equipment is used, or if a spill occurs. Personnel who transport medications are also at risk for exposure from spills. Oncology nurses and other nursing and medical personnel who administer medications are at risk if medication vials are opened at the bedside, if trapped air is emptied from a syringe, if skin contact with drug or a patient's urine occurs, or if soiled linens from a patient administered hazardous drugs are improperly disposed. Housekeeping and maintenance personnel who clean linens and patient rooms similarly have potential for exposure to excreta containing hazardous medication or hazardous medication metabolites. A recent survey of cancer treatment centers in the United States and Canada found surface contamination with antineoplastic agents in 75% of pharmacy preparation areas and in 65% of oncology drug administration areas.⁸⁹

Human epidemiologic studies over the past 15 years have evaluated risk of spontaneous abortion, infertility, ectopic pregnancy, stillbirth, low birth weight or preterm delivery, and congenital anomalies (see Chapter 27.2). Data for many studies were gathered prior to widespread implementation of safety precautions designed to minimize exposures among pharmacy and nursing personnel.

Several studies suggest that spontaneous abortion may occur more frequently among personnel exposed to antineoplastic agents in hospital environments where adequate exposure controls are absent. Two studies which revealed relative risks for miscarriage of 2.3 (95% CI 1.20–4.39) and 1.7 (95% CI 1.0–2.8) respectively were carried out among personnel who were more likely to have had higher exposures based on job descriptions and work practices.^{90,91} A more recently published positive study,

which revealed an odds ratio of 1.5 (95% CI 1.2–1.8) associated with antineoplastic drug exposure, examined pregnancies which occurred primarily before 1986, when OSHA guidelines were issued regarding the safe handling of hazardous drugs. Spontaneous abortion and stillbirth combined was also significantly associated with antineoplastic drug exposure, but stillbirth alone was not.⁹² Studies carried out in work settings where exposures to chemotherapeutics were well controlled generally have not revealed excess rates of spontaneous abortion.^{93,94} Limited studies have suggested that exposure to chemotherapeutic agents is associated with an increase in infertility,⁹⁵ ectopic pregnancy,⁹⁶ and congenital anomalies,^{93,97} while other studies reveal no increased risk.

Several antineoplastic agents are listed as known carcinogens by the International Agency for Research on Cancer (IARC).^{98–100} Elevated risk of secondary tumors, particularly leukemias and lymphomas, in chemotherapy recipients is also well documented. Among healthcare workers with occupational exposures to antineoplastic drugs, however, there are almost no data regarding increased risk of malignancy. One study, primarily designed to assess reproductive outcomes among Danish nurses handling antineoplastic drugs, reported an elevated risk of leukemia (relative risk 10.65, 95% CI 1.29–38.5), based on only two cases.⁹⁴

A number of studies have addressed indices of mutagenic activity among healthcare personnel exposed to chemotherapeutic agents. Investigators have utilized sister chromatid exchange assays in peripheral lymphocytes, micronuclei, chromosomal aberrations, DNA single-strand breaks, urine mutagenicity, and other test methods. No clear consensus regarding dose–response, correlation with measured workplace levels, utility of the testing methods for screening programs, nor association with any increased risk of malignancy has emerged.

Adverse health effects have also been reported among healthcare workers exposed to hazardous drugs other than antineoplastic agents. Upper respiratory symptoms, bronchospasm, and pulmonary function abnormalities have been observed in personnel administering aerosolized pentamidine.^{101,102} Pulmonary function abnormalities have also been reported in healthy adult volunteers exposed to aerosolized ribavirin.^{103,104}

There is no OSHA standard specific to hazardous drugs, though OSHA has developed practice guidelines for personnel handling cytotoxic medications.¹⁰⁵ The guidelines recommend a written hazardous drug safety and health plan to address operating procedures; use of vertical flow biologic safety cabinets (Class II, type B or Class III) for preparation of drug solutions; and use of personal protective equipment including gloves, gowns, eye and face protection. They also specify practices around handling, administration and disposal of drugs, and outline guidelines pertaining to patient care and management of linen and other reusable items. Waste disposal, spill cleanup procedures, medical surveillance, hazard communication, training, and record keeping are also addressed.

Glutaraldehyde

Glutaraldehyde (1,5-pentenedial) is an effective microbicide used for cold sterilization of endoscopes and bronchoscopes. It is also used for histologic tissue fixation and in the development of radiographs. Glutaraldehyde's antimicrobial activity stems from its ability to react with amino groups and cross-link proteins on cell surfaces. Glutaraldehyde is generally used as a 2% aqueous solution. Because it works more efficiently in an alkaline environment, sodium bicarbonate is added to achieve a pH of 7.5–8.0.

Technical personnel assigned to the cleaning and disinfection of endoscopes and bronchoscopes are commonly exposed, but nurses and physicians working within endoscopy or bronchoscopy suites may also have significant contact if fumes are not adequately ventilated or scopes are not adequately rinsed. Radiology and histology technicians have potential air or skin contact. Other hospital personnel may be exposed during glutaraldehyde spills. Use of inadequately rinsed endoscopes has caused adverse effects including tongue swelling and intestinal bleeding in patients undergoing procedures.¹⁰⁶

Glutaraldehyde is a skin, eye, and respiratory tract irritant. Skin contact causes irritation, pruritis, and erythema. Eye contact may result in conjunctival swelling and erythema, and contact with high concentrations may result in corneal injury. Upper respiratory tract exposure may cause nasal irritation, throat irritation, and cough. Epistaxis has been reported rarely.^{107,108}

Healthcare workers are also at risk for developing glutaraldehyde allergic conditions. Allergic contact dermatitis has been frequently reported and does not always abate following cessation of exposure.¹⁰⁹ An association between glutaraldehyde exposure and occupational asthma is well established.^{110–112} Cases may occur at exposure levels below currently applicable guidelines. While the pathophysiology of glutaraldehyde-induced asthma is uncertain, IgE antibodies specifically directed at glutaraldehyde-modified albumin have been detected in some glutaraldehyde-exposed individuals with occupational asthma.¹¹³ Although glutaraldehyde has mutagenic properties, human studies do not implicate it as a carcinogen, teratogen, or cause of spontaneous abortion.

There is no OSHA standard applicable to glutaraldehyde. A detailed set of recommendations for the safe handling of glutaraldehyde in healthcare facilities has been developed by the Association for the Advancement of Medical Instrumentation in conjunction with the American National Standards Institute. The recommendations address engineering and work practice controls, training of staff, and personal protective equipment. Local exhaust ventilation, routed either to a filtering system or an outside duct, is generally necessary to maintain air levels below recommended limits. Eye protection, impervious gowns, and nitrile or butyl rubber gloves are recommended to prevent skin or mucous membrane contact. Due to the potential hazard of eye contact, eyewash stations should be readily accessible to any

personnel with potential for glutaraldehyde contact. Monitoring of workplace levels should take place after initiating use of glutaraldehyde; whenever a major change in protocol, work practices, or ventilation occurs; and on some regular basis based on volume of use and work practices.¹⁰⁷

Formaldehyde

Formaldehyde is usually found as an aqueous solution ('formalin') containing 30–50% formaldehyde and 5–15% methanol (see Chapter 41). Exposure occurs among workers in anatomy, pathology, and histology laboratories, where formalin is used as a tissue fixative. Individuals who use formaldehyde to sterilize dialysis equipment and other medical devices may also be exposed. Elevated breathing zone exposures have been commonly reported. One study of an anatomy laboratory reported time-weighted average exposures up to 2.94 ppm (nearly four times the current OSHA permissible exposure limit), and a second reported peak exposures approaching 5 ppm.^{114,115} Dissection tables which contain local exhaust ventilation systems are capable of reducing formaldehyde in gross anatomy laboratories to as low as 0.03–0.09 ppm.^{116,117}

Inhaled formaldehyde is primarily absorbed by the upper respiratory tract. Exposures <10 ppm may cause intense irritation of mucous membranes, with few pulmonary effects in normal subjects. High exposure levels may cause tracheobronchitis, chemical pneumonitis and pulmonary edema. Among asthmatics, bronchospasm and airway inflammation may occur at levels as low as 0.3 ppm. Allergic reactions to formaldehyde are common, and skin contact or inhalation can result in urticaria, allergic contact dermatitis, or occupational asthma.¹¹⁸

There is limited evidence of formaldehyde's carcinogenicity in humans, but sufficient evidence in experimental animals.^{119,120} The human cancer risks have been evaluated in numerous epidemiologic studies and several meta-analyses.^{121–123} Differing abnormalities were found in two broadly defined groups: professionals (e.g., embalmers, anatomists, and pathologists) and industrial workers (e.g., workers making formaldehyde resins, plywood, particleboard, and apparel). Formaldehyde-exposed professionals had excess leukemia relative risks of 1.1–3.1; brain cancer relative risks of 1.2–3.3; and colon cancer relative risks of 1.1–2.3. None of these cancers was found in excess in the industrial workers, who suffered small, but significant excesses of lung cancer.¹¹⁸

The OSHA permissible exposure limit (PEL) for formaldehyde is 0.75 ppm as an 8-hour time-weighted average. OSHA requires that a baseline medical examination be offered to workers prior to first assignment to an area where formaldehyde levels are expected to be >0.5 ppm. An annual symptom questionnaire and periodic medical examination are required by OSHA to be offered to workers exposed to formaldehyde levels >0.5 ppm as an 8-hour time-weighted average, and to those exposed to formaldehyde levels >2 ppm on a 15-minute time-weighted average.

Ethylene oxide

Ethylene oxide exists at room temperature and standard pressure as a colorless gas. Because it is used as a cold sterilizing agent for medical supplies, exposures are of concern to those involved in surgical sterilizing, as well as to those who manufacture or package medical supplies and medical devices sterilized with ethylene oxide. Contact has been described in healthcare workers exposed to ethylene oxide off-gassing from recently sterilized medical devices. Nurses and hospital central supply workers may experience episodic exposures to high levels of ethylene oxide if closed sterilization equipment malfunctions or if an accidental release occurs.^{124–126} Levels greater than 200 ppm have been described during such accidents.

The most important exposure route for ethylene oxide is inhalation, but contact with high concentrations of its vapor and splash exposures to liquid ethylene oxide can cause burns of the skin and eyes, and also initiate allergic reactions.

Bronchitis, asthma, and pulmonary edema have been associated with high level occupational exposures, and acute high level exposure can cause reactive airway dysfunction syndrome (RADS).^{118,127} However, there are few reports of severe inhalation exposure in humans. Ethylene oxide-related occupational asthma has been reported in a chronically exposed worker with IgE against ethylene oxide–albumin complexes.¹²⁸ Sensitization can occur after skin and inhalation exposure, resulting in contact dermatitis, urticaria, periorbital edema, and allergic rhinitis.

CNS effects reported after acute or subacute inhalation exposure to ethylene oxide include drowsiness, incoordination, headache, nausea and vomiting, seizures, aseptic meningitis and coma. An association has been reported between chronic workplace exposures and progressive cognitive impairment, although these reports have been challenged.^{118,129–132} Peripheral nervous system effects following high-dose exposure include delayed-onset toxic axonopathy and Wallerian degeneration. Sensorimotor disturbances of the lower limbs have been documented after subacute or chronic exposure to high and low concentrations.^{133,134}

Ethylene oxide exposure can cause a variety of genotoxic effects after acute or chronic exposure. Chromosomal aberrations, including breaks, gaps, sister chromatid exchanges (SCE), unscheduled DNA repair supernumerary chromosomes, and suppression of DNA repair capacity, have been described in exposed workers.^{135,136} Exposure of nurses to ethylene oxide has been associated with increased risks of spontaneous abortion.¹³⁷

Ethylene oxide has been judged 'carcinogenic to humans' by IARC and 'known to be a human carcinogen' by the National Toxicology Program.^{120,138} Epidemiologic studies of exposed workers have yielded inconsistent results. Most often cited is an increased incidence of hematopoietic cancers including leukemias of various types. Such cancers have been reported in some studies, but not in others.^{139–142}

The OSHA PEL for ethylene oxide is 1 ppm as an 8-hour time-weighted average and 5 ppm as a 15-minute Excursion Limit. OSHA requires that a baseline medical examination be offered to workers prior to first assignment to an area where ethylene oxide levels are expected to be >0.5 ppm as an 8-hour time-weighted average. Annual medical surveillance, including a detailed work and medical history, physical examination, complete blood count and pregnancy or fertility testing if requested, must be offered to workers exposed to levels >0.5 ppm as an 8-hour time-weighted average for 30 or more days per year.

Elemental mercury

Healthcare workers may sustain exposures to elemental mercury in several settings (see Chapter 39.9). Dentists and dental technicians may contact mercury as a component of dental amalgam. In hospitals and other clinical settings, mercury may spill from broken thermometers or manometers. Mercury has also been used to fill balloons which serve as propulsive weights for bouginage dilators, Cantor tubes, and Miller–Abbott tubes.

The most important exposure route for elemental mercury is inhalation; about 80% of an inhaled dose is retained. The amount absorbed across the skin is estimated to be about 1% of that absorbed from the lungs. Only about 0.01% of an ingested dose is absorbed from the GI tract.¹¹⁸

Dental amalgams have contained as much as 50% elemental mercury.¹⁴³ When amalgam is mixed at the patient's side immediately before use, mercury vaporizes into room air and may also adhere to hands and clothing or spill onto surfaces. Potentially harmful exposures in dental offices have been documented in the past, and elevated mercury levels in urine and tissues have confirmed exposure among dental workers.¹⁴⁴ A study of British government dental clinics in the late 1970s found urine levels >30 µg/L in 8.2% of dentists and 27.4% of dental assistants.¹⁴³ Levels >100 µg/L were found in 6.5% of assistants. A US study from the 1960s found that 30% of dentists had urine mercury levels >50 µg/L.¹⁴⁵ Current exposure levels are better controlled due to improvements in ventilation and use of prepackaged alloys.

The principal effects of elemental mercury exposure involve the nervous system, but generally do not occur at urine mercury levels less than 100 µg/g creatinine. Neurologic effects include motor disorders; intellectual dysfunction; psychologic abnormalities; and peripheral sensorimotor neuropathy.¹⁴⁶ Subclinical changes have been demonstrated with urine levels of 35–50 µg/g creatinine, but such effects are usually reversed following removal from exposure.^{147–149} Under conditions of heavy exposure, renal glomerular effects, due to mercury-induced immunologic mechanisms, may occur.¹⁵⁰ Tubular defects may lead to low-molecular-weight proteinuria.^{151,152}

The OSHA PEL for elemental mercury is a ceiling limit of 0.1 mg/m³. Adequate spill management procedures in settings where mercury is used is an important method to

minimize exposures to healthcare workers. In dental offices, proper training of personnel in preparation of amalgams and disposal of waste, use of precapsulated alloys, provision of adequate room ventilation, and avoidance of skin contact contribute to decreased workplace exposures.

PHYSICAL HAZARDS

Musculoskeletal injury

Healthcare workers have a high incidence of acute musculoskeletal injuries, especially in nursing care facilities (see Chapters 23 and 32). Higher injury rates in nursing care facilities are likely due to greater numbers of non-ambulatory patients compared to hospitals. Acute back disorders, in particular injuries of the low back, occur with high frequency during patient transfers, and are more likely when large non-ambulatory patients are moved by healthcare workers of smaller stature. Risk factors predisposing to injury include heavy patient weight, long horizontal distance between the lumbosacral spine and hands of the healthcare worker, and high frequency of lifting. A number of personal risk factors for back disorders have also been identified. They include increasing age, female gender, obesity, tobacco use, prior back injury, hypertension, systemic arthritis, job dissatisfaction, psychosocial stressors, and poor physical fitness.¹⁵³

Ergonomic interventions in medical centers should consider both task-related and personal risk factors for injury. Proper ergonomics may reduce the incidence of acute injury as well as the incidence of disorders due to continuous repeated trauma. Tasks involving patient transfers, keyboarding, and material handling are reasonable targets of intervention. Increased use of lifting assistance devices has been demonstrated to reduce injury rates substantially.¹⁵⁴ Such devices may include portable total-lift hoists, ceiling mounted hoists, walking belts, shower chairs, shower gurneys, and devices to reposition patients in bed.

Hospitals rank as the third highest industry sector for non-fatal disorders associated with repeated trauma.¹⁵⁵ Clerical and administrative personnel are commonly affected, though risk factors for repetitive trauma disorders remain a subject of debate. Improving the ergonomics of a computer workstation generally increases comfort and decreases symptoms in those complaining of hand, wrist, and other musculoskeletal symptoms. A comprehensively designed ergonomics program has been shown to be effective in reducing upper extremity work related musculoskeletal disorders in a university medical center setting.¹⁵⁶

OSHA has proposed an ergonomic standard, which was published for comment, promulgated, and later rescinded.¹⁵⁷

Noise

Excessive noise exposure may be found in a number of settings involving healthcare workers including central

sterile supply areas, operating rooms, food service areas, laundry, engineering, facilities maintenance, and print shops. For a discussion of the effects of noise and hearing loss, see Chapters 20.2 and 35.

OSHA has set 90 dB as the time-weighted average for an 8-hour work day and a maximum allowable exposure level of 115 dB for a short-term exposure. Noise levels in operating rooms have been measured at 118 dB when powered bone-cutting tools are in use,¹⁵⁸ and occupational hearing loss has been documented in operating room personnel.¹⁵⁹

Noise has deleterious effects on health and performance unrelated to hearing loss, including elevation of heart rate and blood pressure.¹⁶⁰ It may also increase psychologic stress and impair concentration. Chronic over-exposure to noise should be avoided by the use of engineering controls and personal protective equipment when necessary. All areas within a medical center that may approach the OSHA limits for noise should be monitored for noise. Where noise levels exceed the OSHA threshold, a hearing conservation program should be initiated.¹⁶¹

Heat

Excessive heat exposure may occur in several areas in a medical center. Kitchen facilities, the boiler room, and laundry area are most common. Heat overexposure can cause a variety of health effects including dermatitis, syncope, heat cramps, heat exhaustion, and heat stroke (see Chapter 34). Engineering controls such as physically insulating sources of heat and enhancing ventilation provide the best strategy in medical centers to avoid heat stress. Providing water and allowing frequent breaks to those whose jobs require working in heat-exposed areas are other helpful controls in some circumstances.¹⁶²

Lasers

Lasers (light amplification by stimulated emission of radiation) are used in hospital operating rooms, as well as in a number of outpatient settings (see Chapter 33.2). Laser types used include argon, carbon dioxide, dye, excimer, and Nd:Yag. Most lasers used in surgical procedures are considered class 4, which means that eye or skin exposure by direct beam is extremely dangerous, and that eye exposure by specular or diffuse reflection is also hazardous.

Lasers may cause harm via direct transmission of energy to eye or skin tissues, or through generation of potentially infectious or mutagenic aerosols. Damage is principally thermal, leading to vaporization of cells following rapid heating. Damage to the cornea, lens, or retina may lead in some cases to permanent visual field loss or blindness. Wavelengths less than 315 nm and greater than 1400 nm are absorbed primarily by the cornea and may cause a corneal burn. Those from 315 nm to 400 nm are absorbed by the lens and may induce cataracts with chronic exposure. Wavelengths from 400 nm to 1400 nm are transmitted to the retina where they may cause irreparable tissue burns.¹⁶³ Skin damage is a function of laser wavelength and depth of penetration. Wavelengths less than 400 nm

cause primarily photochemical injury, while those between 400 nm and 1400 nm are more likely to result in thermal burns.

Lasers can also generate a smoke plume containing potentially infectious organisms or toxic byproducts of combustion when used on human tissue. Cellular residues and viruses, including human papilloma virus, have been detected in such aerosols. Studies have also demonstrated that pyrolysis products from laser-induced tissue vaporization may have mutagenic activity, as demonstrated by sister chromatid exchange and micronuclei assays.^{164,165}

Operating suites where lasers are used are designed to prevent scatter of laser light. Such suites must also be kept well lit in order to minimize pupillary diameter. Eye protection designed to protect from the wavelengths of light produced by a specific laser type is imperative, as is skin protection. Local exhaust ventilation effectively reduces plume exposure.

The American National Standards Institute has published recommendations for safe practice around lasers, and for the medical evaluation and monitoring of personnel who routinely use Class 3b and Class 4 lasers. The recommendations call for evaluation of visual acuity and macular vision prior to job assignment, following a laser accident, and at the close of employment. Fundoscopic examination or further testing as determined by the examiner should be carried out if an abnormality is detected on the screening exam.¹⁶⁶

Radiation

Healthcare workers represent the largest group of individuals occupationally exposed to radiation, most at levels well below the permissible yearly exposure limit of 50 millisievert (5 rem) (see Chapter 33.1). The average dose among healthcare workers has been reported to be 0.7 mSv/yr, with 53% of the occupationally exposed workforce receiving less than a measurable exposure, and 88% receiving less than 1 mSv/yr (100 mrem/yr). Less than 0.5% of the total workforce received greater than 20 mSv/yr, and less than 0.05% exceeded 50 mSv/yr.¹⁶⁷ Exposure of healthcare workers to radiation is regulated by OSHA, performance of radiation machinery is regulated by the Center for Radiologic devices of the FDA, and use of certain radioactive isotopes is regulated by the United States Nuclear Regulatory Commission. Radiation exposure may occur to individuals involved with diagnostic imaging procedures, radiation oncology treatments, or administration of radioactive isotopes.

In diagnostic imaging, fluoroscopic procedures such as cardiac catheterization, vascular procedures, and certain interventional radiologic procedures have the potential for highest individual exposures. Where staff are required to stand adjacent to a patient receiving x-rays, bodily protection with aprons containing 0.5 mm of lead is required. Substantial radiation doses may also occur to the hands of technicians who repeatedly stabilize body parts, such as the cervical spine of a trauma patient, and 0.5 mm lead-

containing gloves should be used under such circumstances.¹⁶⁸ For imaging procedures which do not require staff to stand adjacent to the patient during x-ray use, most exposure to healthcare workers occurs through scatter of x-rays from the patient. A shielded barrier containing 0.5 mm lead or more provides adequate protection for staff.

Sources of exposure during radiation oncology treatment include external beams from linear accelerators, gamma knives or cobalt-60 therapy machines, and loading of radioactive sources for brachytherapy. External beam machines are housed within thick concrete walls to reduce outside scatter, and gamma knife procedures are performed in similar settings.¹⁶³ Staff who come into direct contact with radioactive sources, such as in the implantation of radioactive seeds for brachytherapy, should utilize bodily protection, such as lead-containing aprons, neck protectors, and gloves. To the extent possible, implantation of seeds should be accomplished quickly to minimize exposure to staff. Certain patients in whom seeds have been implanted may need to be hospitalized in radiation-shielded rooms to minimize exposure to others.

Patients who have undergone nuclear imaging procedures generally present minimal risk to those around them due to the low levels of radiation used in such imaging. Staff who administer radioactive isotopes must see that shielding is utilized for vials and syringes, and should don protection while handling isotopes. Certain patients who receive therapeutic doses of isotopes, such as iodine 125 or iodine 131, may require hospitalization immediately following treatment to minimize exposure to family or others.

Violence

Healthcare and social service workers have a high incidence of assault injuries.¹⁶⁹ Studies describe high incidences of verbal threat and other aggressive behaviors toward healthcare workers that may not result in physical injury. Healthcare workers may face threats from patients, patient family members, visitors or coworkers. The long-term consequences of threats or altercations that do not result in physical harm have not been well studied. Severe physical and emotional consequences of violence on the job have been documented.^{170,171}

Several factors may contribute to the incidence of violence in the medical center workplace. They include deinstitutionalization of the mentally disabled, inadequate staffing, weapons carriage into medical centers, presence of money and drugs, and ease of hospital entry.¹⁷² Several medical center areas may be robbery targets due to perceived availability of money and drugs (i.e. pharmacy, emergency departments). Trauma centers and tertiary care facilities treating high acuity and critically ill patients often host frustrated family members and visitors, predisposing to confrontations with healthcare workers. Victims of intended homicide who are treated in medical centers may remain at risk from a perpetrator, placing staff at risk as well. Lack of training in recognizing and managing

escalating hostility and aggressive behavior may also contribute to risk of violence.¹⁷³

Shift work

Healthcare workers participate in shift work in a variety of ways (see Chapter 38). They may work on rotating shifts, moving between day, afternoon, and night shift, or they may work one shift continuously. The effects of shift work are to disrupt normal circadian physiologic rhythms leading to an altered sleep-wake cycle, in addition to social disruptions with family and friends.¹⁷⁴ Acute effects begin with disturbed sleep and lead to daytime sleepiness and decreased mental focus and performance. Individual variability among healthcare workers to adjust to shift work is important. Studies have shown an increased use of sick leave and, in general, decreased health status among shift workers when compared with day workers.¹⁷⁵ Shift workers who do not successfully adjust to shift work may develop a syndrome of chronic fatigue, sleep disturbance, depression, mood disturbance, and personality changes. There is also an increase in the incidence of cardiovascular diseases among shift workers.¹⁷⁶ Epilepsy can be exacerbated by sleep deprivation. Several studies have shown increased rates of gastrointestinal disorders including peptic ulcer disease. Those with underlying severe medical problems such as insulin-dependent diabetes or asthma may have significant problems with rotating shift work due to interference with medication dosing schedules.

Despite the need for shift work, there are strategies to reduce its ill effects. The natural sleep-wake cycle is approximately 25 hours. Therefore, work schedules that rotate clockwise, i.e. day to evening to night to day, are preferred over day to night to evening to day. In addition, it is preferable to have a slowly rotating schedule rather than weekly changes in rotating shift work.^{177,178} Both the direction of shift change and the speed of rotation remain subjects of controversy.

ALLERGIES IN THE MEDICAL CENTER ENVIRONMENT

Allergies of animal workers

The use of a variety of laboratory animals in medical research is common, particularly in large academic medical centers. Employees who work with animals have an increased risk of developing hypersensitivities to allergens found in hair, dander, urine, serum, and saliva (see Chapter 37.1). Risk factors for allergies include a history of atopy, as well as exposure to laboratory or domestic animals.¹⁷⁹ Employee exposure via inhalation or direct skin contact to offending allergens sensitizes employees through an IgE antibody-mediated immediate hypersensitivity reaction. Symptoms typical of early allergy are rhinoconjunctivitis (80% prevalence), rashes and urticaria (40% prevalence).¹⁸⁰ More serious reactions, such as bronchospasm or anaphylaxis, occur less commonly.¹⁸¹

Preplacement screenings for employees who will work with animals should include history of allergy to domestic pets or laboratory animals, family history of allergy or asthma, as well as a personal history of asthma or other atopic conditions. In the event that the screening process identifies potential risk factors, specific testing (IgE) to allergens relevant for the work scenario should be considered. Employees who are identified on preplacement as having bronchospasm or asthma related to exposure to laboratory animals may be qualified to receive reasonable accommodation under the Americans with Disabilities Act.¹⁸² Continued exposure to laboratory animal allergens may exacerbate their symptoms of bronchospasm and asthma and increase risk of anaphylaxis or life-threatening bronchospasm.

A number of individual animal factors are important in the development of allergy. Rats and mice are the most common animals causing allergy in laboratory workers, though this may result from increased use of such animals in medical research. The source of the protein and the nature of the employee's exposure to it must be considered. Hair and dander are ubiquitous in an animal facility, but it is believed that urine and, in some cases, saliva may be more allergenic.¹⁸³

Efforts at exposure reduction have included use of hairless animals for experimentation, use of laminar flow cage racks, and establishment of ventilation systems equipped with HEPA filters. Dust-free bedding and biologic safety cabinets for manipulation of materials contaminated with animal secretions may also be useful.

The highest employee exposures are associated with tasks of direct animal handling, cage cleaning, and feeding.¹⁷⁹ Generally, researchers themselves have a lower risk of sensitization due to their intermittent animal exposure. Laboratory animal allergens may spread outside an animal facility when proper engineering and administrative controls are not in place, exposing employees who would not normally have direct animal contact. Administrative controls that may be useful to reduce exposure are the appropriate use of washing and showering facilities, and use of employer-provided clothes that are left at work and laundered by an appropriate facility.

Personal protective equipment may be effective in primary prevention of laboratory animal allergy. The use of gloves, gowns, respirators, and goggles as well as shoe coverings and hair coverings will reduce the allergen transport out of the animal facility and will reduce the total allergen accessible to the respiratory tract and mucous membranes of the employee. Rarely are respirators useful to decrease or eliminate symptoms once an animal worker has been sensitized.

Medical surveillance using a symptom questionnaire should be performed on a regular basis for employees at greatest risk of exposure,¹⁸⁴ namely those whose work involves direct handling of animal materials, cage cleaning, and feeding. In the event that symptoms of early laboratory animal allergy are detected, exposures should be reduced or eliminated, and personal protective equipment should be tried. If such efforts are not effective, medical

removal of the employee from animal exposure may be necessary to avoid the risk of worsening symptoms.

Latex allergy

Large numbers of healthcare workers have become sensitized to natural rubber latex due to substantially increased glove use over the past 15 years. While prevalence estimates vary greatly due both to different methods of population selection, and various methods of testing,¹⁸⁵⁻¹⁸⁸ it is generally believed that 5–10% of healthcare workers are sensitized to natural rubber latex. Risk factors for latex allergy include heavy glove use, frequent donning and doffing of gloves, history of atopy, food allergies, and history of surgical procedures early in life. The highest prevalence rates of latex allergy occur among spina bifida patients, due primarily to frequent early life contact between latex antigens and mucous membranes during surgical procedures.¹⁸⁹⁻¹⁹¹

Latex is an elastic and durable material, which accounts for its continued widespread use in barrier protection for healthcare workers. As a naturally occurring material extracted from the commercial rubber tree, its sap is a complex mixture of protein, lipid, and phospholipid. Polyisoprene lends latex its strength and elasticity. The raw sap is often processed with ammonia or sodium sulfate and vulcanized with sulfur. Accelerants such as thiurams, carbamates, and mercapto compounds are used to decrease production time. Latex contains more than 200 proteins, at least 60 of which have been shown to cause type I hypersensitivity.

Three general patterns of clinical disease may result from latex glove exposure. Irritant contact dermatitis is most common, due to prolonged abrasion of gloves, sweating, and the alkaline pH of most powdered gloves. Allergic contact dermatitis, which may resemble an irritant reaction clinically, is due to a delayed type IV hypersensitivity reaction to additives such as thiurams, carbamates, and mercaptobenzothiazole.¹⁹² Chronic allergic contact dermatitis may be debilitating, and may also predispose to type I hypersensitivity reactions by allowing enhanced contact between latex protein antigens and the dermis. Type I immediate hypersensitivity reactions to soluble latex proteins may range clinically from localized urticaria to systemic urticarial reactions, conjunctivitis, angioedema, bronchospasm, or anaphylaxis. Life-threatening anaphylactic reactions have occurred in healthcare workers, and are more common in the spina bifida population. Anaphylaxis to latex proteins has occurred during dental and medical examinations and surgery as well as during the donning of latex gloves and in the presence of others donning gloves.¹⁹³ It is difficult to predict to which specific latex proteins allergic healthcare workers will become sensitized. Specific reactions to proteins hevB1 and hevB3 are common among spina bifida patients, but less so among healthcare workers.¹⁹⁴

Route of exposure may play an important role in latex sensitization. Cornstarch powder is added to gloves to enhance the ease of removal from the mold and donning of the gloves. The powder has been shown to adhere to

protein and contribute to its wide environmental distribution. In addition, it allows for respiratory exposure to bystanders who may not themselves have skin contact with latex protein. Cornstarch powder has been shown to be an irritant to the skin and may enhance the likelihood of latex protein entry into skin.¹⁹⁵ Levels of air-borne latex allergens are substantially reduced with discontinuation of powdered latex glove use.¹⁹⁶

Preplacement evaluations, done for all healthcare workers, should include a latex allergy questionnaire.¹⁹⁷ Most latex-allergic healthcare workers can be accommodated in the medical workplace depending on area of specialty and level of reaction. Type 1 latex allergic personnel with histories of anaphylactic reactions, bronchospasm or hives caused by air-borne exposure should have no direct contact with latex and should work in environments free of air-borne latex proteins. Those with symptoms occurring only on direct contact of latex with the skin should use latex-free gloves, and should be monitored carefully for any symptoms resulting from other latex exposures in the workplace.

Identification of latex allergy early in its natural history provides an opportunity to halt progression of symptoms through reduction of exposure. Several non-latex gloves have been shown to provide comparable protection to that provided by latex gloves.¹⁹⁸

Chapter 18

Work Sectors of Emerging Importance

18.1 Emerging Technologies

Michael L Fischman, Daniel A Goldstein, Mark R Cullen

INTRODUCTION

While traditional manufacturing and agricultural work have engaged increasingly smaller percentages of workers in developed countries, newer production sectors, characterized by the utilization of rapidly evolving technologies, have gained increasing importance in the US and world economy. The most prominent of these are microelectronics, biotechnology, aerospace, and communications technologies. Compared to more traditional sectors, these activities involve different workforce demographics, novel environments, potential exposures to incompletely studied physical, chemical, and biologic hazards under rapid and changing workplace conditions. These characteristics require the development of new paradigms for occupational health practice and workplace hazard control. The purpose of this chapter is to outline some of the workplace health issues in these sectors, focusing on microelectronics and biotechnology, and to propose directions future practice might profitably evolve.

Workforce

Unlike conventional manufacturing, which may entail sharp distinctions between the work experience of minimally skilled hourly workers, skilled technicians, and supervisors, the new high technology workplace usually requires a substantially higher proportion of workers with advanced skills and integration. Engineers and scientists often work closely with skilled technicians. Many will perform multiple, complex tasks which are frequently changing. Moreover, for reasons including economic volatility, advancement opportunities, and competitive hiring practices, workers in these industries tend to change employers, job duties, and locations frequently, creating complex work histories. For obvious reasons, the workforce in most of the sector is relatively younger, more diverse in ethnicity and gender, and there are few unions or trade organizations relative to traditional sectors.

Work environment

The work environment can be even more radically different. Most new technologies involve manipulation of materials and products that are intrinsically costly, such as a silicon wafer or a genetically modified sow, so production systems are organized around product quality assurance. One consequence, evident in both the electronics and biotechnology industries, is the shift of production from

factory environments to 'clean' rooms – specialized, limited-access work areas where workers wear protective clothing and equipment that limits the possibility of contaminating the product physically, chemically, or biologically. Lighting, ventilation and other ambient conditions are set to protect the product, creating environments with unusual characteristics.

For example, any particle inadvertently introduced into the air in semiconductor wafer fabrication rooms (fabs) is rapidly removed by filtration. Likewise, reverse isolation techniques are used to breed genetically engineered animals for biomedical uses. In each setting, the increasingly critical need to separate product (the wafers) from people to avoid particulate contamination – through automation, robotics, and separately exhausted enclosures – has led to reductions in the potential exposure to production chemicals. However, workers frequently wear uncomfortable personal protective equipment, have more limited opportunities for breaks, and have little flexibility to make environmental or task accommodations (such as opening windows) that can enhance and humanize the work experience in more traditional settings. Protection of the product may also impose constraints on the extent to which mechanical aspects of work can be modified, e.g., enhancing ergonomic risks, as occurs in the healthcare sector (see Chapter 17), although use of automation and robotics can reduce some ergonomic hazards.

Work hazards

Perhaps none of this would warrant unique consideration were it not for the nature of the hazards which have been introduced. For example, semiconductor wafer fabrication requires the use of a large number of chemicals, including inert, corrosive, and toxic gases, volatile organic compounds, polymers, and metals and metallic compounds. Many of these chemicals have not been well characterized toxicologically. Not only are there frequent introductions of new chemical agents in microelectronics and biohazards in biotechnology – often poorly tested or of unknown nature – but the exposure conditions can be unpredictable, sporadic, and generally hard to document.

In semiconductor manufacture, exposures are well controlled under usual conditions – samples typically contain very low or undetectable amounts of measured contaminants.¹ However, accidental leaks and spills occur infrequently which, as in other industries, are difficult to characterize and quantify. In biotechnology, as in

other laboratory type settings, accidental exposures are the major concern, often controllable primarily by rigorous training and work practice measures, contrary to the traditional hierarchy of industrial hygiene controls. The potential for infectious, allergenic, or toxic reactions to inadequately characterized intermediate materials or end products is daunting, impeding design of meaningful surveillance programs or the diagnostic evaluation of worker complaints or illnesses. In addition, as in health-care, there is the formidable task of preventing biologic contamination of the product, such as immunocompromised animals bred for biomedical or research purposes.

Finally, rapid advances in technology can result in frequently changing the materials and work processes. For example, in some parts of the semiconductor industry fabrication rooms are reconfigured every several years. Genetic manipulation of organisms may result in the introduction of numerous new strains and variants, rendering the usual notions of a 'complete' exposure history almost meaningless, let alone the feasibility of epidemiologic evaluation of the exposed workforce.

MICROELECTRONICS INDUSTRY

Work processes

Manufacture of computer chips on silicon wafers involves exotic multi-step processes, which change frequently. The following is a brief overview; more complete discussion can be found in the suggested readings.²⁻⁴

The first step is making the wafer – a large round platter of almost pure silicon or, less commonly, gallium arsenide. Wafer manufacturing occurs in a few separate dedicated manufacturing facilities, which are not part of the semiconductor wafer fabrication environment. To achieve this, quartz is reduced to silicon under very high temperature, ground to a powder then gassified in hydrogen and chlorine to trichlorosilane, which is reduced to pure silicon. A small crystal 'seed' is then dipped into the liquid silicon at the ends of a rod, allowing the crystal to grow while intentionally introducing very small quantities of impurities ('doping') such as boron, arsenic or phosphorus. These huge crystals are then machined (including grinding, slicing, and lapping), etched (in acid) and polished to form the wafer on which hundreds of chips (die) will then be fabricated.

The majority of the potentially toxic chemicals are introduced during fabrication. First a layer of silicon dioxide is applied, which is then protected by coating with a layer of photoresist. Photoresists contain light-reactive chemicals, polymers, and carrier solvents. As in conventional photography, the wafer is exposed to a light source, intense ultraviolet (UV) light. The light passes through a mask, containing the pattern for the circuitry, causing polymerization or solubilization of the exposed photoresist, dependent upon the type of photoresist (negative or positive). The resulting surface is developed, requiring use of chemicals, primarily strong bases. For the typical positive resist, exposed areas of solubilized photoresist are removed by the developer. The resulting unprotected silicon dioxide

surface can then be etched off by application of etchants – acids (wet etch) or excited gases (plasma etch).

Doping involves the introduction of desired chemical impurities into that portion of the surface of the wafer, which is now unprotected. This process may be accomplished by diffusion at high temperatures of dopant gases through the surface of the silicon or by ion implantation, in which the dopant ions are beamed, under vacuum and high electric fields, onto the wafer from heated filaments. In thin film, thin layers of materials, including silicon, silicon dioxide, and silicon nitride, are placed onto the surface of the wafer, in furnaces or chemical vapor deposition tools, to provide a layer that protects the underlying surface or serves as an insulator. Typically one wafer will go through repeated sequences of these steps to create multiple layers of complex circuitry.

When the circuits are complete, the wafer is metallized – the introduction of metallic circuit connectors, typically by vapor deposition. The fab and associated processes can thus be divided into four major functional areas, photolithography, etch, thin film (which includes ion implantation and metallization), and diffusion. Final processing includes inspection and chip separation, assembly into packaging, and testing, with the last three activities conducted outside the wafer fabrication facility, typically at a separate location.

Chemical/physical hazards

As noted, there is an extensive array of chemicals used in the manufacturing process, mostly, but not exclusively, in enclosed areas. Although a detailed review of the chemicals is beyond the scope of this chapter, some of the major chemical and physical hazards are shown in Tables 18.1.1 and 18.1.2.

Hazard	Reference
Organic solvents, including glycol ethers	Chapter 40
Inorganic acids	Chapter 47
Organic and inorganic silanes	Fischman, 2001 ⁴
Arsenicals	Chapter 39.2
Boron, gallium tungsten and other exotic metals and organometallic compounds	Chapter 39.9 and Fischman, 2001 ⁴
Hazardous gases including arsine phosphine, nitrous trifluorine and diboranes	Chapter 47 and Fischman, 2001 ⁴
Resins	Chapter 11
Diazonaphthoquinones and other photoactive chemicals	Fischman, 2001 ⁴

Table 18.1.1 Chemical hazards in the microelectronics Industry

Hazard	Reference
Ionizing and non-ionizing radiation	Chapters 33.1 and 33.2
Ultraviolet light	Chapter 33.2
Noise	Chapter 34
Heat	Chapter 35
Low humidity	Chapter 50
Ergonomic stressors	Chapter 32

Table 18.1.2 Physical hazards in the microelectronics industry

Health risks and concerns

Despite the plethora of potential risk factors and the exotic nature of the chemicals and work, most health problems reported by physicians in the industry or practicing in areas where the industry is concentrated have been fairly commonplace. Skin irritation, possibly exacerbated by low humidity and protective clothing, is common. Eye irritation is also frequently encountered.^{4,5} Respiratory complaints may be more common than in other industries,^{5,6} although the majority are self-limited and poorly characterized irritative symptoms. Asthmatics and others with pre-existing airway disorders may find the environment problematic, perhaps due to the dry air in the fab or low-level irritation, although some allergic asthmatics report improvement in symptoms in an environment free of pollens and other particulates. Not surprisingly, syndromes resembling non-specific building-related illness and multiple chemical sensitivity have also arisen (see Chapter 49).

In addition to these medical reports, musculoskeletal problems have been encountered,⁷ as might be expected from the complex and constantly changing organization of the clean rooms, although, compared with other industries, the work is not generally heavy or repetitive. Complaints related to heat and protective clothing occur, although significant heat-related illness does not. Complaints of difficulty hearing also occur in the fab environment, which is noisy but rarely exceeds noise action levels. Noise-related hearing loss does not appear to occur, with the possible exception of workers in mechanical support areas outside the fab.⁴

The greatest concerns in the industry have centered around reproductive health and cancer. Spontaneous abortion excess was first reported in a Massachusetts company in the mid 1980s.⁸ This prompted two large studies on an industry-wide basis, which confirmed excesses of about 1.4-fold in the fab overall and ranging up to 70% in certain job categories.^{9,10} Although the specific cause for the early fetal losses could not be ascertained with certainty, the clustering around jobs with exposure to photoresist solvents implicated ethylene glycol ethers because of their known reproductive/developmental toxicity in animals. In response, the industry has substituted less toxic glycol ethers, such as propylene glycol monomethyl ether acetate, or other alternative solvents, such as ethyl lactate, for these compounds. In addition, the industry has enhanced some engineering and other controls and generally created procedures that facilitate accommodations or transfers for concerned pregnant employees. Only a portion of the observed excess of spontaneous abortion in one of the studies could be explained on the basis of potential exposure to glycol ethers; excesses in other areas, such as etch, remain unexplained, raising the question of other contributing factors, e.g., unrecognized developmental toxicity of another agent or other factors, such as ergonomic factors or stress.

The issue of cancer risk remains unresolved. In addition to compounds which have been poorly studied, there are potential exposures, albeit well controlled, in the fabrication process to numerous known or suspect carcinogens, such as arsenic and sulfuric acid. The levels of exposure, however,

are typically far below those observed in epidemiologic studies of other worker groups exposed to these materials. Only one small study of cancer has been undertaken among workers in this environment; it failed to show any consistent risk, although the power to detect an effect was very low.¹¹ Given the concerns, it is likely that further attempts to quantify cancer risks will be undertaken in the future.

Surveillance and control of occupational health and safety in the industry

Current practice in the industry is widely variable; a few companies have responded to public and worker concerns by instituting extensive medical monitoring, in some cases with data analysis for groups by job or work area. At present there is little data to support specific surveillance activities beyond those currently required in the US under OSHA, namely the reporting of occupational illnesses and injuries. Unfortunately, even the more intensive approach, providing questionnaire and medical information on a regular basis, will be of limited value in addressing the major unanswered questions about worker risks. For one thing, the outcomes of interest are not known with any certainty, and include a wide range of possible health effects; there is no single specific condition to perform surveillance around. Traditional health surveillance is intrinsically cross-sectional in nature, and therefore unlikely to provide a barometer to track more chronic effects of exposure should these occur. Moreover, the absence of linkage between symptoms or other health information and exposure reduces the ability to compare rates among groups with divergent exposures of interest. High employee turnover, combined with rapid changes in production processes and exposure patterns, further compound the difficulties associated with a traditional medical surveillance approach.

An alternative approach, perhaps in combination with ongoing symptom and health status surveillance, would be an aggressive 'sentinel event' approach. In this model, proactive scrutiny of all reported workplace events, combined with routine scrutiny of health insurance data to evaluate patterns of chronic diseases such as cancers among workers and retirees, may provide a more sensitive way to detect unsuspected adverse health consequences of the work. Although each observation would require confirmation by application of more formal epidemiologic methods, such an approach offers a coherent alternative when traditional surveillance strategies have limited efficacy given the nature of the exposures and the industry.

Any surveillance approach would require institution of three important prerequisites. First, it would be crucial that company personnel records are coded in such a way as to distinguish to the fullest extent possible the actual nature of an employee's job, rather than generic job titles which might be administratively simpler but inadequate for surveillance purposes. Second, records must be retained electronically, with appropriate documentation, for a minimum of three, and preferably four or five decades. This is crucial to evaluate the risks of chronic health effects. Finally, it would be desirable for health insurance records

to be maintained by appropriate health data management companies, so that rates of illness and disease can be evaluated without complex and costly epidemiologic reconstructions as has been the case up until now.

BIOTECHNOLOGY

The advent of biotechnology allows us to move genetic material within and between species. In theory, this allows us to produce any desired gene product in the species of our choice, including the alteration of the human genome for therapeutic purposes. In practice, the applications of biotechnology have focused on certain key areas that show agronomic, economic, and/or therapeutic promise. This technology has created new potential hazards and newly exposed worker populations within the biotechnology industry.

Two key areas of concern will be addressed here: the handling of plants genetically modified for food and feed purposes, and the production of biopharmaceuticals. In the former circumstance, the inserted genes and their products are characterized and selected to be appropriate for human or animal consumption. Human health risks in this area appear to be of lesser concern and do not appear to differ qualitatively from the risks inherent in the conduct of conventional agriculture. Issues of ecologic harm, such as environmental changes in neighboring plants or organisms sharing the same ecosystem, continue to be hotly debated, given the vast and diverse settings in which these food crops may be introduced. In the pharmaceutical area, however, proteins with known or anticipated human pharmacologic activity are being produced in a wide variety of species, resulting in a higher potential for adverse effects upon worker health.

Food and feed crops

Genes may be inserted into food and feed crops for a variety of reasons – to confer selective resistance to herbicides; to confer resistance to pests; to confer agronomic traits such as drought or salt tolerance; to alter storage, processing, or cooking characteristics; or to improve the nutritional characteristics of a food or animal feed. In order to function, an inserted gene must be accompanied by gene regulatory sequences that allow expression of the gene within the plant. At present, many gene inserts also contain a marker for antibiotic resistance which is necessary to select for plant cells which have successfully acquired the desired gene insert, but such sequences are either not utilized in newer products or are removed from these products during development. The inserted gene is generally intended to produce a functional protein, although in some cases (antisense DNA mediated resistance to viral pathogens), no protein expression occurs. The protein products used in food and feed crops fall into several categories.¹² They may express pesticidal activity as in the case of the Bt (*Bacillus thuringiensis*) toxin, or confer resistance to herbicides by incorporating a resistant variant of a normally occurring enzymatic activity or by allowing a plant to degrade a

particular herbicide. The inserted gene may result in new plant structural proteins, or may confer new or enhanced enzymatic activity upon the plant so that new nutrients or enhanced levels of nutrients are produced. Inserted genetic material may also act by down-regulating or up-regulating existing genes, and may potentially have unintended effects upon other genes within the plant cell either by direct insertion into those genes or by indirect regulatory (so-called pleotropic) effects.¹³

Potential novel occupational exposures resulting from the production of genetically modified feed and food crops include: (1) exposure to the novel protein; (2) exposure to the products of enzymatic activity conferred by the inserted protein, which may be either anticipated or unanticipated; (3) exposure to endogenous or novel plant toxins resulting from pleotropic effects; (4) effects mediated by antibiotic marker genes; and (5) effects of the inserted gene sequence itself.

Fortunately, food and feed products undergo safety evaluation prior to marketing,¹² greatly reducing some of these hypothetical risks. Although gene insertion is random, genetic events in crop plants are characterized to assure that normally expressed genes are not disrupted. Inserted novel genes and proteins are isolated and sequenced to assure that the intended material has been inserted without alteration. The novel proteins themselves are subjected to acute animal toxicology testing. Modified crops are characterized biochemically to assure appropriate nutrient properties and composition, feeding studies are performed in animal species, and levels of known toxins endogenous to the particular plant species quantified. To address food allergenicity concerns, inserted proteins are examined for structural similarity to known food allergens and to assure that they are readily digestible and heat labile; testing which is believed to reduce the likelihood of gastrointestinal allergy.¹⁴ DNA itself is not likely to be directly harmful; thus far no transfer of plant DNA to human, animals, or bacterial species has been demonstrated.¹⁵

Currently available genetically modified crops are produced, processed, and sold in a manner identical to, and usually admixed with, conventional crop varieties. Thus, the worker population exposed to these materials and the modes of exposure are no different from those of the traditional food/feed workforce. An exception would be workers involved in the development of new and not yet fully characterized crops, whose exposure potential may be more like that in the biopharmaceutical industry discussed below.

Thus, the introduction of biotechnology crops, given the pre-market safety assessment of these products, does not appear to introduce significant novel risk to the food and feed production workforce. Toxic or other adverse effects from the gene insert, protein products, and products of enzymatic activity are not, in general, anticipated from a material suitable for food consumption. Any novel protein, even one which is not a gastrointestinal sensitizer, may be a potential human respiratory or skin allergen. Foods in general, particularly in the grinding or milling environment, are recognized occupational allergens, as are fungal and other contaminants of commodity crops.

Overall, the general nature of the hazards for workers employed in the food and feed production industries does not appear to be qualitatively altered by the introduction of marketed biotechnology crops, and it appears unlikely that quantitative risks are increased to any meaningful extent once one looks beyond the product development laboratory. The area of biopharmaceuticals presents a very different picture.

Biopharmaceuticals

Historically, development and production of pharmaceutical agents and biomedical devices involved well-delineated, traditional work activities readily identifiable by today's occupational physician. Compounds of interest were synthesized in chemistry laboratories, purified, and tested for their chemical properties. Using animal facilities, the products of these laboratories were then tested for therapeutic and adverse effects first in smaller, then in larger animals. If the results were satisfactory, production would begin, typically on a small scale at first, to provide enough material for further trials and testing. Finally, successful drugs went into large-scale production in chemical production facilities, unique only in that they are equipped as necessary to meet the standards of pharmaceutical production. Health hazards for each of these sets of activities – the chemistry lab, the vivarium, and the factory – could be addressed using relatively traditional industrial hygiene techniques, complicated perhaps by the novelty of some of the compounds tested, the need to utilize hazardous microorganisms to test antimicrobial agents; and the potential for zoonotic infections in animal facilities.

With the development of recombinant DNA technology and the explosion in knowledge of the genome, the traditional pathway to drug development is changing. Although chemistry laboratories have not disappeared, the 'source' of an increasing fraction of new pharmaceuticals is not organic synthesis but biologic synthesis, i.e., a protein product of a selected gene or a metabolic product resulting from gene insertion. In this new paradigm, the initial steps in drug development involve identification of a relevant DNA sequence which codes for a desired protein (or occasionally DNA or RNA) product. This sequence may be an existing gene from a plant or animal species, a modified gene, or even a fully synthetic DNA sequence. This DNA sequence, along with appropriate regulatory sequences (promoters, etc) is then inserted into the genome of an organism which will become, in effect, the 'factory' producing the desired agent.

Until recently, biosynthesis most often occurred in bacterial, mold, or yeast cultures or in immortalized lines of human or animal cells. The hazards of such classical 'fermentation-like' systems, regardless of scale, are reasonably well understood. However, in the coming decade, the organisms engineered to yield the voluminous quantities of proteins needed for commercial purposes will primarily be agricultural crops such as corn or tobacco. To accomplish plant-mediated synthesis, a gene of interest is inserted into plant cells under laboratory conditions using bacterial or

viral vectors or mechanical (micro-projectile) means. Cells bearing the desired gene are identified, and the desired cells are grown into adult plants, from which further clones or stock can be obtained. Plants are then grown and selected to cull out offspring lacking desired expression of the trait of interest, typically at a seed production facility. Once the seed stock is established, 'production' occurs on a farm; the therapeutic agent is then isolated and purified from the harvested product.

Biotechnology is not limited to plants. Increasingly medical 'devices' may be grown in animals, such as the genetically modified swine expressing human rather than porcine cell surface markers, which may become the major source of organs for transplantation. As with drugs, breeding of these unique clones occurs in something resembling a laboratory, but once bred, the livestock are raised and harvested in a setting more like a farm. However, these highly specialized animals require more than just food and water; they require isolation from any organisms which could harm them and, especially, from any organisms which might persist in tissues, with or without harm to the pig, and subsequently harm an immunocompromised patient. Thus, the farm setting is modified to provide isolation from pathogenic organisms.

Undoubtedly, there will be many variations on these themes as the full potential of new genetic technologies becomes clear. The sea-change, however, has already occurred: the practice of occupational health and safety for the population of genetic technology workers will require coping with a new and rapidly changing set of hazards, with work occurring in surprising new settings, and with worker populations (e.g., farm workers) dealing with many hazards – both novel and traditional. At present there is virtually no road map for the practice of occupational medicine in this domain.

Hazards

Hazards in the biotechnology industry are best thought of in categories, since strategies for control are relatively unique to each class. The major groupings are: chemical, physical, and infectious and non-infectious biohazards. Since the first two groups are comprised of standard occupational health concerns, the focus of the discussion that follows will be on the infectious and non-infectious biologic risks. However, traditional health hazards (such as noise) can be easily overlooked when occurring in novel settings, and the need for continued vigilance for these traditional hazards cannot be overemphasized.

Infectious risks

Biomedical and pharmaceutical laboratories have a long tradition of utilizing infectious agents. The control of the associated hazards, using containment levels appropriate for the specific organism involved and for any genetic modifications present, has worked reasonably well over time. Existing documents^{16,17} provide clear criteria for application of the different biosafety levels, and clear prescriptions as to the appropriate precautions. To date, there is no

evidence that laboratory recombination per se has incrementally altered the risks from any organisms handled in the lab, although concerns about the potential of new strains, especially those with markers for antibiotic resistance, may pose new concerns about waste and environmental disposition.

Animal use in the laboratory is not new, although it has received proportionally less attention in occupational health than in the veterinary medicine literature. Traditional zoonotic infections such as Q-fever, while not novel, continue to be an issue. The risks of agents as Herpes B from primates and prion diseases from the handling of human or animal CNS tissue represent some of the most daunting new threats, requiring that any lab handling potentially infectious material have appropriate consultation and control mechanisms in place.

In addition, new possibilities are raised by the emerging genetic technologies. Foremost is the use of vectors for transfection of animal cells. Although usually harvested from wild-types with limited pathogenicity to human hosts, viral agents selected for this work are themselves modified in the process, but are typically not well studied, since their role in the research is circumscribed and generally short-lived. Whether, for example, a non-human adenovirus carrying one or more modified genes could pose a risk to workers remains unexplored, and is unlikely to be explored until an 'incident' occurs. Although viral and bacterial vectors are also utilized for plant transfection, these agents do not appear to have any propensity to infect humans or animals.

Of greater concern may be the viral vectors utilized for human gene therapy since, by design, these agents will infect the human host. These agents may be derived from a wide variety of viral strains including the retroviruses, adenoviruses, adenovirus-associated viruses, vaccinia, and the herpesviruses.¹⁸ In general, these agents are replication deficient and thus cause only transient viremia. While most agents result in the transient, epichromosomal presence of the novel genes, some agents (primarily retroviruses) can permanently incorporate novel DNA into the human genome.¹⁸ In general, large inocula are needed to have a significant effect, since the agents do not replicate. However, large accidental inoculations or inadvertent infection with replication-competent strains could cause serious occupational illness. Also the possibility remains that a replication-incompetent strain could acquire the ability to replicate via unintended genetic events or as a result of co-infection with another viral strain.¹⁸

Likewise, laboratories will likely utilize genetically modified, rather than traditional laboratory animals. Until now this has been largely limited to transgenic rodents whose potential to spread infection to humans appears limited. However, with the advent of larger genetically modified species, such as pigs, new possibilities arise, such as human transmission of new agents or more efficient transmission of old ones. Many if not most of the major viral infections of humans are suspected to have had animal origins, and many viruses are quite remarkable in the range of hosts they may infect. The 2003 outbreak of severe acute respiratory syndrome (SARS), traced to

food workers handling wild civet carcasses, is a compelling example. The emergence of prion variants in new host animals, as occurred in the 1980s with bovine spongiform encephalopathy (mad cow disease), indicates that particular caution is necessary regarding the handling of any CNS tissues or contaminated material.

Unfortunately, the range of possibilities is virtually infinite; possibilities specific to a given lab or technology will necessarily require detailed attention to the particular exposures, with broad appreciation for the 'possible'. The emergence of new human pathogens in animal species has been occurring as a natural phenomenon with great regularity, especially in the case of influenza viruses. It is not presently clear how the risks of this phenomenon in biotechnology systems compare with the risks inherent in the natural environment.

Non-infectious biohazards

A larger concern is the non-infectious occupational risk associated with genetically modified organisms and their products. Generally, these can be grouped into three classes. First are the potential toxicities of the protein products themselves. As discussed above, genetically modified plant products developed for human and animal consumption are of relatively limited concern in this regard, beyond the risk of newly introduced allergens and some alterations in plant composition.

We can be less confident about the risks of pharmaceutical protein products. Technology now allows constructs of various cytokines, cytokine inhibitors, agonists, and antagonists of numerous 'receptors' or other proteins in the body, including highly specific agents such as monoclonal antibodies. Although these proteins generally constitute a small portion of total protein production, many of these agents manifest remarkably high levels of biologic activity following parenteral administration, with effective doses in the microgram range. These proteins are unlikely to be well absorbed via the upper or lower respiratory tract, intact skin or gastrointestinal routes. However, some proteins and/or possibly peptide fragments may be absorbed, especially under dusty conditions. While some dust exposure may occur in the harvest or handling of whole crops, greater potential for dust exposure exists when crops such as corn or tobacco leaf are ground or milled to allow extraction of the desired material. Given the high biologic activity of these materials, systemic effects may be possible despite very low bioavailability.

It is possible that genetically modified agents may directly affect mucous membranes of the upper and lower respiratory tract and even the gastrointestinal tract. For example, a monoclonal antibody directed against inflammatory mediators, or cell surface markers, might precipitate lung injury by modulating pulmonary immune function of the airway epithelium. Although this risk is, at present, entirely theoretical, vigilance is required as we proceed into the future.

The majority of therapeutic proteins have undergone development in non-plant systems prior to initiating plant-mediated production, and many of these agents

have undergone preclinical and early clinical testing either in animals and/or appropriate patient groups (often patients with rare or fatal conditions). However, the general safety of these materials for working adults typically has not been established. In particular, since protein agents must generally be administered parenterally for therapeutic purposes, these agents have rarely been studied via traditional routes of occupational exposure. Assessment of occupational risks is further complicated by the often high degree of biologic specificity of the proteins, which may have activity in only a limited number of species or be active only in humans. Thus, depending upon the degree of species specificity, traditional animal testing may fail to reveal hazards relevant to the workplace. The development of numerous such protein agents annually increases the likelihood of difficulties arising in exposed workers, but the ultimate magnitude of these difficulties remains undefined.

Another concern, and the one which has received the most attention in relationship to genetically modified foods, is the potential for exposed workers to develop allergic responses to new protein antigens. While proteins inserted into crops intended for food or feed use are selected to minimize the risk of gastrointestinal sensitization, the potential for pharmaceutical proteins to incite allergic pulmonary responses may be more substantial. Although there are algorithms and approaches for predicting gastrointestinal (i.e. food) allergenicity,¹⁴ the predictive value of these algorithms for respiratory allergenicity is unknown, especially for workers who may be repeatedly exposed. Given that new proteins can potentially be allergenic, allergic responses such as dermatitis, urticaria, asthma, rhinitis, and anaphylaxis are potential adverse effects. It will generally not be feasible to screen workforces for sensitivity to these new products, since the antigens will likely be novel to humans and markers for sensitivity not developed until allergic responses occur and are fully evaluated.

The introduction of new or enhanced enzymatic activities and synthetic pathways may also introduce novel metabolic products, either intentionally or otherwise. Similarly, one may see so-called pleotropic effects in which the insertion of a foreign gene alters cell metabolism in unexpected ways as a result of changes in protein or cell function.¹³ For example, a plant which previously expressed low levels of a toxin may express larger quantities of the toxin, or a previously unexpressed pathway may become active. Again, while food and feed products undergo substantial testing which may uncover such phenomena, such comprehensive testing is not necessarily undertaken for plants intended for biopharmaceutical production.

At this time, there is no simple way to look singly or collectively at these metabolic effects; singly, because it is unknown in advance what single product to study, and collectively because laboratory animals are limited in their food consumption. Even if a crop is tested, the animals may not consume enough of the whole plant product to assess the toxicity of a low-concentration material. Although there are presently no recognized cases of occupational illness resulting from pleotropic effects induced by modern

genetic technologies, pleotropic effects of traditional breeding have, on at least one occasion, precipitated an outbreak of occupational illness in the form of photodermatitis resulting from unanticipated increases in psoralin levels in celery.¹² Hopefully, rapidly evolving technology in the area of gene expression profiling and metabolite analysis¹³ will allow a more comprehensive approach to this area of hazard assessment in the near future.

Health studies in the biotechnology sector

For the reasons proposed above, current knowledge about occupational health for non-traditional hazards, particularly in the biopharmaceuticals area, remains extremely limited. There are a handful of reassuring reports that the recombinant DNA technologies in microbes of the last generation has not conferred important new infectious risks, as noted, but relevance to the new enterprises is unclear. Moreover, it appears inevitable that the production of new gene products will rise dramatically given the recent sequencing of the human genome and other advances in biotechnology. This assures that many workers will be working with unknown materials for the foreseeable future, many in novel workplace circumstances.

Occupational health surveillance – approaches

For workers in the traditional food and feed industries, including farming, the introduction of evaluated biotechnology crops will probably produce at most modest change in qualitative and quantitative health risk. This is in contrast to the evolving situation in the area of biotechnology research and biopharmaceuticals. Regarding these latter two areas, the potential for adverse outcomes, albeit remote in any single situation, is likely high in the aggregate, and the safety of the technology – given already high levels of public scrutiny – as well as the workers hangs in the balance.

The fact that there are neither well-defined surveillance approaches nor specific regulations should encourage higher, not lower, levels of professional input. Moreover, unlike some traditional aspects of occupational health in which intimate knowledge of modern medicine and biology is generally not critical, consultants in this industry will need to have substantial scientific expertise as they evaluate product by product, and class by class, the potential for human exposure and risk created by new developments. In these novel environments, care providers must be careful not to overlook obvious traditional risks like animal allergy, zoonoses, noise, and ergonomic issues. Beyond this, a number of suggestions from the authors may prove useful to the care provider in approaching the biotechnology work environment. The ultimate need for, and efficacy of, these approaches remain to be determined.

1. For farm workers and other food/feed industry workers handling approved genetically modified plants, no unique surveillance beyond usual measures appears to be mandated at this time. One plausible risk is allergy

to inserted proteins, a risk already common to foodstuffs and contaminants such as molds. If immunologic studies of exposed workers are performed, consideration should be given both to novel and to the far greater number of non-novel antigenic proteins present.

2. In evaluating and managing the infectious/transmissible risks of recombinant vectors and modified organisms in the laboratory setting – including microbes, plants, and animals – current guidelines from the National Institutes of Health¹⁶ and the American Society for Microbiology¹⁷ appear adequate. However, it is important to recognize that these criteria are based upon planned (or readily anticipated) and controlled events. Unanticipated genetic events may occur, particularly in animal species, with resulting novel pathogens, although the likelihood and extent of such events is unclear. Practitioners must therefore remain alert to the possibility of unique infectious presentations within the biotechnology workforce.
3. In evaluating the risks of biopharmaceutical products, the occupational physician should consider several characteristics which may not be evident on casual consideration of available toxicology data. These factors include the following.
 - Is the molecule biologically active as produced in the organism, or is further processing necessary to result in an active moiety?
 - Does the molecule produce biologic effects independently or is some other exogenous factor required for toxicity (i.e., an antibody designed to carry a radioisotope to tumor cells would not likely present a hazard until radio-labeled)?
 - Does the target of the molecule occur in the general population, or is it only manifest in specific diseases?
 - Does the receptor for the protein exist on externally exposed surfaces such as the mucous membranes of the gastrointestinal or respiratory tract, or exist in the mucous coating of these surfaces?
 - What is known, if anything, about absorption of the particular molecule or about the activity and absorption of fragments derived from it?
 - Is the molecule known to have acute toxicologic effects (i.e., cholera toxin) or is it structurally or functionally analogous to a known toxin based upon bioinformatic (e.g., protein sequence homology) analysis?
 - What degree of species specificity does the molecule exhibit, and how will this affect the ability of animal testing systems to reveal useful information in regard to human hazards?
 - Given such specificity, can a sufficiently predictive animal model be developed (such as an animal transgenic for the human receptor, or a homologous molecule having a different species specificity to allow testing)?
 - Does a human disease model exist which may shed light on the possible effects of the product? For exam-

ple, acquired immunodeficiency could model potential effects of a protein which eliminates T-cell function or interferes with interleukin-2 activity.

- Is the protein a known human allergen and/or does it exhibit homology to known allergens?
 - Is the protein of human origin or has it been 'humanized' in sequence to reduce antigenicity?
4. In the absence of adequate predictive data, care should be exercised in the handling of biopharmaceutical proteins outside of the well-controlled laboratory environment. This is particularly true for dry operations such as grinding or milling. While it is highly likely that, in most situations, no unusual effect will arise, exposure should be carefully controlled using industrial hygiene and personal protective equipment as necessary. The occupational physician should be vigilant for anticipated and even unanticipated clinical effects, especially those which might be mediated by direct action of the product upon the lining of the respiratory and/or gastrointestinal tracts.
 5. In assessing allergic responses in the workplace, one should consider both the novel and existing antigen potential of the biotechnology product.

Several additional administrative and technical practices may be helpful in addressing the occupational health needs of the biotechnology community.

First, we would propose that every development facility, including seed farms and other agricultural facilities where biotechnology products (other than approved food/feed products) are handled, have available internal and/or external medical resources whose responsibilities are separate from product development and production. Such groups would have regular meetings with investigators developing new products, and would have both the resources and authority to provide caution where unforeseen risks are contemplated. These resources should include consultants knowledgeable in the necessary areas of molecular biology, virology, infectious disease, etc, depending upon the nature of the hazards involved.

Secondly, we would recommend that each development facility constitute a biosafety committee to review the worker-related safety aspects of biotechnology projects before inception. While this function is mandated for facilities receiving Federal dollars in the USA, privately funded research groups would be advised to follow this model and to provide the committee sufficient resources and authority to assure effectiveness. Inclusion of occupational medicine on the IBC seems well advised. We believe that community member participation is an important aspect of biosafety committee function, and encourages community involvement with the need for business confidentiality and the freedom to disclose public hazards appropriately balanced.

Finally, institutional review boards (IRBs) can contribute to the oversight of biotechnology projects when those projects involve human subject research. Recent liability concerns, may, unfortunately, limit the access of private industry to independent IRBs in university settings.

Hopefully, a more systematic approach to occupational medicine in biotechnology will result, including productive and cost-effective approaches to surveillance, control and, if necessary, regulation.

18.2 Occupational Health of Police and Firefighters

Sandy Bogucki, Peter M Rabinowitz

INTRODUCTION

The events of September 2001 dramatically highlighted the occupational hazards facing police and firefighters. Of the rescue workers fatally injured in the World Trade Center attacks in New York, 335 were firefighters and 61 were police officers or detectives.¹ The evolving homeland security roles of the public safety sector encompass domestic consequence management of a broad spectrum of threats of terrorist or trans-national attack. Clinicians evaluating police officers and firefighters either for preventive services, including fitness for duty determinations, or for acute or chronic medical complaints potentially related to work must take into account the unique aspects and expanding scope of firefighting and police duties. Even in the absence of major disasters, both professions experience high rates of work-related illness, injury and mortality. While many hazards of law enforcement and fire service work are by necessity sporadic and unpredictable, a more thorough understanding of the risks facing these public safety workers could lead to improvement in current preventive efforts.

This chapter will outline hazardous exposures faced by police and firefighters and summarize studies of health outcomes related to exposures and recommendations for preventive interventions. Many of the specific hazards are discussed in greater detail in other chapters of this book.

FIREFIGHTERS

There are approximately 1.1 million firefighters in the US, organized into more than 26,000 local fire departments.² Interior structural firefighting is a complex operation that can be divided into several stages. These include (1) alarm, during which personal protective equipment including self-contained breathing apparatus (SCBA) is donned prior to and during transportation to the incident scene; (2) entry, when the burning structure is breached and rescue operations begin; (3) suppression, involving venting and extinguishment of the fire; (4) overhaul, when the firefighters remove furnishings, open walls, and pull ceilings to ensure that the fire is completely extinguished, and (5) termination, during which equipment is recovered, and hundreds of feet of 1.5 to 6 inch diameter hoselines are drained and re-packed onto the engines. While fighting structure fires remains a core function of fire departments, the number of responses to medical emergencies and hazardous materials incidents has more than doubled in the past 20 years.³ Other dangerous aspects of the firefighter's job include responding to emergencies using warning lights and sirens through traffic, operating in poorly controlled environments such as motor vehicle accident or crime scenes, and operating in a wide array of technical rescue situations, including working in confined spaces, high elevations, extremes of temperature, and urban environments.

Approximately three-fourths of firefighters are volunteers and the remainder are career personnel. The occupational hazards facing each group may differ in frequency and depend on the operational scope of the local department. Career fire departments generally respond to a greater number of calls, and typically protect larger populations and occupancies than volunteer departments.

As Figure 18.2.1 shows, there has been a 38.9% decrease in the number of US structure fires over the last 20 years.⁴ This has been associated with a moderate decrease in total line-of-duty firefighter fatalities, though the occupational injury and mortality rates per fire appear to be stable or rising, with rates of 25 injuries per 1000 fires and 6.5 fatalities per 100,000 fires.⁵⁻⁷

Firefighting accounts for only 9% of fire service emergency call volume nationally, yet roughly 50% of line-of-duty deaths and 60-80% of injuries occur on the fire-ground⁷ as shown in Figure 18.2.2. While the high rate of fatalities on the fireground might suggest that such deaths could be due to physical trauma or direct exposure to heat and smoke, in fact roughly half of firefighter deaths on the fireground are caused by heart attacks⁶ or motor vehicle crashes (see below).

Specific hazards of firefighting

Table 18.2.1 summarizes the occupational hazards facing individuals in this profession and the possible health outcomes resulting from these exposures.

Physical hazards

Fighting structure fires involves many physically demanding and potentially hazardous tasks, including climbing ladders, crawling through confined spaces, lifting heavy tools and building materials, and maneuvering on elevated surfaces where there is a risk of falls. These activities must be performed while wearing heavy fire retardant clothing, a helmet, self-contained breathing apparatus (SCBA) respirator, and other protective gear that may weigh in excess of 50 pounds. There is consequently a need for physical fitness and a constant potential for traumatic injury or death. A study of National Fire Incident Reporting System data found that risk factors for acute injury while fighting fires included a greater than 5 alarm fire, structures greater than three stories, and at least one civilian being injured.⁸ While there is a risk from physical assault violence by patients and others during provision of emergency medicine services (EMS), this risk has been found to be low.⁹

Heat is a critical exposure hazard when fighting fires. Interior structural firefighting can transiently involve exposures to temperatures exceeding 700°F, and the protective clothing worn by firefighters is designed to afford thermal protection from such environments in a time/dose-related manner¹⁰ (see Chapter 34). Unfortunately, the heavy thermal and flame protective equipment adds significant weight and ergonomic disadvantage. It severely impairs the

Figure 18.2.1: Twenty-year trends in US fire incidents and total line-of-duty firefighter (FF) fatalities, 1981–2000, based on data published by the US Fire Administration and National Fire Protection Association.⁴

Figure 18.2.2: Ten-year pattern of firefighter activity at the time of death based on 1991–2000 fatality data.^{5,6} Nearly three-fourths of line-of-duty deaths occur on the fireground or in motor vehicle crashes during emergency responses. The remaining fatalities are associated with training, EMS or rescue calls, and non-emergency fire service functions.

body's normal mechanisms for heat dissipation, and the inability to release heat generated by muscular activity during firefighting (despite profuse sweating) puts firefighters at increased risk for clinically significant heat stress. Even without thermal stress from a fire, the clothing has been shown to significantly increase core body temperature during physical activity.¹¹

Typical noise exposures are of relatively short duration and high intensity, which may be different from the steady-state noise in many industrial environments. Amplified electronic or mechanical sirens are designed to be louder than background traffic noise, and are capable of sound pressure levels of 120 dB or more. The exposures to personnel riding in an ambulance or fire apparatus can exceed 100 dB. Since such exposures are short duration, the OSHA permissible exposure levels of 85 dBA may not be exceeded over an 8-hour time weighted average.^{12–14} The high rate of hearing loss in firefighters, however,

Hazard	Potential health outcome
Physical hazards	
Falls	Back and other musculoskeletal injuries, other traumatic injuries
Falling building material	
Ergonomic stressors	
Violence	
Heat and flame	Heat illness, cardiovascular demand, burns
Noise	Hearing loss
Chemical hazards	
Smoke inhalation	Inhalation injury, systemic exposure
Carbon monoxide	Hypoxia, myocardial ischemia, mental status impairment
Diesel fumes	Lung function, cancer
Hazardous materials	Systemic absorption and specific toxic effects
Psychologic hazards	
Traumatic events, shiftwork, other job stress	Post-traumatic stress disorder, suicide, sleep disturbances
	Possible link to hypertension, other cardiovascular disease
Biologic hazards	
	Tuberculosis, hepatitis, HIV, other respiratory and blood-borne infections
Other	
Motor vehicle accidents	
Traumatic injuries	

Table 18.2.1: Occupational hazards for firefighters

suggests that such short exposures may be intense enough to cause lasting damage. Pump operators, who stand next to the diesel engines that are maintained in high idle throughout incidents to power the apparatus' water delivery capability, may experience the highest overall noise exposure during a shift. A number of engineering controls have been used to reduce siren noise exposures, so that the noise exposure may vary by the type and locations of sirens used by a particular department. In addition, active noise cancellation hearing protective devices employing radio communication can reduce noise exposures due to predictable sources such as sirens, but to date are not widely in use.

Chemical exposures

Smoke from burning materials exposes firefighters to a wide range of potentially toxic gases, fumes, vapors and particulates. The most common and significant is carbon monoxide.¹⁵ The use of synthetic polymers and materials in building construction and interior furnishings since the 1930s has added to the complexity of the gases released during structural fires¹⁶ (see Chapter 19.5). The exact mixture of chemicals depends on the material that is burning as well as the temperature of the fire. Materials that contain nitrogen, sulfur, and halogens can release hydrogen cyanide, nitrogen oxides, sulfur dioxide, ammonia, and halogen acids. Silk, polyvinyl chloride, plastics, wool, and insulation can release hydrogen chloride, hydrogen fluoride, isocyanates, and acrolein.¹⁷ Other potential components of smoke include aldehydes, benzene, benzpyrenes and other polyaromatic hydrocarbons, phosgene, and

particulates.³ Until recently, training fires were often conducted using reclaimed oils from gas stations or industries and such oil fires may have contained PCBs, metals, and other contaminants. Additionally, stored chemicals like pesticides, manufacturing compounds or intermediates, and hydrocarbon fuels all produce toxic products of combustion in fires involving commercial, public and residential occupancies.

Since the 1970s, inhalation exposure has presumably decreased significantly due to the widespread use of SCBA for respiratory protection during firefighting and Hazardous Material (HAZMAT), emergency operations.¹⁸ Recent studies suggest, however, that despite the use of protective equipment, there is ongoing evidence of exposure to polyaromatic hydrocarbons and other products of combustion during firefighting.^{19,20} One reason may be the common practice of removing SCBA during overhaul operations, when the dense smoke and heat have cleared,^{21,22} despite knowledge that the density of visible or carbonaceous smoke is not correlated with toxic gas concentrations in combustion environments.¹⁷ Furthermore, recent testing of commercially available SCBAs for exclusion of weaponized chemicals by NIOSH has demonstrated that certain organic agents rapidly permeate some face pieces. HAZMAT responders use special protective equipment to provide an impermeable vapor-liquid barrier that completely encapsulates the wearer, including the SCBA. The implications for firefighters using SCBA alone for respiratory protection in fire environments with high concentrations of organic or non-polar gases require further investigation.

Most fire departments respond to HAZMAT incidents in their local jurisdictions, yet this function, when performed with proper protective equipment as described above, probably adds little to lifetime occupational chemical exposures in firefighters.^{23,24} A recent study found that even though elevated levels of PCBs and polychlorinated dibenzofurans were found on the protective suits of firefighters, there was no evidence of significant exposure.²⁵

Diesel fumes are a potentially significant hazard. Inadequate attention was paid to ventilation of fire stations when diesel engines replaced horses early in the last century. Traditionally, living and sleeping accommodations for on-duty firefighters have been located above apparatus floors with open stairwells and pole passages providing direct conduits for exhaust fumes and gases generated by the trucks. High ambient diesel emissions levels in fire station living quarters have been documented²⁶ leading to efforts to design fire stations with better separation of living quarters from apparatus bays. Many departments have also installed emissions management systems in their apparatus garages to actively vent each vehicle's exhaust. Despite availability of such solutions, many personnel are still headquartered in old construction fire stations where diesel fumes and other environmental threats persist.

Psychologic hazards

Firefighters routinely face both personal danger as well as exposure to potentially upsetting traumatic events in

others. It has been proposed that these activities would predispose firefighters to post-traumatic stress disorders and other psychologic problems.²⁷ The need for functioning at high levels of physical exertion, even in the absence of physic danger, has been associated with psychologic strain.²⁸

Biologic hazards

In their role as emergency medical responders, firefighters are at risk of exposure to blood-borne pathogens, tuberculosis, and other infectious disease agents.^{29,30} Other potential biologic hazards include mold and bacterial growth from building materials.

Motor vehicle crashes

An important cause of line-of-duty fire service fatalities is motor vehicle accidents. As with many other hazards, the risk of motor vehicle accidents differs between career and volunteer departments. Career fire departments respond to a greater number of calls, and have significant losses due to apparatus accidents. Volunteer firefighters often respond to incident scenes in privately owned vehicles, and may be at increased risk for accidents due to excessive speed and crossing of intersections without sirens or warning lights. An additional cause of apparatus accidents in the volunteer fire service involves tanker trucks. Water for firefighting must be shuttled to incident scenes in rural areas without fire hydrants by water tankers. The high center of gravity and tendency of water loads to shift have contributed to incidents of tanker vehicle rollovers and volunteer fatalities.³¹

Studies of health outcomes in firefighters

A number of studies have examined patterns of morbidity and mortality in firefighters. The results of such studies must be viewed in light of at least two important epidemiologic aspects of firefighter health. First, career firefighters generally have to demonstrate above average physical stamina and strength at the time of entry into the profession. Individuals who remain actively employed as firefighters are also likely to be healthy enough to continue performing the physically demanding job duties. There is consequently a significant 'healthy worker effect' in cohorts of firefighters, and rates of illness would be expected to be lower than the general population due to this selection bias. Secondly, exposures to chemicals and particulates during firefighting operations should have decreased in recent decades due to the increased use of respiratory protection. Changes in patterns of diseases resulting from such exposures may only emerge slowly, over decades, due to the protracted latency of many of these conditions.

Musculoskeletal disorders

Acute musculoskeletal disorders are the most common type of line-of-duty injuries for firefighters, followed by lacerations and bruises. Together, these categories accounted for 77% of all reported US firefighter injuries in 2000.⁷

Muscular sprains, strains and chronic, recurring pain are also the leading causes of lost time and disability in the career fire service.^{7,32} Back injuries are the most prevalent permanently disabling problem in most departments, accounting for over half of line-of-duty disability retirements of career firefighters.³³ The incidence may be higher in departments that provide emergency medical services.

Cardiovascular disease

As mentioned above, myocardial infarction and cardiac sudden death account for about half of line-of-duty deaths in firefighters. Workers' compensation statutes in many localities include a presumption that if heart disease or hypertension develops in a firefighter, a work-related association due to occupational stress is present. Cohort mortality studies have failed to consistently demonstrate that the rate of death from cardiovascular disease is greater than the general population,^{34,35} although an apparent absence of the healthy worker effect has been noted in firefighter cardiovascular mortality rates.

Clearly, firefighting involves periods of extreme physical exertion, with high aerobic demands and static loads. The physiologic workload of fireground tasks may exceed 15–18 METs,³⁶ and typically involves asymmetric upper body work. Carbon monoxide exposures lead to tissue hypoxia and worsened cardiovascular demand. These factors alone or in combination could potentially unmask occult coronary artery disease not detected by standard cardiac stress testing. The sporadic nature of these occupational demands, however, is not sufficient to maintain either strength or aerobic fitness, and until recently little attention has been paid to the need for vigorous, ongoing, job-specific fitness programs. A study of body mass index in firefighters found that 87% were overweight, and the obesity was correlated with increased cholesterol and blood pressure.³⁷

While the ranks of career firefighters thin rapidly over age 50, largely due to job-related disability retirements,^{32,33} volunteer firefighters may remain active into their eighth decade, serving as fire police or otherwise assisting at emergency scenes. The data show that many of the fatal, line-of-duty heart attacks occur in these older, predominantly male volunteers. Most firefighters who die of heart attacks in the line of duty have a previous medical history of coronary artery disease.⁵

Cancer

A number of cohort studies have examined malignancy-related mortality in firefighters.^{34,35,38–46} Increased standardized mortality ratios for malignant melanoma, multiple myeloma, leukemia, and cancers of the bladder, kidney, brain, and colon have been reported, although results have not been consistent among studies with respect to these cancers. Furthermore, many of these studies did not show an increasing risk with duration of employment.³ The inconsistency of these studies must be viewed in light of the variability of individual and local exposure histories and the healthy worker effect discussed earlier. About one-third of the states in the US have

presumptive occupational cancer statutes in place for firefighters.

Respiratory disorders

Despite the use of respiratory protection, firefighters continue to be at risk for respiratory effects of exposure to irritant chemicals and particulates. Severe smoke inhalation can lead to burns of the respiratory tract, pulmonary edema, and ARDS (see Chapter 19.5). Less severe exposures can cause significant irritant effects, including reactive airway dysfunction syndrome (RADS) and asthma. After the World Trade Center attacks, an increase of cough ('World Trade Center cough') and bronchial hyper-responsiveness was noted in firefighters exposed to high concentrations of particulates.⁴⁷

In addition to airway irritation and asthma, other acute respiratory effects may result from exposure to particulates and smoke. A recent case report described acute eosinophilic pneumonia in a firefighter involved in the World Trade Center disaster.⁴⁸ An increased rate of sarcoidosis has been reported among firefighters compared to emergency medical service controls,⁴⁹ but this association remains unclear.

While respiratory hazards are also encountered in responding to hazardous materials incidents, a study of hazardous material firefighters found no excess of respiratory disease compared to other firefighters.⁵⁰

Thermal injuries

The two main clinical results of heat and/or exposure in the fire service are burns and heat stress. For the past 10 years, burns have accounted for approximately 6% of firefighter line-of-duty injuries and fatalities.^{6,32,33} First degree and small, second degree burns are probably vastly under-reported in the fire service, and are common during structural and wild land firefighting.

In recent years there have been several firefighter deaths due to heat stroke during training and emergency operations. The incidence of heat-related illness or symptomatic heat stress, like small burns, is undoubtedly underestimated by fire service statistics. Prevention of heat stress is discussed further below.

Psychologic disorders

High rates of post-traumatic symptoms have been noted in firefighter populations.^{51,52} Following the 2001 World Trade Center attack, the rate of psychologic stress-related incidents among firefighter rescue workers increased 17-fold.¹ A study of firefighters with post-traumatic stress disorder complaints revealed an association of such symptoms with alcohol-related problems.⁵³ The efficacy of post-incident interventions aimed at reducing their psychologic impact on emergency services personnel is unproven.

Hearing loss

Despite the fact that firefighter noise exposures do not exceed OSHA limits when adjusted for intermittency, several studies have found that rates of hearing loss for

firefighters are in excess of what would be expected from aging alone. Due to often asymmetric exposures such as sirens on vehicles, such hearing loss may exhibit a predominantly unilateral pattern more often than in other working populations.^{54,55}

Occupational infections

Despite their risk of exposure to blood-borne pathogens, studies of public safety workers have not detected an elevated risk of hepatitis C above the background population.^{56–58} Similarly, occupational transmission of HIV or tuberculosis to firefighters appears to occur infrequently.

Occupational medicine services for firefighters

Most fire departments require physician involvement in two very dissimilar roles. These are emergency medical services (EMS) medical direction and provision of occupational medical services. Some departments also include physician officer(s), referred to as fire surgeon(s) or chief medical officer(s). These individuals may serve in EMS, occupational medical, or other advisory capacity, but are distinguished by their status as sworn members of the department and their assigned responsibilities in emergency operations. In some small, rural departments, it may be necessary for a single community physician to provide both EMS medical direction and occupational medical services, although the qualifications are different, and there may be intrinsic conflicts between the roles.⁵⁹ Some fire service consensus standards require the occupational medical provider to serve on the department's safety committee.⁶⁰ This requires a level of operational involvement that has not been typical of contract medical providers, but is consistent with plant-based industrial occupational medical models.

A key aspect of providing occupational medicine services to firefighters is an awareness of existing guidelines for medical evaluations of fire service candidates and members. The International Association of Fire Fighters (IAFF)/International Association of Fire Chiefs (IAFC) Joint Labor-Management Fitness and Wellness Initiative⁶¹ prescribes a comprehensive, annual program of medical and fitness evaluations for fire service personnel. Piloted by the fire departments in ten large, metropolitan areas in the US and Canada, this program's objectives include not only decreasing the morbidity and mortality of a career in firefighting, but also collection and analysis of the aggregate data to better define and track them. The second set of medical evaluation specifications for firefighters is published by the National Fire Protection Association (NFPA) in NFPA 1582, Standard on Medical Requirements for Fire Fighters and Information for Fire Department Physicians.⁶² These standards are regularly updated, and serve as the basis for many individual health and safety programs for firefighters.

NFPA 1582 includes a model list of essential job tasks of interior structural firefighters that can be used by medical professionals to understand the demands of the job provided it has been validated by the administration of the

contracting fire department. Efforts to merge the similar but distinct sets of requirements published by the IAFF/IAFC and the NFPA into a single, coherent standard are in progress.

Preplacement evaluations

In order to be eligible for hire, a prospective firefighter must generally pass a series of rigorous physical performance tests, requiring significant muscular strength and overall physical fitness. A preplacement evaluation by a clinician occurs after a candidate is accepted or hired by the department, but before beginning training or participating in emergency responses. The two main purposes for this initial evaluation are detection of any medical conditions that could interfere with the individual's ability to safely perform all of the essential job functions, and establishment of baseline values for a number of clinical parameters that should be followed throughout a firefighter's career.

Clinicians performing such preplacement examinations should attempt to get a detailed description of the duties required of firefighters or other members of fire departments, and customize the medical evaluation process to match the job. The most rigorous medical certification processes generally involve those whose essential job tasks include interior structural firefighting in urban environments, driving fire apparatus, and certain technical rescue specialists such as divers, flyers and others. In evaluating fitness for duty in such positions, the clinician must take into account the impact of any medical limitations on both the firefighter, as well as coworkers and the public.

Firefighters in departments that employ only defensive (exterior) fire suppression tactics, members of fire police squads, and command staff in many departments may not need to meet the same medical requirements as interior structural firefighters. Likewise, firefighters in small suburban jurisdictions may not need to be able to climb six or more flights of stairs carrying high-rise hose packs if there are no occupied structures more than three stories high.

A comprehensive discussion of the medical conditions that could compromise a firefighter's fitness for duty is beyond the scope of this chapter. Most of the potentially disqualifying conditions are readily recognized by medical providers, as they interfere with an individual's normal functioning, and it is clear that they could not routinely meet the physiologic demands of firefighting. The most common, problematic medical conditions confronted by fire department physicians include monocular vision, hearing deficits, diabetes mellitus, seizure disorders, and, of course, coronary artery disease. NFPA 1582 sets disqualification criteria for each of these conditions. The following brief discussion serves only to introduce some of the key issues related to these conditions.

New monocular vision results in impaired depth perception and narrows visual fields. These are significant concerns on the fireground, as awareness of surrounding hazards, and ability to negotiate ladders, crawl along floor joists and work on roofs are all essential job tasks. With training following loss of vision in one eye, firefighters

can compensate for their impaired depth perception, but the loss of peripheral vision should disqualify them from driving fire department apparatus during emergency responses.

Unaided hearing in noisy conditions is a medical prerequisite for safe functioning on the fireground. There are a number of sounds at various volumes and frequencies that a firefighter must perceive on the fireground. It is essential that personnel be able to hear and communicate effectively over portable radios. They must also hear and localize calls or cries in fire rescue situations. Firefighters engaged in an interior fire attack are typically notified of the need for immediate evacuation due to untenable conditions or impending structure collapse by the sounding of apparatus air horns. All of these critical sounds must be detected and understood by firefighters in an environment of high background noise. Furthermore, this must be accomplished without the use of hearing aids, as there are currently none available that are certified to work when soaked in water, and this is a common condition during fireground operations.

Both epilepsy and insulin-requiring diabetes mellitus with a history of incapacitating hypoglycemia are associated with unpredictable episodes of impaired sensorium and functioning. Many individuals with these conditions, however, are fully capable of doing the physical work required of firefighters, although considerable clinical judgment is required to clear them for full duties. The emergency response and fireground environments may increase the risk and certainly compound the consequences of sudden incapacitation due to seizure or hypoglycemia. Shift work and night responses result in personnel fatigue while busy shifts or protracted incidents requiring personal protective equipment can result in transient dehydration and irregular food intake. Photoc stimulation from flashing strobe lights together with the noise and emotional content of the fireground could serve as triggers for seizure activity. The early symptoms of hypoglycemia are indistinguishable from those experienced by many firefighters maximally exerting themselves under situational-induced catecholamine excess, and may be more likely ignored.

Coronary insufficiency or other cardiac condition that can compromise a firefighter's capacity to perform work requires comprehensive evaluation and definitive intervention. Once a diagnosis of cardiac disease has been established and treated, a candidate or firefighter can only be considered medically qualified for duty if there is no evidence of significant ongoing ischemic disease. The individual must be able to exercise to a high workload on cardiac stress testing without symptoms or electrocardiograph changes, and the left ventricular ejection fraction (LVEF) must be normal. This last requirement is a main reason for aggressive evaluation of personnel with cardiac risk factors and/or suggestive symptoms. Interventions such as revascularization, medication and modification of cardiac risk factors performed prior to actual myocardial infarction result in preservation of LVEF and may represent the difference between permanent medical disqualification and job retention for firefighters with cardiac disease.

Periodic examinations

Periodic, frequently annual, evaluations of firefighters are performed to detect early changes that could individually or in aggregate indicate interim exposures during emergency operations or failures in workplace occupational safety measures. These evaluations also screen for development of medical conditions that could compromise a firefighter's fitness for duty. OSHA requires a regular respiratory history and examination program for personnel using respirators, including SCBA, and this is conducted as part of the periodic medical evaluation in most departments. NFPA and IAFF/IAFC have developed guidelines for fire service-specific periodic examinations.

Return to duty examinations

Many fire departments also require firefighters to undergo medical evaluation prior to returning to duty following acute exposure to hazardous chemicals or certain infectious agents, after protracted absence for significant illness or injury, and prior to retirement, especially where service-connected disability may be involved. Medical and work capacity evaluation must consider the specific requirements of the individual's job. For example, following a cardiac or other systemic illness it may be advisable to refer a firefighter for exercise stress testing to ensure physiologic capacity to perform at high workloads. Prescriptive, job-specific work hardening with a physical therapist may be appropriate in some cases. It may also be necessary to recommend restricted duty for some firefighters during rehabilitation from injury or illness.

Other preventive services for firefighters

Occupational medical programs for fire departments should be more than just periodic, medical fitness-for-duty evaluations. Such programs should also help co-ordinate fitness and wellness initiatives for personnel, and should co-ordinate with fire department administrators to integrate traditional injury prevention strategies into departmental safety protocols. A physician should serve on the department's safety committee, which is mandated by NFPA 1500, Standard on Fire Department Occupational Safety.⁶⁰ In this capacity, the physician would participate in investigations of incidents that resulted in line-of-duty illness or injury to personnel, and should provide guidance for local programs requiring the use of hearing protection and vehicle restraints while riding in fire apparatus and hoods, gloves and SCBA during fire suppression.

Despite the rigorous physical fitness standards for initial hire into the fire service, many departments do not require that firefighters continue to maintain optimal physical conditioning. Inclusion of physical fitness initiatives in fire service occupational medical programs has been effective in reducing this toll in some studies.⁶³ Aerobic fitness is the best predictor of tolerance to heat,⁶⁴ adding even more incentive to fire departments to include physical fitness in their occupational medical programs. It is also vital that organized rehab sectors and procedures be established at fire incident scenes in order to rest and rehydrate crews, while sheltering them from environmental extremes, on a

rotating basis. This will decrease the morbidity associated with uncompensable heat stress, especially in unacclimated personnel. Fire department occupational medical physicians may be contractually responsible for co-ordinating with EMS physician medical directors to develop rehab sector medical protocols.⁶²

Fire department medical programs should include early access to specialty burn centers for definitive care of firefighters who sustain significant burn injuries, hyperbaric chambers for treatment of severe carbon monoxide intoxication, and other contingencies as dictated by local hazards.

Fire service occupational medical providers should maintain and compare records longitudinally in order to remain vigilant for clusters of medical conditions that may be related to a point source exposure, like a large pesticide fire, or ongoing exposure to environmental threats like asbestos, infectious organisms or noise. As in any industrial setting, such occurrences should be investigated, documented, reported as required or appropriate, and proactively mitigated where possible.

POLICE OFFICERS

As of 2000, there were 710,000 full-time sworn personnel in US state and local law enforcement agencies.⁶⁵ Police officers experience high rates of injuries and work-related fatalities. As an occupational group, however, they have not been as extensively studied as firefighters. Compared to firefighters, there is a lack of published guidelines regarding optimal occupational medicine services for police officers.

Occupational hazards of police work

Police officers, during the course of their career, encounter a variety of physical, chemical, and psychologic hazards. Many of these are similar to those faced by firefighters, and are listed in Table 18.2.2. Current understanding of the importance of these hazards and their impact on morbidity and mortality in this occupational group is limited due to a lack of carefully designed studies.

Hazard	Potential health outcome
Physical hazards	
Workplace violence	Injuries
Ergonomic stress	Back injuries
Traffic radar	? neoplasia
Chemical hazards	
Vehicle exhaust, other air pollutants	Respiratory disease
Psychologic hazards	
Traumatic events, shift work	Post-traumatic stress disorder, suicide, sleep disturbances ?Cardiovascular disease, motor vehicle accidents, sleep disturbances
Biologic hazards	
Blood-borne pathogens	Hepatitis, HIV
Respiratory pathogens	Tuberculosis, other

Table 18.2.2 Occupational hazards for police officers

Physical hazards

Police officers may experience direct physical violence such as gunshot or blunt trauma, resulting in injuries and death. In addition, pursuit of suspects may involve climbing, running and jumping, which further exposes them to risk of falls and acute musculoskeletal injuries.

Radar used for traffic surveillance is capable of emitting small amounts of microwave radiation. Actual measurements of microwave levels at the level of the testicles have indicated that exposure levels are minimal,⁶⁶ but efforts should be made to avoid excessive exposures.

Chemical exposures

Several studies have studied the effect of prolonged exposure to traffic fumes and other air pollutants for police officers engaged in traffic work. Elevated exposures to lead, polyaromatic hydrocarbons, and benzene have been reported.^{67–69}

Psychologic stress

Psychologic stressors include the need for heightened awareness of potentially life-threatening dangers for prolonged periods of time, as well as the reaction to incidents of violence and other psychologically disturbing events. Such 'critical incidents' are considered to be a major risk factor for impaired psychologic functioning, including sleep disturbances and decreased functioning.⁷⁰ They are also potentially risk factors for cardiovascular conditions and motor vehicle accidents.

Infectious risks

Infectious disease risks encountered by policemen are similar to those reported for other emergency first responders, and include tuberculosis, hepatitis, and HIV exposures.^{29,30,71,72}

Studies of health outcomes in police

Similar to firefighters, it is likely that studies of police cohorts are affected by both selection bias and the healthy worker effect. It has been noted that police workers differ anthropometrically from the general population, being taller and heavier than other occupational groups.⁷³ The level of physical conditioning required for entry into police work could select for individuals with lower overall risk for chronic disease, making it more difficult to detect occupation-specific increases in disease rates.

Cardiovascular disease

The psychologic stress experienced by police officers may lead to an increased risk of cardiovascular disease. As with firefighters, many workers' compensation statutes include presumptive compensation for heart disease or hypertensive conditions developing during the course of a police officer's career. While it seems biologically plausible that the psychologic stress of police work could lead to sympathetically mediated elevations in blood pressure and development of cardiovascular complications, there

has been insufficient study of this association, and the existing studies provide conflicting results. A study of Iowa police officers found that the reported rate of cardiovascular disease was increased compared to the general population,⁷⁴ while a study of vital statistics found an increased risk of ischemic heart disease associated with the police profession.⁷⁵ A study of police officers in Rome did not demonstrate an elevated risk of cardiovascular mortality.⁷⁶

Musculoskeletal disorders

Other occupational hazards linked to police work include back injuries and other musculoskeletal injuries due to ergonomic hazards. However, it is not clear that the overall risk and incidence of such injuries are greater than the general population. A 40-year follow-up study of a police cohort did not find an excess of death due to all accidents compared to the general population.⁷⁷

Cancer

A recent report of a cancer cluster in police discussed the possibility of cancer effects due to police radar. Concern has been raised about risk of testicular and brain tumors due to microwave radiation from radar devices.⁷⁸ There is a lack of definite scientific evidence to support such an association (see Chapter 33)

Psychologic disorders

A study of 551 police officers found that while critical incidents predisposed to nightmares, the general work environment was associated with increased sleep disturbances compared to a reference population.⁷⁹ In a study of police work and aging, maladaptive behaviors such as gambling and drinking were associated with perceived work stresses.⁷⁹ A study of police officers who had experienced traumatic events found that 7% met criteria of post-traumatic stress disorder based on a structured interview, while 34% had post-traumatic stress symptoms.⁸⁰ Psychologic stress may also lead to an increase in the risk of suicide for police officers. A study which compared police workers to municipal workers found a relative risk of 2.65 for suicide over homicide and accidents combined;⁸¹ however, a recent review of studies of suicide and police officers did not find strong evidence of an increased risk.⁸²

Occupational medicine services for police

Clinicians providing occupational medicine services for police officers face many similar issues to their work with firefighters. There is a need for both initial preplacement screening to identify medical conditions that could interfere with the demands of the job, periodic medical surveillance for work-related conditions, and preventive programs to reduce morbidity due to medical and psychologic problems. For example, concern that acute exposure to traumatic events could lead to the development of post-traumatic stress disorder has led to the development of mental health interventions such as critical

incident debriefing⁸³ although the effectiveness of such interventions is uncertain.⁸⁴ Ongoing programs to maintain physical fitness and reduce risk factors for cardiovascular disease have also been initiated. However, many police departments have not instituted such preventive services, and there is a dearth of published guidelines for police health and safety relative to those promulgated for firefighters.

SUMMARY

Occupational medical programs for fire and police department include initial and periodic medical evaluations to identify conditions that could interfere with a firefighter or police worker's ability to safely perform their duties. Occupational medical providers should also be actively involved in safety programs, including serving on health and safety committees and collaborating with administrators on policies and procedures relating to prevention of line-of-duty injuries and fatalities. Assistance in development of rehabilitation sector protocols, hearing conservation programs, physical fitness programs and investigating incidents involving injuries or deaths of firefighters and police, as well as clusters of suspected occupational disease, are examples of occupational medical support for these individuals. Ongoing research to better define the most important risks and adverse health outcomes for these professions will help focus future efforts toward enhanced prevention.

Chapter 19

Diseases of the Lung and Pleura

19.1 Approach to the Patient/Diagnostic Methods

Nargues A Weir, Mridu Gulati, Carrie A Redlich

INTRODUCTION

This chapter provides an overview of the different modalities available to assess patients with potential occupational or environmental respiratory illnesses. Regardless of the suspect etiology, a respiratory disease or symptoms should be characterized using the essential instruments of a pulmonary evaluation, including special features of the history and physical examination. Crucial to the assessment is also the understanding and implementation of radiography and lung function assessment. The chapters following will provide detailed discussions of specific pulmonary diseases of occupational or environmental etiology. This chapter will introduce the reader to the fundamental tools used to evaluate such respiratory diseases. Several recent publications provide a more detailed discussion of radiographic, physiologic, and pathologic methods used to evaluate occupational and environmental lung disorders.¹⁻⁵

HISTORY

As with any occupational or environmental disease, the history is critical in evaluating a patient with a respiratory disorder. The causal occupational or environmental agent may be obvious from the initial assessment, but it is not uncommon to have a non-specific respiratory complaint without an evident etiology. The clinical history is important in better characterizing the disorder and its progression. A thorough occupational history should chronicle previous jobs, job titles, descriptions of job activities, years of employment, and potential toxins at each job, with a more detailed focus on the jobs most likely pertinent to the pulmonary problem. The duration and severity of the respiratory complaints, along with the presence of associated symptoms, should be determined.

As with other occupational and environmental diseases the temporal relationship between exposures of concern and symptoms or disease is critical. For most pneumoconioses the onset of respiratory illness occurs many years after the onset of exposure. Change in symptoms during vacations or weekends should be documented. Details of personal protective gear should be noted, with attention to proper fitting and appropriate use of equipment such as respiratory protective devices, as well as a description of the general ventilation and overall hygiene in the workplace. It is helpful to ask patients whether they believe their respiratory disorder is related to their job or environment. Presence of similar symptoms among coworkers should also be pursued.

In addition to the work history, an environmental history including the home environment and hobbies should be explored for potential exposures that may cause or exacerbate the respiratory disorder. The presence of pets, travel history, tobacco use, and military history should also be determined.

Obtaining a thorough history is not always possible. The latency of many respiratory diseases due to occupational exposures can be quite long, making it difficult to document important past clinical or exposure information. Medical records can be of assistance in such cases. These records may establish onset and duration of symptoms or potentially clarify the work history, as well as providing objective data such as previous radiographs and physiologic tests. This information may clarify temporal associations and providing a comparison for any current abnormalities found during the evaluation of a respiratory disorder. All of these clues may play an important role in establishing cause.

PHYSICAL EXAMINATION

As with other occupational or environmental diseases the physical findings in the patient with respiratory disease of occupational or environmental etiology rarely differ from the examination performed in non-exposure settings. The physical examination typically is most useful in detecting non-occupational disorders that may be causative of or contributing to the patient's respiratory condition, such as cardiac disease, connective tissue disorders or sinusitis. In addition to the lung and chest exam, particular attention should be given to the heart, skin, mucosal surfaces, and extremities. The physical exam can also help assess for severity of disease, i.e., breathlessness, cyanosis or clubbing.

Chest radiographs

Conventional chest radiography

Radiography is critical in the evaluation of the patient with respiratory complaints. Conventional chest radiography is the initial step in the radiographic assessment and can evaluate the lung parenchyma, pleura, hilum, and mediastinum. Patients with airway disease, such as asthma, rhinitis or bronchitis, as well as patients with early interstitial lung disease may have normal radiographs. Parenchymal opacities are a common feature of the pneumoconioses and other environmentally induced lung disorders, as well as non-occupational disorders.

Due to the variability in radiographic parenchymal and pleural changes, the International Labor Organization (ILO) classification was adopted to provide a standardized uniform system of reading chest radiographs and has enabled increased inter- and intra-observer reliability in epidemiologic investigations and in the clinical evaluation of patients. In the United States accreditation for the ILO classification is administered by NIOSH. The most current guidelines were adopted in 2000.¹ The ILO classification relies mainly on the posteroanterior radiograph at full inspiration on a 14 × 17 inch film and requires that readers have available to them the standard set of radiographs for comparison. Additional views may be obtained to aid the clinical assessment; however, these films are not incorporated into the classification. Film quality is also evaluated and graded as part of the system: grade 1 corresponds with excellent technique and quality, and grade 4 signifies an unreadable film.

Parenchymal opacities are categorized by size, shape, profusion, and extent of involvement. Size of the opacity is detailed as small, measuring up to 1 cm in diameter, or large, measuring greater than 1 cm. Small opacities are further subclassified according to their shape. Rounded opacities are represented by *p*, *q*, and *r* if they are up to 1.5 mm, 1.5–3 mm, and 3–10 mm in diameter respectively. Small irregular opacities are represented by *s*, *t*, and *u* to correspond with reticular or linear opacities of up to 1.5 mm, 1.5–3 mm, and 3–10 mm respectively. Not infrequently, there is more than one type of opacity seen on a radiograph. The system allows for two letters (e.g., *s/p*) describing the primary or prominent opacities, as well as the secondary opacities observed.

The classification arbitrarily divides each lung into three zones. The system allows designation of which zones are affected by the opacities, and the scoring system averages those zones most heavily involved. A profusion score indicates the concentration or aggregation of the opacities and is determined by comparison with a standard set of radiographs. The four main categories depicting profusion (0, 1, 2, 3) range from normal (category 0) to most affected (category 3), from which a 12-point scale is derived, ranging from 0/c (less than the profusion of a standard 0/0 radiograph) to 3/+ (more than the profusion on the standard 3/3 radiograph) (Figs 19.1.1 to 19.1.3). The following grid is used to score radiographs:

0/–	0/0	0/1
1/0	1/1	1/2
2/1	2/2	2/3
3/2	3/3	3/+

Large opacities (> 10 mm) are designated as category A, B or C depending on size. Large opacities usually are seen only in the setting of silica and coal dust exposure (Fig. 19.1.4).

Pleural abnormalities are also scored by the ILO classification. This is particularly important in the assessment of asbestos exposure. These abnormalities are characterized according to thickness, location (focal or diffuse), extent, presence or absence of calcification, and presence or absence of an effusion. Also, involvement of the chest wall, diaphragm or costophrenic angle is noted. The extent of

Figure 19.1.2: Category 1/1 film of small irregular opacities predominantly in lower lung fields. (Courtesy of ILO U/C International Classification of Radiographs of Pneumoconiosis.)

involvement and degree of pleural calcification are scored, with grade 3 being the most severe changes.

Computed tomography

While the plain chest radiograph remains an essential part of a diagnostic evaluation of occupational lung disease, computed tomography (CT) can provide clinicians with additional key information in selected patients. The CT

Figure 19.1.3: Category 3/3 film of small irregular opacities throughout both lung fields. (Courtesy of ILO U/C International Classification of Radiographs of Pneumoconiosis.)

Figure 19.1.4: Chest x-ray study demonstrating progressive massive fibrosis (category C large opacities) and egg shell calcification of lymph nodes. (Courtesy of ILO U/C International Classification of Radiographs of Pneumoconiosis.)

scan findings of pneumoconioses such as asbestosis or silicosis typically follow the same patterns as seen on plain chest radiographs. However, the higher resolution of CT can provide a more sensitive and specific radiologic assessment of various abnormalities, including diffuse interstitial lung disease, lung masses, mediastinal and hilar lesions, and

pleural abnormalities. Certain findings on CT may provide diagnostic clues, but less commonly confirm a specific occupational etiology not suspected by plain chest radiograph. CT can also identify diseases that can coexist, such as emphysema and interstitial fibrosis.

Conventional CT is performed on the supine patient during an inspiratory breath-hold. Cross-sectional images are taken at 10 mm intervals and are collimated from the apex to the base. Two-dimensional imaging enables radiologists to more accurately and confidently identify the presence of abnormalities. High resolution computed tomography (HRCT) further modifies conventional CT by utilizing thin collimation (1–2 mm thickness). These slices are reconstructed at high spatial frequency, reducing the artifact seen with conventional CT. This method provides for sharper resolution and superior characterization of parenchymal abnormalities and is preferred over conventional CT in assessing diffuse lung disease. In addition, prone and end-expiratory HRCT images may further clarify early findings of interstitial lung disease and air trapping found in airways disease.

Radiologists use specific terminology to describe pulmonary abnormalities involving the alveoli, airways, and interstitium. For example, ground glass refers to a hazy opacity that does not obscure associated pulmonary vessels and is typically seen with an acute alveolitis, such as hypersensitivity pneumonitis (Fig. 19.1.5). Alveolar consolidation typically is more localized and obscures the underlying vascular structures. CT can define the extent of consolidation but is less useful in distinguishing the underlying cause. Honeycombing refers to extensive cystic radiolucencies and fibrosis, and typically is seen in advanced stages of interstitial lung diseases such as idiopathic pulmonary fibrosis or asbestosis (Fig. 19.1.6). CT findings of a specific disease can vary greatly, depending in part on the stage and severity of the disease. For example, a variety of HRCT patterns are associated with hypersensitivity pneumonitis including

diffuse ground glass, multiple small nodules, honeycombing, and emphysema (discussed further in Chapter 19.6).

CT scans are especially useful in identifying early radiologic abnormalities in workers with normal chest radiographs. Thickened intralobular lines, subpleural curvilinear lines, and basilar abnormalities can identify early fibrosis in asbestos workers with normal chest radiographs⁶ (Fig. 19.1.7). In a study of former coal miners with normal chest radiographs, more than half of the coal miners had nodules on HRCT.¹ The sensitivity of HRCT is substantially better than plain chest radiographs in hypersensitivity pneumonitis.^{7,8} CT is also more sensitive than chest radiography in detecting emphysema,⁹ and can identify mixed obstructive and interstitial processes.

Conventional CT may have a role in lung cancer screening. The National Cancer Institute sponsored trial of CT for lung cancer screening will provide further information regarding the utility of this screening modality in smokers with occupational exposures.¹⁰

Investigators have yet to establish a standard similar to the ILO classification system for HRCT. However, inter- and intra-observer agreement is superior⁶ to conventional chest radiography. Several scoring systems have been proposed.^{11,12} How well HRCT reflects lung function likely varies, but studies suggest that HRCT correlates with lung function in both obstructive and restrictive diseases.¹²⁻¹⁴

Although an important diagnostic modality, CT and HRCT have not replaced the normal chest radiograph. Despite limitations, chest radiography is widely available, relatively inexpensive, and remains the cornerstone of surveillance and screening programs, as well as being the initial imaging modality in evaluating clinical patients.

Positron emission tomography

While not an integral diagnostic modality in the assessment of occupational pulmonary disease, positron emission tomography (PET) may have an increasingly important role in the evaluation of malignancies related to work exposure. Chest radiography and CT are useful in the primary detection of nodules, but PET scan may better differentiate malignant from benign lesions. Subjects are injected with fluoro-deoxy-glucose (FDG), which is taken up by metabolically active lesions such as tumors. While PET can be more accurate in identifying cancer than CT, it has limitations.^{15,16} PET's accuracy decreases significantly with smaller lesions (less than 10 mm) and with less metabolically active tumors. Inflammatory process can result in increased FDG uptake, raising the concern of false-positive results. Therefore, while the role of PET in the evaluation of suspicious lesions continues to evolve, its current application only complements the use of CT scans.¹⁵

Summary

In conclusion, radiography of the chest is a key part of the evaluation of occupational and environmental lung diseases. Familiarity with the different modalities, their strengths and shortcomings will help the provider make the appropriate test selection. Caution must be exercised, however, in the interpretation of these radiographs, and the radiography information should be synthesized with the clinical, occupational, physiologic, and other data obtained.

Physiologic assessment

Spirometry

The measurement of lung function is an important tool in the evaluation and management of patients with potential occupational and environmental lung diseases, impairment and disability assessments, as well as in the screening and surveillance of exposed workers. This important topic is discussed in greater detail in several recent publications.^{2-5,17,18} The use of pulmonary function testing to

assess pulmonary impairment is discussed in Chapter 8. Spirometry, a measure of dynamic lung volumes based on the forced vital capacity maneuver, is most commonly performed. The forced vital capacity (FVC), the forced expiratory volume in one second (FEV_1), and the FEV_1/FVC ratio are the measures most commonly evaluated from the FVC maneuver. Peak expiratory flow rate (PEFR), maximal mid-expiratory flow (MMEF or FEF_{25-75}) are also typically recorded. Spirometry can be performed in most outpatient settings as long as attention is paid to technique, instrument calibration, qualified technicians, equipment maintenance, and proper recording of collected data. Similar standards for the performance, standardization, and interpretation of spirometry are published by the American Thoracic Society and the European Respiratory Society.¹⁹⁻²²

Interpretation of the test depends on the quality of the test, normative values, and criteria for determining abnormality. Reference values are typically derived from large population-based data sets, which traditionally included non-smoking, healthy Caucasians. Spirometry values are corrected for age, height, gender, and race. At extremes of height and age, these population values are less representative of the normal variation present. Individuals of Asian or African origin on average have lower FEV_1 and FVC than European and North American whites after adjusting for other factors, but normative data for various ethnic groups are limited. The third National Health and Nutrition Examination Survey (NHANES III) provided population data for more than 7000 healthy, non-smoking African-Americans, Mexican-Americans, and Caucasians as a more accurate estimation of normal spirometric values.²³ The American Thoracic Society (ATS) and American College of Occupational and Environmental Medicine (ACOEM) recommend using these reference values if possible. Population data for Asian-Americans and other ethnic groups are more limited. Underlying lung disease as well as suboptimal test performance can result in unacceptable spirograms and greater intra-subject test variability.²⁴

Spirometry measurements are used to distinguish obstructive from restrictive or mixed disorders. The ratio of FEV_1/FVC is the best indicator of the presence of airflow obstruction. Because the FVC may be reduced with severe obstruction (due to trapping of gas), the severity of the obstruction cannot be reliably determined from this ratio. FEV_1 and FVC measurements that are $> 80\%$ of predicted values and FEV_1/FVC ratio $> 70-75\%$ are typically considered normal. However, the use of a lower limit of normal based on 5th percentile rather than a fixed cutoff is recommended by the ATS.²² The severity of the obstruction is assessed by the degree of reduction in FEV_1 . The pattern of reduced FEV_1 and FVC with a normal FEV_1/FVC ratio is suggestive of restrictive impairment. Reduction in MMEF or FEF_{25-75} is sensitive for mild airflow obstruction, but not very specific nor reproducible, and therefore the ATS does not recommend diagnosing obstruction solely on the basis of a reduced mid-flow rate.²²

The flow-volume spirograms obtained during spirometry are also very helpful in determining the presence and severity of disease. Obstructive disorders result in concav-

ity of the expiratory loop, with prolonged expiratory time seen in more advanced disease. Restrictive disorders result in a typical narrow, compressed spirogram. Information regarding the presence of upper airway obstructions such as vocal cord dysfunction can also be obtained from flow-volume loops. The interpretation of the respiratory spirometry is complementary to the evaluation of spirometry measurements.

In the setting of obstructive disease, reversibility of airflow obstruction can be assessed by performing postbronchodilator spirometry. A 12% increase in FEV_1 and a 200 ml increase in either FEV_1 or FVC are considered as a clinically significant bronchodilator response.²⁵ Bronchodilator response indicates airway hyper-responsiveness or asthma.

Lung volumes

Lung volume measurements are useful in assessing diseases with altered lung volumes, such as interstitial diseases or neuromuscular disease. Spirometry provides a reliable estimate of the vital capacity, but is unable to measure the volume remaining in the lungs at the end of expiration. Lung volumes can be measured using gas-dilution techniques or body plethysmography. The former is more commonly used and involves the helium or nitrogen washout methods to calculate the patient's functional residual capacity (FRC), which is used to determine the total lung capacity (TLC). Body plethysmography involves a chamber in which the patient sits; lung volumes are measured as a function of the pressure the patient generates against a closed mouthpiece, and provides a more accurate measure of lung volumes in severe obstructive disease, especially in bullous emphysema. However, availability is limited due to the space necessary for the equipment and the expense. TLC is used to both diagnose and assess the severity of restrictive disorders. Lung volumes can also document air trapping and hyperinflation.

Gas transfer

The gas exchange capacity of the lung can be measured using several techniques. Oxygen's ability to cross the alveolar-capillary membrane and be carried by blood is dependent on several factors, including surface area available in the lung, the thickness of the alveolar-capillary membrane, blood flow to the lung, and the hemoglobin concentration of the blood. The diffusion capacity of carbon monoxide (DLCO), a gas with much higher affinity for binding to hemoglobin, is most commonly measured since CO transfer is limited by diffusion only. The DLCO is usually determined by single-breath techniques. The DLCO is adjusted for hemoglobin concentration and alveolar volume. In its 1995 spirometry update the ATS reiterated that reference values for DLCO are problematic.²⁶ The lack of uniformity is due to large differences between population data available for comparison. Therefore, the ATS recommends using reference equations that are appropriate for the population being studied.²⁶ Finally, DLCO measurements will vary according to which calculation

is utilized by the laboratory. Consistency in use of one method will lead to reproducible results.

A reduced DLCO can be an early manifestation of interstitial lung disease, such as asbestosis, silicosis or hypersensitivity pneumonitis. This reduction may precede other evidence of restrictive disease, making it more sensitive than lung volume or chest radiography in early disease.¹³ Decreased DLCO also occurs with severe obstructive disease, pulmonary vascular disease, smoking, and anemia, among other causes. Increased DLCO is seen with asthma exacerbations, pulmonary hemorrhage, polycythemia, and altitude, in addition to other etiologies.

Gas transfer can also be assessed by measuring oxygenation by non-invasive oximetry or by arterial blood gas sampling. The former involves a near-infrared light that measures oxyhemoglobin and can reliably report arterial oxygen saturation within 3–5% of actual saturation. Its accuracy decreases below 70% saturation, and it cannot distinguish between oxyhemoglobin and other reduced hemoglobins. In the outpatient setting, it is a simple method of estimating gas transfer in the resting or ambulating patient. Arterial blood gas sampling is helpful in accurately measuring the partial pressure and saturation of oxygen, but involves arterial puncture. It also allows for calculation of the alveolar–arterial oxygen gradient and carbon dioxide.

Peak flow measurement

Peak expiratory flow rates (PEFRs) can be helpful in evaluating patients with possible work-related asthma and can be measured easily using portable inexpensive PEF meters (discussed further in Chapter 19.2). Serial PEFR measurements can be used to document increased diurnal variation (typically greater than 20%) and changes in PEFR in relationship to exposures. Optimum length and frequency of measurements at and away from work is unclear and has to take into account practical considerations. Careful patient education and compliance are essential. Three measurements should be recorded for each occasion, and concomitant medication use, symptoms, and exposures noted in the log. The patient has to still be in the workplace of concern, and clear improvement away from exposure is more likely earlier in the course of the disease. At least four daily measurements for a minimum of 2–3 weeks are likely necessary to be useful, including several consecutive days away from work, which can be problematic.

Problems with the use of PEFRs can include compliance, reproducibility, proper technique in performing the maneuver, and falsification of records.^{25,27} Electronic devices can address many of these issues but are not widely available and are more costly. In addition, there are no uniformly accepted criteria for the interpretation of PEFRs, although qualitative interpretation has been shown to be comparable to quantitative analyses.²⁸ Computer programs are being developed to assist with interpretation.²⁵ Despite these limitations, careful records showing a clear pattern of work-related changes in PEFRs strongly support a diagnosis of work-related asthma, and have been found to have better sensitivity and specificity than spirometry.²⁹ Given that specific inhalation challenge is

rarely available or feasible, PEFRs are usually the best hope of documenting work-related changes in lung function.

Cardiopulmonary exercise testing

Cardiopulmonary exercise testing (CPET) has a potentially informative role in the functional assessment of selected patients with suspected occupational respiratory disorders when specific questions persist after more standard cardiac and pulmonary evaluation. CPET can help evaluate unexplained dyspnea and exercise intolerance, and distinguish cardiac from respiratory causes of dyspnea. CPET can also provide objective data quantifying the degree of impairment. The indications for, methodology, and interpretation of CPET were thoroughly reviewed in a recent American Thoracic Society/American College of Chest Physicians statement on CPET.³⁰

During CPET, a subject is asked to exercise on a cycle or treadmill at increasing work loads while electrocardiogram, heart rate, blood pressure, O₂ uptake from the air, and CO₂ output from the body and oxygenation (arterial blood gas measurements or oximetry) are monitored. Evaluation of the physiologic data derived from CPET can usually clarify whether the patient's exercise is limited by cardiac or pulmonary abnormalities or deconditioning. For example, Agostoni evaluated dyspnea in asbestos workers with a high prevalence of asbestosis (over 50%) and reported that almost 40% of the workers had a cardiac rather than respiratory exercise limitation.³¹ The ATS and ACCP have endorsed a set of guidelines using pulmonary function testing as well as cardiopulmonary testing to classify the level of functional impairment based on VO_{2max}.³⁰ For most patients with occupational lung disorders respiratory impairment can be assessed with routine pulmonary function testing. CPET may be indicated when such testing does not appear to explain the patient's symptoms or adequately assess the degree of impairment. CPET is labor intensive and costly and should be used only when there is a clear indication.

Bronchoprovocation testing

Bronchoprovocation testing can provide useful information in the evaluation of patients with asthma or asthma-like symptoms (discussed further in Chapter 19.2). Methacholine or histamine challenge testing to assess non-specific bronchial hyper-responsiveness importantly can clarify the diagnosis of asthma in patients with normal spirometry. Serial changes in bronchial hyper-responsiveness in relationship to work can be used to support a diagnosis of occupational asthma. Specific inhalation testing is considered the gold standard for the diagnosis of immune mediated occupational asthma, but is rarely performed in most countries due to technical, financial, and practical considerations (discussed in Chapter 19.2).

Immunology testing

Immunology tests that demonstrate specific IgE antibodies or positive skin reaction to high molecular weight sensitizing

agents can be helpful in confirming exposure and demonstrating immunologic sensitization to a specific agent, but are frequently not available, and by themselves do not confirm a diagnosis of occupational asthma (discussed further in Chapter 19.2). Such testing is typically less helpful with small molecular weight sensitizing agents, and has no role in the evaluation of RADS or irritant-aggravated asthma. Specific IgG antibodies in the evaluation of suspected hypersensitivity pneumonitis or asthma are typically found in asymptomatic exposed workers as well as those with disease, and more likely reflect exposure in most settings (see Chapters 19.3 and 19.6). However, they can be helpful in confirming sufficient exposure to the agent to generate a humoral immune response.

Bronchoscopy and surgical lung biopsy

Bronchoscopy and surgical lung biopsy can aid in the investigation of occupational and environmental interstitial disorders under certain circumstances. Several recent publications review the mineralogic analysis of lung tissue and bronchoalveolar lavage (BAL) specimens in greater detail.^{3,4,32} Transbronchial biopsies yield small tissue samples that are most helpful in diagnosing granulomatous interstitial diseases, such as chronic beryllium disease or hypersensitivity pneumonitis. Such biopsies provide only limited amounts of lung tissue architecture for pathologic examination or mineralogic analysis. BAL cell analysis can aid in the evaluation of selected disorders such as hypersensitivity pneumonitis or chronic beryllium disease, for which the beryllium lymphocyte proliferation test is diagnostic (see Chapters 19.6 and 19.7).

Transbronchial biopsy and bronchoalveolar lavage are often insufficient to make a pathologic diagnosis of occupational lung disease. Lung biopsy is typically not needed when there is a clear exposure history and the clinical and radiographic presentation is characteristic of the pneumoconiosis caused by that exposure. However, lung biopsy can be helpful when the history is unclear, the individual is unaware of exposure or the presentation is atypical. In obtaining a lung biopsy, thorascopic or open procedures can be performed, with the former being less invasive. Lung biopsy provides superior size specimens for histologic and mineralogic analysis. The information obtained should be used in conjunction with the exposure history and other information known concerning the patient. Physicians should communicate in advance with pathologists to ensure that specialized analytic techniques are applied. At times pathologic examination may suggest an unanticipated diagnosis. For example, the presence of poorly formed non-necrotizing granulomas and lymphocytic interstitial infiltrates characteristic of hypersensitivity pneumonitis in a patient presumed to have usual interstitial pneumonitis may uncover unsuspected exposure to an agent associated with hypersensitivity pneumonitis.³³

Light microscopy will demonstrate the pathologic changes, such as fibrosis or honeycombing, and can detect large, colored particles such as asbestos bodies or coal. Iron staining can better detect asbestos bodies. Light polarization

techniques will detect birefringent silica particles, talc, and mica. X-ray diffraction and atomic absorption spectroscopy can detect minerals and elements such as different forms of silica, beryllium, titanium, and aluminum. Electron microscopy may help identify inhaled particulates and chemically similar fibers such as talc and anthophyllite asbestos, and can also provide important quantitative data.³²

These techniques have limitations. The presence of a specific substance confirms exposure to that substance but does not prove causation. The concentration found in the lung may not reflect actual exposure, depending on issues such as clearance, durability, and solubility of the substance. Quantitative advanced techniques are not routinely available and standardization of techniques or 'normative' values are frequently limited. Regardless of these limitations, histopathologic examination and mineralogic assessment of lung biopsies may be invaluable in the diagnostic workup of suspected occupational lung disease.

19.2 Occupational Asthma

Susan M Tarlo, Moira Chan-Yeung

INTRODUCTION

Occupational asthma (OA) is defined as a disease characterized by variable airflow obstruction and/or airway hyper-responsiveness due to causes and conditions attributable to a particular working environment and not to stimuli encountered outside the workplace.¹ Agents can give rise to OA through immunologic and non-immunologic mechanisms. Pre-existing asthma aggravated by work exposure is usually considered as distinct from OA. However, the resulting disability to the worker can sometimes be as severe in asthma aggravated at work as for those with OA. Both OA as defined above and pre-existing asthma aggravated by work exposure can be grouped together as work-related asthma but it is important for the physician to make as accurate a diagnosis as possible since the management implications in respect to further work options often differ with the different forms of work-related asthma.

This section focuses on OA caused by sensitization to a substance and OA caused by exposure to high-level irritants encountered in the workplace. Work-related aggravation of asthma will also be discussed although there have been few studies to document the prevalence or optimal management of this condition. Asthma-like syndromes such as byssinosis are addressed separately in Chapter 19.3.

CAUSES

Sensitizer-induced OA (immunologically mediated)

Over 300 agents in the workplace have been implicated in causing asthma.² Table 19.2.1 summarizes some of the commonly recognized agents and workplaces associated with immune-mediated OA. These agents can cause asthma by immunoglobulin IgE-dependent or IgE-independent mechanisms. Although many of these have been confirmed by specific challenge tests, others have been less well investigated. Such a list serves a useful function in alerting physicians and other health professionals that their patients may be suffering from OA if they were exposed to one of the agents. Because new substances are introduced into industries, the absence of previous reports of association should not rule out the possibility of sensitizer-induced OA if diagnostic evidence is strong.

Irritant-induced OA (non-immunologically mediated)

The best example of occupational asthma caused by non-immunological mechanisms (i.e. irritant-induced asthma) is reactive airways dysfunction syndrome (RADS),³ arising from exposure to a single, high level of exposure to irritant gases, fumes, and smoke. Any chemicals, irritant gases, fumes, and smoke, if present at very high concentrations,

can give rise to RADS. There remains controversy as to whether moderate exposures to similar irritants can also induce new onset of asthma. Some examples of irritants which have been reported to cause RADS are given in Table 19.2.2.

Aggravation of asthma

Workplace aggravation of asthma can also be caused by irritants such as those listed in Table 19.2.3, but at exposure levels which can be far less than that usually associated with RADS. The reason is that the presence of airway hyper-responsiveness is a feature of established asthma (occupational and non-occupational) so that relatively low levels of irritants (both in workplace settings and outside the workplace) can provoke bronchoconstriction. This is illustrated in the laboratory setting by the increased responsiveness of asthmatics to inhaled histamine, methacholine, cold or dry air. In the workplace, this response may be provoked by second-hand smoke, dusts, fumes, and sprays, as well as by cold air, dry air and exercise – even in exposures low enough that they would not provoke symptoms in non-asthmatic workers.

PATHOPHYSIOLOGY

The pathophysiology of OA has been reviewed in depth by Fabbri and colleagues.⁴

Sensitizer-induced OA

Both environmental and genetic factors interact in the development and progression of asthma. Sensitizer-induced asthma results from a complex pathogenic cascade involving a number of different inflammatory cells and mediators. Exposure to inhaled allergens (which can include proteins and chemicals) results in sensitization to the allergen, chronic airway inflammation, and hyper-reactivity. Th2-like CD4 T cells (secrete IL-4, IL-5, and IL-13) play a key role in recognizing antigens and coordinating the complex acute and chronic asthmatic responses, including IgE production by B lymphocytes, airway inflammation and airway remodeling. Numerous mediators, including cytokines, growth factors, chemokines, leukotrienes, and reactive oxygen species are produced by a variety of lung cells, including epithelial cells, monocytes, mast cells, and lymphocytes. These mediators likely amplify recruitment of inflammatory cells such as eosinophils, basophils, neutrophils, and lymphocytes, as well as promoting airway remodeling. Active participation of the airway epithelium and oxidative stress in this process is an emerging concept.

High molecular weight compounds (>5 kDa) include flour, laboratory animal proteins, and detergent enzymes. They are usually proteins or polysaccharides, and induce

Agent	Common sources of exposure
High molecular weight agents	
Animal-derived material	Animal, poultry and insect work, veterinary medicine, fishing and fish processing, laboratory work
Dander	
Excreta	
Secretions	
Serum	
Plant-derived material	
Flour	Bakery
Grain	Grain elevator and terminal and feed mill
Castor bean	Oil manufacture
Coffee bean	Food processing
Wood dust	Sawmill, carpentry, furniture work
Vegetable gum	Printing
Psyllium	Healthcare
Latex	Latex
Enzymes	
α -amylase	Bakery
Papain	Food processing
Alcalase	Pharmaceutical industry
<i>Bacillus subtilis</i> derived enzyme	Detergent enzyme industry
Low molecular weight agents	
Spray paints	
Toluene diisocyanate	Manufacture of plastic, foam insulation
Dimethylphenyl diisocyanate	
Hexamethylene diisocyanate	Automobile spray paint
Wood dust	
Western red cedar	Sawmill worker, carpenter, furniture maker
Acid anhydride	Users of plastics, epoxy resins
Biocides	
Formaldehyde	Healthcare workers
Glutaraldehyde	
Chloramine T	
Colophony – fluxes	Electronic workers
Irritant agents	
Chlorine	Pulp and paper mills
Acetic acid	Hospital setting
Isocyanates	Spray paint
For further information please refer to reference 2.	

Table 19.2.1 Selected agents that cause immunologically mediated occupational asthma

Agents (with high-level exposures)	Exposure example
Volatile diisocyanates, e.g., TDI	Spills in polyurethane foam manufacture
Chlorine spills (puffs)	Paper mills
Acid spills, e.g., acetic acid	Hospital workers, metal platers
Hypochlorite fumes	Accidental mixing of bleach and ammonia while cleaning
Chemical fires	Industrial settings, firefighters
Calcium oxide	World Trade Center collapse with exposed aid workers and building occupants
Nitrogen oxides	Silo gas
Welding fumes	Welders
Tear gas	Police officers
Spray paint	Paint sprayers
Metam sodium	Pesticide use

Table 19.2.2 Selected causes of irritant-induced OA

Agent	Exposure example
Cigarette smoke	Bars or restaurant workers
Fumes from cleaning agents	Domestic cleaners
Dusts	Cleaners, factory workers, construction workers
Paint	Painters, secondary exposure during workplace renovations
Cold air	Outdoor workers in cold winter climates; grocery workers near refrigerators/freezers
Exercise	Manual workers
Any irritants from Table 19.2.2, even at relatively low levels of exposure	As in Table 19.2.2

Table 19.2.3 Common triggers to work-related aggravation of asthma

specific IgE antibodies that mediate the asthmatic response. These agents often affect atopic subjects and IgE specific antibodies can be detected in most affected asthmatics.

Low molecular weight agents such as platinum, anhydrides, and isocyanates likely act as haptens, combining with amino groups on proteins to form an antigen. The asthmagenic potency of a compound may be determined to a certain extent by its chemical structure. Some low molecular weight agents such as platinum induce specific IgE antibodies, similar to large molecular weight agents. Other low molecular weight compounds such as diisocyanates and plicatic acid (the agent responsible for Western red cedar asthma) may utilize IgE-independent mechanisms. In both diisocyanate and Western red cedar asthma, specific IgE antibodies have been found in only a small proportion of patients proven to have the disease, and non-atopic subjects are affected. Specific IgE antibodies to diisocyanate-HSA antigens are found in variable fractions of workers (5–50%) with proven occupational asthma induced by diisocyanates, depending in part on the type of diisocyanate, exposure setting, and technical aspects of the IgE assays.⁵ In Western red cedar asthma, the significance of specific IgE antibodies is not clear since anti-IgE antibodies failed to inhibit the release of histamine by plicatic acid from granulocytes of patients with the disease.⁶

Antigen-specific T lymphocytes likely play a role in mediating the inflammatory response in the airways. Supporting evidence comes from studies of asthma induced by nickel, cobalt, diisocyanates, and Western red cedar demonstrating proliferation of peripheral blood lymphocytes from sensitized subjects upon stimulation with appropriate antigens.⁴ CD 8 T cell clones derived from bronchial mucosa of two isocyanate asthmatics produced mixed Th1 (IL-2 and IFN- γ secreting) and Th2 cytokines.⁷ Similarly in patients with Western red cedar asthma, peripheral blood lymphocytes released IL-5 and IFN- γ after stimulation with plicatic acid.⁸

There is no clear difference in the pathology of airways in patients with sensitizer-induced (immune-mediated) occupational asthma and non-occupational atopic asthma. Irrespective of the sensitizing agent, the final pathologic features in the airways are similar. There is subepithelial fibrosis, hypertrophy of airway smooth muscle, edema of

the airway wall, accumulation of inflammatory cells and obstruction of the airway lumen by exudate and/or mucus. In both isocyanate-induced asthma and in Western red cedar asthma, T lymphocytes are found in the mucosa and submucosa.⁴ Some studies have suggested that IgE-mediated OA is mostly associated with eosinophilic inflammation whereas OA due to low molecular weight sensitizers such as diisocyanates can be manifest in some patients predominantly as a neutrophilic inflammation. Cessation of exposure to the sensitizing agent is associated with a decrease in the number of inflammatory cells in the airway mucosa. In diisocyanate-induced asthma, some reversal of the subepithelial fibrosis has been found.⁷

Irritant-induced asthma

Classic RADS is caused by a single exposure to a high dose of irritant gases, fumes, or smoke in a previously healthy subject. The mechanism of irritant-induced asthma is not known. It has been postulated that RADS is a 'big bang' phenomenon. Exposure to high level of irritants leads to acute sloughing of the epithelium potentially exposing nerve endings, leading to neurogenic inflammation. In addition, there is airway edema and non-specific release of mediators from various cells including mast cells and macrophages, resulting in recruitment of cells into the airway, leading to airway inflammation.³

More controversial is the concept of 'low-dose RADS', suggested by Kipen⁹ and by Brooks.¹⁰ Kipen described workers who developed asthma during their working life, which coincided with exposures at varying times to agents including second-hand smoke, perfumes, and freshly cleaned carpets.⁹ A larger group of asthmatics with similar exposure histories was described by Brooks¹⁰ who reported an increased prevalence of underlying atopy and smoking history. He suggested that the relatively moderate to low irritant exposure may have 'unmasked' a tendency to asthma. It has been well described that smokers and individuals with allergic rhinitis are more likely than others to have airway hyper-responsiveness and therefore could have symptoms of asthma provoked by irritant exposures more easily than workers with normal airway hyper-responsiveness. Whether this is considered to be aggravation of subclinical asthma or new-onset asthma, or even with some reported cases coincidental onset of asthma, can be debated. Recent studies of firefighters following the collapse of the World Trade Center have documented the development and persistence of hyperactivity and RADS in these workers which was associated with the intensity of exposure to dust and smoke. Similarly it is not clear whether moderate or low irritant exposures can truly induce persistent increases in airway responsiveness (or long-term aggravation of asthma) rather than merely inducing a short-term exacerbation of asthma symptoms as has been previously believed.

The pathology of RADS is similar to that of typical asthma although the number of cases of RADS with reported histology is small. In some reports subepithelial fibrosis is more evident in RADS. The airway epithelium is

extensively damaged and the submucosa infiltrated by mononuclear cells.¹¹

Work-related aggravation of asthma

The pathogenesis of work-related aggravation of asthma does not differ from that of non-work-related aggravation of asthma. Airway hyper-responsiveness is a key feature of asthma such that relatively low levels of respiratory irritants will induce bronchoconstriction. In addition, some inhaled irritants such as ozone and cigarette smoke, and respiratory viral infections can induce an inflammatory response and transiently increase airway responsiveness which may produce a more symptomatic response in people with asthma due to their underlying airway hyper-responsiveness. While individuals with asthma can usually control their exposure in the home to irritants such as second-hand smoke, fumes from cleaning agents, strong perfumes, and dusts relatively easily, they often have less personal control of such exposures in the workplace and may develop worse asthma symptoms at work.

EPIDEMIOLOGY

Occupational asthma has become the most common occupational lung disease in developed countries.¹² Estimates of the incidence of OA have been made using registers based on mandated or voluntary physician reporting, medicolegal statistics, and various national or disability registries. There are considerable between-country differences in the estimated incidence of OA, ranging from 22 per million per year in the United Kingdom to 187 per million per year in Finland.¹² The differences are likely to be in part due to methods used to derive these estimates and in part to differences in local industries and employment opportunities.

In the United States, the 1978 Social Security Disability Survey showed that 7.7% of the participants identified asthma as a personal medical condition and 1.2% attributed it to workplace exposure.¹³ Recent studies in the United States have shown that about 8% of adult patients with new-onset asthma, from community pulmonary physicians' practices, had a history of exposure to sensitizers and another 5% had exposure to irritants.¹⁴ This finding was subsequently confirmed in asthma patients from physicians in primary care.¹⁵

Asthma affects 5–10% of the population worldwide and in developed countries. There has been an increase in prevalence during the past two decades in many industrialized countries.¹⁶ There is a great deal of interest in determining whether the increase in prevalence of asthma can be partly accounted for by occupational exposure. Community-based studies on population attributable risk of occupational exposure for asthma carried out as part of the European Community Respiratory Health Survey have shown that there is considerable variation, from 5% in Spain to 41% in New Zealand, depending on local industries, options for employment, and population susceptibility.^{17–20}

- Onset of asthma symptoms, usually within 24 hours following exposure to a high level of a respiratory irritant agent.
- Persistence of symptoms for at least 12 weeks.
- Objective evidence of asthma: airway hyper-responsiveness on histamine or methacholine challenge, or airflow limitation with significant bronchodilator responsiveness (at least 12% increase in FEV₁).
- No previously documented evidence of asthma or other chronic lung disease.

* Based on references 3, 34

Table 19.2.4 Criteria for diagnosis of irritant-induced asthma*

There is considerable variation in the prevalence of *sensitizer-induced* OA due to various industries from 2% in latex-exposed workers to 50% among detergent enzyme workers.²¹ While between-workforce differences may due to methodology such as the definition of OA and the intensity of exposure, the asthmogenic potential of the agents is likely to be important.

There are fewer studies on the prevalence of *RADS or irritant-induced asthma*, and very little data on the prevalence of aggravation of asthma at work. The definition of irritant-induced asthma has been modified from Brook's strict criteria for RADS in many reports (Table 19.2.4). Some variations include non-massive exposures on one or more occasions and some include asthma onset up to several days after the exposure incident(s). The prevalence clearly will be modified by such changes in definition. In an occupational lung disease clinic population 8% of patients with OA fulfilled criteria for RADS (3% of all consecutive referrals) while 17% of OA patients fulfilled expanded criteria for irritant-induced OA (6% of all referrals).²² Similar findings, suggesting that irritant-induced OA accounts for a minority of all OA, were reported from compensation data in Ontario, Canada: 5% of all accepted work-related asthma claims were for irritant-induced OA (3% fulfilled RADS criteria).²³

Among 623 inhalation accidents reported to the British Surveillance of Work-related and Occupational Respiratory Disease (SWORD) project, 9% had asthma-like symptoms which persisted for at least a month, of which 72% of those with further information were considered by their physician to have new-onset asthma (i.e. about 6%).²⁴ A report by Cone et al.²⁵ gives further information, both about the incidence of respiratory symptoms after an accidental exposure, and the natural history of irritant-induced asthma. They reported the effects of a pesticide spill (metam sodium) following derailment of a tank car, in which the plume traveled 40 miles over 3 days, exposing about 3000 people. About 7% of those exposed were referred for symptoms and 1.6% reported respiratory symptoms for at least 3 months. However, only 1% (30 subjects) fulfilled the historical criteria used in this study for irritant-induced asthma, even with expanded criteria for the time of onset of symptoms; their symptoms began between 4 hours and 7 days after the spill and they had no preceding respiratory history.

Although prevalence data for work-aggravated asthma are very limited and the condition frequently is not recognized by some compensation systems, it is likely quite common. This is supported by a recent study which found

that 50% of all accepted work-related asthma claims from the same compensation database in Ontario, Canada, were for work-related aggravation of asthma, i.e., the same number accepted as for OA²³ condition.

EXPOSURE FACTORS

Sensitizer-induced OA

Exposure is the single most important determinant of the incidence of OA. During the past decade, improved industrial hygiene techniques for measuring several low molecular weight compounds including diisocyanates, formaldehyde, and amines have become available. More importantly, immunochemical techniques have been developed for quantitating some aeroallergens.

Several studies have shown that there is a dose-response relationship between the level of exposure to occupational agents and the prevalence of sensitization and/or non-allergic bronchial hyper-responsiveness and/or asthma. These include exposure to high molecular weight allergens such as α -amylase, laboratory animal allergen, and low molecular weight compounds such as Western red cedar, acid anhydride, and colophony.²⁶⁻³⁰

The ability to measure exposure has led to the establishment of permissible exposure limits for some sensitizing agents. For OA, the minimum concentration or dose of the allergen that causes sensitization and the minimum concentration that causes symptoms after sensitization are likely different, and generally not well defined. There is a latency period during which time individuals become sensitized to the specific agent, usually more than a month and less than 2 years, but variable latency periods have been reported, and are likely related to the dose and timing of exposure, as well as host factors. Once an individual is sensitized to an agent, a minute dose can trigger an attack of asthma; the concentration necessary for sensitization is most likely greater. Although human data are limited, sensitization to certain agents such as isocyanates may occur through skin in addition to inhalational exposure, as has been shown in certain animal models.

Concomitant environmental exposures such as low levels of irritants and cigarette smoke may enhance sensitization to some occupational agents. As examples, it has been found that cigarette smoking is a significant risk factor for the development of sensitization and OA from exposure to complex platinum salts and to acid anhydrides as described below.^{30,31} Diesel exhaust has been shown to have an adjuvant function in development of IgE-mediated sensitization to aeroallergens, and animal studies have also suggested an enhancing effect from ozone exposure. Further studies are required in this area as recently reviewed.³²

Irritant exposures and RADS

Exposure conditions are central to the diagnosis of irritant-induced asthma and RADS. The more extreme an acute irritant exposure has been, and the shorter the period following this exposure that asthma symptoms have devel-

oped and been documented, the more credible is the diagnosis of irritant-induced asthma. Thus, the initial reports of RADS with new-onset asthma starting within 24 hours of a massive irritant exposure were very unlikely to be due to coincidental onset of asthma. Conversely, onset of asthma in a worker who has been exposed to presumed low to moderate concentrations of solvents or other potential respiratory irritants for several years could well be coincidental to the workplace exposures. Between these two extremes of exposure and symptom onset, the diagnosis of irritant-induced asthma is controversial.³²

Exposure and work-aggravated asthma

In contrast to the exposure conditions for irritant-induced asthma, even low concentrations of respiratory irritants can aggravate pre-existing asthma. Second-hand cigarette smoke, cleaning agents, paints, and other fumes, as well as dust, can worsen symptoms and induce bronchoconstriction in individuals with asthma. Those who have mild asthma, well controlled with appropriate medications, may have no significant response to low concentrations of respiratory irritants while those with severe asthma (with severe underlying airway responsiveness) are more likely to have an exacerbation of asthma with lower exposure concentrations of irritants, or with exercise or cold air. Viral upper respiratory infections can increase airway responsiveness for up to 6 weeks and asthmatics who have or have recently had a cold may thus be worsened by irritant exposures at work which may not affect them at other times.

Similarly, a relevant allergen exposure can also increase airway responsiveness for several weeks. For example, a worker with asthma who is allergic to cats, after visiting a home with a cat on a weekend, might subsequently, for several weeks, notice that workplace irritants such as fumes from cleaning agents, which were previously tolerated, now worsen symptoms. If airway responsiveness improves, and/or asthma is well treated with medications and allergen avoidance measures, such patients may then be able to work with the same low-level irritant exposures without difficulty, unlike the patient with OA induced by a sensitizer which is still present in their work environment.

HOST DETERMINANTS

Not all subjects develop OA given the same degree of exposure. The following host susceptibility factors may be important in *sensitizer-induced* OA.

1. *Atopy*. Atopy (defined as positive skin test to one or more common allergens) has been shown to be associated with sensitization to some high molecular weight agents such as detergent enzymes^{33,34} but not in others such as clams and snow crabs.^{35,36}
2. *Smoking*. The effect of smoking appears to be dependent on the type of occupational agent. An interaction between smoking and atopy has been found in laboratory animal handlers³⁴ and in workers exposed to tetrachlorophthalic anhydride³⁰ atopic smokers had the

highest and non-atopic non-smokers had the lowest prevalence of sensitization. Among platinum workers, smoking, not atopy, is the most important risk factor for sensitization.³¹ When agents cause OA by predominantly IgE-independent mechanisms, such as isocyanate-induced asthma and Western red cedar asthma, neither atopy nor smoking are important risk factors.⁴

3. *Non-allergic bronchial hyper-responsiveness*. The role of non-allergic bronchial hyper-responsiveness as a pre-existing risk factor for occupational asthma requires further study. In most instances, non-allergic bronchial hyper-responsiveness is the result rather than a predisposing host factor.³⁷
4. *Genetic markers*. An association between certain HLA class II genes as well as other genes such as glutathione-S-transferases and diisocyanate, trimellitic anhydride, platinum or Western red cedar-induced asthma have been reported.^{38,39} However, the results of such studies are preliminary and they cannot be used for screening of susceptible subjects. Moreover, asthma is likely to be a polygenic disease with multiple genes contributing to the disease rather than one.
5. *Upper airway symptoms* such as rhinitis and conjunctivitis often precede the lower airway symptoms. It has been suggested that they may be used as an early marker of OA.⁴⁰

Little is known about the host determinants of *irritant-induced asthma*. RADS probably affects both atopic and non-atopic, smoking and non-smoking workers alike. Initial reports of RADS included more smokers than non-smokers. Recent studies have shown an increase in small particle deposition among smokers compared with non-smokers, and among those with baseline airflow limitation,⁴¹ suggesting the possibility that such individuals might be more susceptible to airway effects of irritant small particulate inhalations. However, a history of smoking or the finding of atopy, while not excluding the diagnosis of irritant-induced asthma, may make the diagnosis somewhat less certain in that there may be more likelihood of previous underlying airway disease which may confound the diagnosis, even if not formally documented in medical records. This is particularly problematic in considering a diagnosis of new-onset irritant-induced asthma after moderate or low level irritant exposures.

Very little has been documented about the host determinants of *work-related aggravation* of asthma. However, as noted above, the response to non-occupational irritant exposures is known to relate to airway hyper-responsiveness (and asthma severity and control) and it is likely that the same factors are important in work-related aggravation of asthma.

CLINICAL FEATURES AND DIAGNOSIS

Sensitizer-induced OA

Occupational asthma is first suspected in clinical practice from the history. Any patient with a history suggestive of

asthma (one or more symptoms of episodic cough, wheeze, retrosternal chest tightness, and dyspnea), which began during working life, should raise the diagnostic suspicion of OA. Suspicion increases if these symptoms are worse at work, and improve during weekends or holidays away from work.

Knowledge of the typical clinical features of sensitizer-induced asthma is essential in obtaining and evaluating the occupational history. Sensitizer-induced asthma affects only a portion of exposed workers and develops after a variable latent period of exposure. Thus symptoms typically develop from several months to years after the onset of exposure. The typical asthma symptoms can occur within a few minutes of exposure, several hours after exposure, or in a biphasic or atypical more prolonged pattern. Allergic rhinitis type symptoms may predate asthmatic symptoms and symptoms commonly worsen over the week and improve away from work. Delayed symptoms after work in the evening suggest sensitizer-induced rather than irritant-induced asthma. The latency period and delayed evening symptoms can make the association with work less obvious to the patient and healthcare provider.

As asthma progresses, it is not uncommon for patients with sensitizer asthma to also respond to non-specific triggers that commonly affect typical atopic asthmatics such as cold air, irritants, and exercise. Improvement away from work may also become less dramatic. Thus careful documentation of the onset, timing, and progression of asthmatic symptoms in relationship to occupational and environmental exposures is essential for diagnosis. Particularly helpful is clarifying these patterns when the symptoms first started, when the association between work exposures and asthmatic symptoms may be more clear-cut.

The history of OA is a sensitive diagnostic tool for asthma related to a sensitizer, but has low specificity and requires additional investigative measures. Malo and colleagues⁴² found the sensitivity and specificity of the clinical history to be 96% and 25% as compared with diagnoses based on objective investigations. The differential diagnosis includes asthma starting or worsening coincidental to the workplace, unrelated asthma aggravated by non-specific irritant exposures at work, and non-asthmatic causes of asthma-like symptoms (such as rhinitis with post-nasal drip, hypersensitivity pneumonitis, acute or chronic bronchitis, gastro-esophageal reflux, or cardiac asthma). Therefore the initial step in the investigation should be the objective confirmation of asthma by pre- and post-bronchodilator spirometry or methacholine or histamine challenge testing. These tests are best performed within 24 hours of the suspected work exposure, since if they are performed after a longer period, negative tests for asthma may be caused by an improvement away from exposure to a workplace sensitizer.

Although, in many cases the patient may not be aware of the exact chemical exposures at work, material safety data sheets can be requested from the workplace and may be of help in clarifying the presence of a workplace sensitizer. In this regard, the sheets should be requested not only for substances directly used by the patient but also for all

agents to which there may be air-borne exposure, even intermittently. These sheets can be very helpful in assessing possible exposure agents, but they may be incomplete in respect to respiratory sensitizers since there is only the requirement to list known hazardous components of a compound, and only if these are present in amounts greater than 1%. Since new sensitizers are described each year, and once sensitized, respiratory responses to a sensitizer can occur at minute levels, a relevant exposure may not be detected unless the product manufacturer is specifically requested to provide full information.

Several studies have assessed the value of new and older investigations for occupational asthma, as reviewed in a consensus statement from the American College of Chest Physicians,⁴³ guidelines from the Canadian Thoracic Society,⁴⁴ and a recent review.⁴⁵ An objective assessment of asthma and its work relationships is generally accepted as necessary where possible for appropriate medical management but also for appropriate compensation decisions to be reached, although in practice this can sometimes be difficult to obtain. Non-occupational asthma is common and frequently has its onset in adult life. Each investigative measure used for OA can have false-positive and false-negative responses (Table 19.2.5), and therefore, it is advisable to combine as many investigations as are feasible in an individual patient.

Spirometry and non-specific challenge testing

An objective diagnosis of asthma is reached by pulmonary function tests (PFTs), pre- and post-bronchodilator, and/or a histamine or methacholine challenge test, using standard protocol.⁴⁶ If normal, these do not exclude OA if performed when the patient is off work and free of symptoms. However, whether they are normal or abnormal, they can serve as a baseline for comparison with subsequent spirometry and methacholine or histamine challenge responses after the patient returns to work, preferably performed towards the end of a typical work week and within 24 hours of the occurrence of symptoms. Results at this time which do not show evidence of asthma virtually exclude a diagnosis of OA, although a few such cases have been reported with diisocyanate-induced asthma.⁴⁷

Serial monitoring of bronchial hyper-responsiveness

Alternatively, if the patient is working when first assessed, and if a methacholine or histamine challenge at that time confirms the presence of airway hyper-responsiveness, then repeat testing after a holiday period of 10–14 days before the patient returns to work is useful to objectively assess changes in reactivity while away from work. A significant improvement would support a diagnosis of occupational asthma unless explained by confounding factors. Depending on the individual pulmonary function laboratory, a minimum three-fold improvement in PC₂₀ while off work is significant. However, lack of significant improvement in PC₂₀ on holiday does not exclude OA since some sensitized asthmatics (perhaps those with longer duration of OA) can require a longer period away from exposure before

Assessment	False positive	False negative
History	Aggravation of coincidental asthma, rhinitis or other non-asthma diagnosis.	Uncommon. Lack of full weekends off work.
MSDS	Exposure does not prove sensitization.	Sheets may not list all sensitizers. Not all relevant sheets may be obtained by the worker.
PFTs pre- and post-bronchodilator, Methacholine or histamine challenge	Response indicates asthma, but not necessarily OA. Recent upper respiratory infection, significant COPD. True response indicates asthma, not necessarily OA.	Masking of variability by medications. Performed when asymptomatic or off work. Performed when asymptomatic or off work. Failure to stop asthma medications before the test.
Paired methacholine or histamine challenges	Intercurrent upper respiratory infection, or exposure to a non-occupational allergen trigger during period of work.	Insufficient time off work to see improvement. Intercurrent upper respiratory infection, or exposure to a non-occupational allergen trigger while off work.
Peak expiratory flow readings	Work-related aggravation of asthma. Poor effort at the end of a work day: fabrication of results.	Masking of changes by asthma medications. Only occasional exposure or no exposure to the sensitizer during the recording weeks at work.
Skin tests and in-vitro immunologic tests	Presence of immunologic sensitization without OA. Non-specific skin irritant effects of extract. Dermographism.	Inadequate or wrong allergenic extract. Masking of skin test response by antihistamines.
Workplace challenge	Coincidental aggravating exposures on the test day. Placebo effects.	Lack of exposure to the relevant sensitizer on the test day. Masking by medications.
Laboratory-specific challenges	Irritant exposure conditions. Placebo effect if not blinded. Unstable asthma or coincidental worsening on active exposure day.	Incorrect exposure agent, or inadequate concentration, duration of exposure, or absence of correct conditions such as heating, mixing with other chemicals. Masking by medications. Reduction of airway reactivity after a prolonged period off work. Failure to measure methacholine/histamine responses pre- and post-exposure.
Induced sputum and exhaled NO	Mainly research uses.	Mainly research uses.

Table 19.2.5 Some potential causes of false-positive and false-negative assessments in OA

significant improvement occurs. In the occurrence of a positive history, peak flow responses suggestive of an occupational component and a trend to improvement in histamine or methacholine PC₂₀, a longer period off work with repeat tests may help.

Serial monitoring of PEF

Serial peak expiratory flow (PEF) readings continue to be useful as a component of occupational asthma investigation.⁴⁸ Serial peak expiratory flow readings require careful patient instruction in the correct use of the peak expiratory flow meter. Suggested use is often three times on each occasion at least four times a day on working days and days off work, while also recording symptoms and medication use. However, optimum frequency to enhance compliance and accuracy of diagnosis remains unproven. Medications, other than as needed bronchodilators, are kept at a stable regular dosage during this time if possible, sufficient to control but not completely suppress symptoms. Compliance has been shown to be poor with such peak expiratory flow recording, especially when patients were asked to record values six times per day.⁴⁹ Nevertheless, if the patient does keep a record that has enough information over several weeks at work and over a holiday period, and if the record shows a clear pattern to support or refute asthma with a work relationship, then the sensitivity and specificity have been shown to be high compared with other tests for OA.

Electronic peak flow meters or portable spirometers give more objective information as to patient compliance

but their current costs limit their practical usage. In a comparison with serial FEV₁ recordings using a portable ventilometer, Leroyer et al.⁵⁰ found better sensitivity and specificity of peak expiratory flow recordings. Using the best value at each time period, the sensitivity and specificity for occupational asthma were 73% and 100% for peak flow recordings, adding further validation to the use of this simple test as a component of investigations for OA.

There are no uniformly accepted criteria for the interpretation of peak expiratory flow recordings. Attempts have been made to develop objective criteria, but qualitative interpretation of plotted graphs by an experienced physician relates favorably to quantitative analyses.⁵¹ If peak flow or portable spirometric recordings in work week periods show no significant changes of asthma, there may have been masking of such changes by regular asthma medications and the recordings should be repeated with use of less medication.

When interpreting changes in peak expiratory flow and methacholine or histamine responses during working weeks vs. weeks off work, consideration should be given to confounding factors. These include intercurrent respiratory viral infections within the preceding 6 weeks, or non-occupational relevant allergen exposures (as assessed from the history at the time of these tests, and from environmental allergy assessment, including skin prick testing to common aeroallergens).

Work-related changes in asthma severity, as assessed by serial peak expiratory flow monitoring and methacholine

Figure 19.2.1: Serial PEF monitoring in a 42-year-old polyurethane foam worker (exposed to toluene diisocyanate) at work and off work showing improvement in PEF and methacholine PC20 while off work, supporting a diagnosis of sensitizer-induced OA.

or histamine challenges in combination, generally provide a clear objective method to confirm or refute the diagnosis of occupational asthma (e.g., Fig. 19.2.1). If peak flow monitoring can be adequately performed and interpreted, but not methacholine or histamine challenges, or vice versa, and the resulting changes are clearly positive or negative, although not ideal, this is usually sufficient to confirm or refute the diagnosis also. However, unfortunately in practice such data can be difficult to obtain. If the patient has left the implicated work exposure and cannot or will not return on a trial basis for such tests, or the work exposures in question have changed, then the diagnosis is more difficult to make.

Immunologic tests

Immunologic tests to demonstrate IgE antibodies in high molecular weight workplace sensitizers can be useful, when feasible, to confirm immunological sensitization, but are often limited by the lack of commercially available or standardized reagents. Hamilton and colleagues⁵² have shown that a commercial skin prick test preparation of natural rubber latex at two different dilutions had a sensitivity and specificity between 95% and 100% relative to a history of latex allergy symptoms (combined with glove provocation tests when there was discordance between the history and skin test results). A positive skin test response supports a diagnosis of OA if associated with appropriate pulmonary function changes but as a sole investigation is not diagnostic. Similar conclusions could be drawn from a study by Bernstein and colleagues⁵³ in pharmaceutical workers sensitized to lactase: skin test-positive workers were nine times more likely to have upper or lower respiratory symptoms than skin test-negative workers but over 60% of skin test-positive workers had no respiratory symptoms.

Several methods are available to measure specific IgE antibodies in serum, with variable predictive value, depending on the workplace allergen and method used to measure specific IgE. Unfortunately there are relatively few well-characterized workplace allergen extracts for which reliable in-vitro allergen assays can be performed. Even for allergens such as those in natural rubber latex, which have been extensively studied and characterized, the role of in-vitro

assay of IgE antibodies remains controversial since there can be significant cross-reactivity with non-occupational allergens.

An example of a useful assay in a university laboratory setting with careful controls is the assessment of specific antibodies to the occupational sensitizer trimellitic anhydride. The predictive value of in-vitro measures of serum IgE antibodies was assessed by Grammer and colleagues⁵⁴ using ELISA methods. Nine of 16 exposed workers with specific IgE antibodies either had asthma or developed it within 5 years of follow-up versus one of 165 without these antibodies. Similar predictive value for specific IgG antibodies was found for immunologic respiratory disease in that study although most studies of other sensitizers (e.g., of diisocyanates) have shown that IgG antibodies are more reflective of exposure than of occupational asthma. Therefore, when performed in the university research laboratory, the tests can be highly predictive but results cannot necessarily be extended to performance of these tests in other laboratories.

Other in-vitro tests to assess specific sensitization to occupational chemicals currently remain research tools but may become clinically useful in the future, e.g. assessment of mononuclear cell activation or chemokine production by diisocyanates^{55,56} or by adducts of diisocyanates with epithelial cell proteins.⁵⁷

Specific challenge tests

Occupational specific laboratory challenge tests are performed in very few centers, and generally are not available in many countries including the United States.⁵⁸ Nguyen et al.⁵⁹ have shown that a positive challenge response to high molecular weight occupational allergens in an individual sensitized patient relates to the total dose delivered rather than the concentration or duration of exposure alone. Therefore, a serial progressive increase in exposure duration can be used in such testing rather than progressive increases in concentration, potentially increasing the safety of the test. Although still considered to be a gold standard for diagnosis of OA, there are potential false-positive and false-negative responses.⁶⁰ A false-negative response may occur if the wrong agent is used or if the exposure conditions are not comparable to those in the

workplace. For example, some patients can be sensitized to toluene diisocyanate (TDI), but not diphenylmethane diisocyanate (MDI), some to a prepolymer but not a monomer of a diisocyanate, and some to a specific isomer, e.g., 2,4-TDI but not 2,6-TDI. MDI is poorly volatile and therefore needs to be heated to generate respiratory exposure during a challenge test. After a long period away from exposure, sensitivity may be lost or there may be a need for multiple days of re-exposure to diisocyanates before measurable changes in peak flow, spirometry or methacholine/histamine responsiveness occur.

Laboratory-specific challenges can be useful in the following circumstances: when the diagnosis of OA remains in doubt despite other investigations; if other investigations could not be performed; or in the setting where a patient clearly has OA but it is necessary for their management to confirm what is their causative agent. These tests require specialized facilities which are only available in a few centers,⁵⁸ are time consuming and very costly, and false positives and false negatives can occur. Occupational hygienist support is necessary to generate, maintain and monitor appropriate exposure levels of the suspected sensitizer. During challenges, levels of exposure must be continuously monitored, since excessive levels could induce a severe asthmatic reaction, or can be irritating or potentially newly sensitize the patient.

New techniques

Two new techniques have been evaluated in the diagnosis and impairment assessment of OA: exhaled nitric oxide and induced sputum analysis. In patients with Western red cedar asthma, Obata et al.⁶¹ found an increase in induced sputum eosinophils at 6 and 24 hours following a positive plicatic acid challenge but increases in exhaled nitric oxide at 6 and 24 hours after challenge did not correlate with a positive challenge. Similarly, in follow-up of patients with OA from Western red cedar, there was a significant association between respiratory impairment class and sputum eosinophils counts, but no correlation with exhaled nitric oxide.⁶² Lemiere and coworkers⁶³ also reported a significant increase in induced sputum eosinophils and eosinophil cationic protein (ECP) in patients with OA

from various causes, during periods of work exposure as compared with periods off work, suggesting that in centers where this test can be performed, it can add to other tests in the investigation of OA.

Conclusion

The extent of objective testing and the choice of investigations will vary according to the degree of proof of diagnosis which is required and the facilities available. Depending on the assessment facilities and compensation system requirements, workplace exposure studies or laboratory chamber studies may be selected. It is recognized that objective proof or disproof of OA is not always feasible and less definitive evidence may be accepted by some compensation systems. However, the incorrect acceptance of a compensation claim may still lead to poor socioeconomic results for the patient by restricting their future employment options. A diagnosis which is confirmed as fully as possible by objective testing is recommended both for correct compensation decisions and for optimal medical management and occupational advice to the patient.

Irritant-induced OA

In contrast to the history of OA related to a sensitizer, the history may be of the acute onset of asthma symptoms within 24 hours of a high exposure to a respiratory irritant, raising the possibility of irritant-induced asthma/RADS.^{3,22} This diagnosis should be suspected particularly if symptoms were severe enough to lead to an acute visit to a physician or hospital emergency department, persist for at least 3 months, and occur with no previous history of respiratory disease. Unfortunately, this remains a circumstantial diagnosis (Table 19.2.2). It relies largely on the history of exposure, and associated onset of symptoms, objective findings to support a diagnosis of asthma, and the lack of evidence of previous chronic respiratory disease. No prospective physiologic or histologic investigations can further prove the association with the workplace. Industrial hygiene data documenting the high exposure are rarely available as such events are frequently accidental or sporadic.

Figure 19.2.2: Serial PEF monitoring in a 50-year-old dry cleaner with asthma since childhood (exposed to solvents at work), at work and off work showing improvement in PEF but no change in methacholine PC20 while off work, supporting a diagnosis of work-related irritant aggravation of underlying asthma.

Work-related aggravation of asthma

The diagnosis of work-related aggravation of asthma is made on the following basis.

1. A history of asthma symptoms which worsen at work and improve to some extent after the work shift or on weekends or holidays off work, and a history of exposure at work to potential respiratory irritants such as fumes, sprays, or dusts.
2. Objective evidence of asthma based on a significant bronchodilator response or positive histamine or methacholine challenge test.
3. Objective demonstration of worsening of asthma at work by documented work-related changes in symptoms, medication requirements, and preferably peak expiratory flow recordings *without* other manifestations of sensitizer-induced OA as discussed above (i.e., not associated with changes in methacholine responsiveness at work versus off work, no findings of an immunologic response to an occupational sensitizer). Although the serial peak flow records may appear similar to those of patients with sensitizer-induced OA, it would be expected that an irritant aggravation of asthma would cause a reduction in peak flow results within minutes of exposure whereas some sensitizers (especially low molecular weight sensitizers) produce isolated late asthmatic responses starting several hours after exposure. In addition, the recovery from bronchoconstriction due to an irritant aggravation of asthma may occur sooner than the recovery from a sensitizer response. However, there may be significant overlap between the timing of these two types of response (e.g., Fig. 19.2.2).

The initial onset of asthma symptoms may have occurred prior to starting the current employment or during the current employment. If asthma began during a work period, careful assessment as to initial irritant-induced asthma or sensitizer-induced OA is appropriate since a diagnosis of current work-related aggravation of asthma does not exclude a previous work-related *cause* of asthma.

MANAGEMENT

A firm diagnosis as far as possible is essential for appropriate management of work-related asthma.

Sensitizer-induced OA

Workers with OA induced by a respiratory sensitizer who have had an objective diagnosis of OA should be removed from further exposure to that agent, in addition to receiving the same types of medical treatment as are given to non-occupational asthmatics. Removal from exposure to the sensitizer is sometimes achieved by a change in the work process. As an example, for a healthcare worker with OA from natural rubber latex, personal avoidance of contact with natural rubber latex gloves and other products, and use of only powder-free, low allergen latex gloves

by coworkers. Encapsulation of enzymes in the detergent industry, or removal of usage of epoxy glue can eliminate exposure to these sensitizers. If the sensitizer is only occasionally used in the workplace, then it may be feasible for the worker to wear protective equipment such as a helmet respirator with separate air supply, as has been shown to protect some workers sensitized to latex or farm allergens. Complete removal from exposure unfortunately is not always achieved due to variable workers' compensation systems and socioeconomic factors. As noted in the discussion of outcomes below, under select circumstances, very low exposures rather than complete removal may be adequate in some patients. Such workers require close monitoring to assess for worsening asthma.

The role of protective respiratory devices in farmers with OA has been considered for patients unable to leave areas of exposure to the workplace sensitizer. Muller-Wening and Neuhauss⁶⁴ show that use of three types of Racal respirators (including an 'Airstream helmet'), each with a P2 filter, worn during challenge tests with their workplace dusts reduced symptoms and responses but did not prevent them in most patients. In a workplace study of farmers with OA, Taivainen et al.⁶⁵ evaluated similar respirators, comparing symptoms and peak flows with the results from a period without the respirator. They found a significant improvement in symptoms and peak flow responses with the respirator use, but in only 8 of 33 patients did symptoms clear. These findings suggest that for farmers with OA who face severe financial consequences of avoiding allergen exposure, the use of a powered dust respirator helmet may limit the ongoing exacerbation of their asthma.

These studies recognize the real difficulties that may occur in providing complete avoidance of exposure to a sensitizer. Nevertheless, where feasible this remains the best option for sensitized patients. Laoprasert and colleagues⁶⁶ similarly assessed the use of HEPA-filtered helmets in preventing airway responses to natural rubber latex. Although the use of the respirator significantly reduced symptoms and FEV₁ changes during specific challenge tests, equivalent benefit was obtained by the use of powder-free low-allergen latex gloves. Substitution with these gloves would therefore appear to be a simpler solution to this problem. For patients with other causes of sensitizer OA, to remove the worker completely from exposure often requires a move to a different building at work, or a change in occupation.

Irritant-induced OA

Workers with OA induced by an irritant exposure at work should be managed in the same way as those with aggravation of underlying asthma (see below), except that appropriate precautions need to be in place to ensure that the patient is not at risk of further high-level irritant exposures. In some patients with irritant-induced OA who return to work, exposure to even relatively low levels of the same, or other, workplace irritants may induce asthma-like symptoms. This may be either on the basis of aggravation of asthma, as described above, or on the

basis of vocal cord dysfunction/hyperventilation through a presumed subconscious response (see Chapter 49).

Work-aggravated asthma

Workers who have asthma which is not caused by their work may have their asthma aggravated by exposure to respiratory irritants at work, such as smoke, dusts, fumes, sprays, cold air, extremes of humidity, or marked exercise requirements. The degree of symptomatic exacerbation will depend not only on the severity of the airway non-specific triggering factor, but also on the severity of underlying asthma, and the adequacy of medical treatment and control of asthma. Therefore, the approach for these patients is to optimize the medical management of their asthma. This includes limiting exposure to relevant environmental allergens and non-occupational irritants such as tobacco smoke, and optimizing asthma medications, education, and compliance. In addition, reduced exposure to non-specific exacerbating triggers in the workplace should be attempted. Depending on the exacerbating triggers, recommendations may include a move to a different work area; changes in ventilation or process; the use of an appropriate respirator for short-term exposures to respiratory irritants; or work modification to avoid extreme cold or exercise. If asthma is severe, then a change in occupation to a relatively sedentary job in a clean environment may be needed to enable the patient to continue work.

COMPENSATION AND CONSIDERATION OF THE WORKPLACE

Many workers with asthma related to their workplace will be eligible for workers' compensation. Some workers' compensation systems are beginning to recognize and provide some degree of compensation for work-related aggravation of asthma as well as new-onset OA. The treating physician has a responsibility to submit the appropriate documentation for this and to ensure that as clear and objective a diagnosis has been achieved. An appropriate compensation decision is greatly facilitated if the patient has been thoroughly investigated with objective tests to confirm the diagnosis of asthma and demonstrate the work relationship. Early advice by the physician to leave the workplace before reaching an objective diagnosis will make further investigations more difficult to obtain, may unfairly deny the patient appropriate compensation for OA, and can have severe adverse socioeconomic consequences.

Healthcare providers should consider the public health implications when diagnosing a patient with work-related asthma. Once a diagnosis of OA due to a sensitizer has been reached, the treating physician should consider this as a 'sentinel event', suggesting that there may be others with OA or at risk for OA in the same workplace. Therefore there should be appropriate notification of public health officers and/or the company physician with the patient's consent. This may lead to further case-finding and preven-

tive measures. Similarly, if a diagnosis of RADS is reached, the healthcare provider should assess if other workers were similarly affected and ensure that the risk of future high irritant exposures is low.

IMPAIRMENT/DISABILITY EVALUATION

Evaluation of impairment for compensation purposes also requires objective criteria. Since asthma is characterized by variable airflow limitation, simple spirometry is usually not sufficient to reflect impairment. The American Thoracic Society guidelines for evaluating impairment in patients with asthma⁶⁷ have recommended that other factors also be considered: minimal medications required to control asthma, degree of airway hyper-responsiveness to histamine or methacholine when this can be safely assessed, and/or pre- and post-bronchodilator spirometric results (see Chapter 8). In addition, other factors to consider include: environmental control of non-occupational relevant allergens such as cats or dust mites, and triggers such as tobacco smoke at home, compliance with prescribed medications and correct usage of delivery devices for inhaled medications.

In addition to the assessment of medical impairment by objective assessment of asthma severity, for patients who have *sensitizer-induced* OA the degree of functional disability is affected by the need to completely avoid further exposure to the sensitizer. Thus a spray painter with OA from diisocyanate exposure in paints who has stopped working may have mild or no ongoing asthma but may still be disabled by the inability to return to his established trade. This needs to be considered in the physician's report to assist in the compensation system assessment of disability (which is a non-medical assessment, in contrast to the impairment assessment), and also needs to be considered in addition to the ongoing asthma severity if the physician is asked to provide advice as to future work restrictions.

OUTCOME Sensitizer-induced OA

A number of studies have demonstrated that the majority of patients with OA fail to recover after removal from exposure, with worse outcomes associated with longer duration of symptoms and exposure, delayed diagnosis, and greater severity. Such studies support early recognition and removal from exposure. Recent studies provide additional insight into the outcome of OA. Perfetti et al.⁶⁸ have shown that among patients with OA from various causes, the outcome is significantly better in the group removed from relevant work exposure for over 5 years compared with those removed for 5 years or less. Their findings of continued improvement in outcome of asthma beyond 5 years of removal from exposure to the sensitizer suggest that permanent disability ratings of patients with OA should be periodically re-evaluated during this time period.

Although there are a few anecdotal reports of death from occupational asthma, there has been limited mortality data for these patients. In a preliminary report by Liss and colleagues,⁶⁹ three deaths from asthma were identified among workers previously compensated for OA. This led to a comparison of mortality between over 1000 patients compensated for work-related asthma (OA or work-related aggravation of asthma), compared with non-work related asthmatics from a secondary/tertiary referral clinic, and workers compensated for work-related injuries. Mortality from respiratory disease among compensated asthmatics was slightly greater than expected in the general population (SMR 1.3). Although reported mortality from respiratory causes except asthma was greater among the secondary/tertiary asthma clinic patients than among the work-related asthmatics, these findings indicate the potential serious consequences of work-related asthma.

Among the same population, Liss et al.⁷⁰ have also reported on the morbidity of patients with OA as assessed by hospital admissions for respiratory disease. Those with OA had a significantly high rate of hospitalization for asthma compared with other compensated workers, but as might be expected, the rate was less (about 50%) compared with asthmatic patients from a secondary/tertiary referral practice. In support of the findings from Perfetti et al.⁶⁸ suggesting an improvement in asthma severity over time, admissions for the OA group were mainly in the first 5 years after onset of asthma.

Merget and colleagues⁷¹ report some unexpected findings in the follow-up of workers with confirmed OA induced by complex platinum salts. Most workers had transferred to work outside the plant production building but 11% continued to be exposed in the same area and 19% had been transferred to other areas within the production building. The follow-up was at a median period of 54 months after transfer of work site. Not surprisingly, those who remained in the same exposure area all continued to be symptomatic while 50% of those who left the production building had clearing of symptoms. Surprisingly, however, 50% of those transferred to other areas within the production building also had clearing of their asthma symptoms despite the likelihood that they still had exposure to low levels of platinum salts. This is contrary to previous studies, which have led to the conclusion that complete removal of exposure to the sensitizer is necessary in those with OA. Despite symptoms clearing and negative skin tests in many subjects, bronchial hyper-responsiveness to methacholine persisted in 91% of all subjects, perhaps on the basis of airway remodeling. The duration of exposure time with symptoms, among those who were transferred out of the production building, was 14 months for those moving to other buildings and 18 months for those who left the plant. This suggests that, at least for platinum-salt induced OA, the window of opportunity for reversing airway hyper-responsiveness by removing the worker from exposure after the onset of OA is very short, perhaps within a year of asthma onset. As the authors of this study discuss from their earlier work, this might be achieved by a medical surveillance program.

Despite the clearly improved medical outcome by removal from exposure to the workplace sensitizer, the socio-economic outcome of such removal is often worse (despite acceptance of a workers' compensation claim), especially if the patient is required to leave their company to avoid further sensitizer exposure. Changes in the exposure conditions within the same workplace are preferable if these can be achieved, as for example in healthcare workers with occupational asthma from natural rubber latex, where changes in glove use by the worker and coworkers to minimize air-borne allergen exposure may allow continued work⁷² with better socioeconomic outcome.⁷³ However, for most occupational sensitizers there is no known safe exposure level for those with related OA and early removal remains the current medical advice after a confirmed diagnosis. If the patient is relocated within the same building where even very low exposures to the sensitizer may occur, they should be very carefully monitored (with serial peak expiratory flow recordings and methacholine challenges) to assess the effects on their asthma and should be removed from even very low exposure areas if asthma worsens in relation to those areas.

Irritant-induced OA

There is much less information available as to the outcome of irritant-induced OA as compared with information on sensitizer-induced OA. From the initial reports by Brooks on patients with RADS,³ some individuals had persistence of asthma for several years while other had clearing within a few months (in his initial criteria, a minimum 3 month duration of asthma was required for diagnosis of RADS). Information from poison control centers and accidental spills suggests that short-term symptoms are more common than long-term asthma but prognostic factors have not been clearly identified to date. It is not known whether the duration of irritant-induced asthma relates to the degree of irritant exposure, and/or factors such as gender, smoking history and atopy.

Work-related aggravation of asthma

Similarly there is little published documentation as to the outcome of work-related aggravation of asthma. Clinical experience suggests that often there is a temporary aggravation of asthma at work if there have been unusually high exposures to irritants such as when the workplace is being repainted, or is under construction. Such exposures are not known to cause long-term worsening of asthma and clinically usually resolve within a few weeks after cessation of such exposures, so that the patient can return to their usual work. Workers' compensation data from a system where work-related aggravation of asthma was compensatable showed that the duration of work-attributed symptoms and time off work after a workplace accidental exposure was in the range of a few days to weeks for most patients with work-related aggravation of asthma as compared with several months for those with irritant-induced asthma.⁷⁴

Some asthmatics have a long-term worsening of asthma which they may relate to a mild or moderate irritant exposure at work. Asthma severity is variable, often for no identified reason and currently it is not known whether mild or moderate workplace exposures can truly cause long-term or permanent asthma worsening or whether this represents the natural history of asthma in that patient for other/unknown reasons. Such questions might be resolved in the future by prospective studies of workplaces with and without irritant exposures.

PREVENTION

Sensitizer-induced OA

Primary prevention

Control of exposure in the form of substitution, improvement of ventilation, and change of process and enclosure have been used in occupational asthma. The most successful example is the virtual disappearance of detergent enzyme-induced asthma after the introduction of various forms of control.⁷⁵ Other studies also support a reduction in workplace aeroallergen exposure levels to prevent OA. For example, Houba et al.⁷⁶ in the baking industry showed a relationship between exposure levels and allergic symptoms. Reeb-Whitaker et al.⁷⁷ showed that in animal facilities aeroallergen levels could be significantly reduced by: (1) housing mice in cages with a filter-sheet top or a fitted filter-bonnet top, (2) using a negative pressure in the cage and (3) handling animals under a ventilated table.

Restriction of employment has been used with success in some instances in the primary prevention of OA, such as in the platinum refinery workers,⁷¹ but knowledge of host susceptibility factors is limited. Atopy is a risk factor in asthma due to large molecular weight occupational allergens, but the positive predictive value is low. Moreover, over 30% of young adults are atopic subjects, thus screening for atopy is not recommended. Ensuring the workplace is free from tobacco smoke may be helpful in reducing sensitization to some allergens.

Secondary prevention

Medical surveillance programs for the early detection of OA have been suggested for occupational settings at high risk. However, there has been little published as to the effectiveness of these. In Ontario, a program of medical surveillance for diisocyanate-induced asthma was initiated in 1979 under government regulations. It has been reported that diisocyanate-induced OA is diagnosed earlier in Ontario than other causes of OA and these patients have a better outcome.⁷⁸ Nevertheless there has been no direct assessment of the program or its components.

A study by Kraw et al.⁷⁹ retrospectively assessed the outcome of 39 workers in one large foam-producing plant who were identified on the basis of the surveillance program and referred for specialist assessment. Only one was eventually found to have OA, although two who had a history of OA were quickly removed from exposure prior

to assessment, and had resolution of their symptoms with no airway hyper-responsiveness. The questionnaire component in this study appeared to be the most useful screening measure. Spirometry did not add to the benefit of the questionnaire. However, further studies to assess the role of medical surveillance components are needed to more fully assess the value of such programs.

Irritant-induced OA

Some prevention of exposure to high concentrations of respiratory irritants in the workplace may be achieved by good occupational hygiene practices in the workplace and the inclusion of worker education as to the appropriate actions to take in the event of accidents, such as containment measures, appropriate respiratory protection and evacuation. However, because of the accidental nature of such exposures it may not be possible to prevent all cases of irritant-induced asthma.

Work-related aggravation of asthma

Unlike the preventive measures for irritant-induced asthma, which are indicated for all potentially exposed workers, the prevention of work-related aggravation of asthma is largely directed at the individual who has asthma, since they may not tolerate work environments which would be considered safe for non-asthmatics. The measures taken relate to the individual's asthma severity and control as well as to the work exposures.

Optimum non-occupational environmental control measures, asthma education, and pharmacologic control of underlying asthma are clearly beneficial to the patient to reduce the likelihood and severity of asthma exacerbations.

Patients with asthma would be expected to benefit from pre-employment counseling by their physician as to which types of occupation may aggravate their asthma symptoms, depending on the severity and control of asthma. Work in a relatively clean environment with limited expected exposure to dusts, smoke, fumes, and sprays, with moderate workplace temperatures and exertional requirements which are not known to trigger asthma in such a patient would be ideal. Conversely, shoveling snow in the winter months or work in an industrial setting with glues, solvents or irritant cleaning agents, for example, would be expected to exacerbate symptoms in most asthmatics. It is of interest that individuals with childhood onset of asthma may self-select to appropriate occupations. For example, a recent study⁸⁰ comparing medical x-ray technologists and physiotherapists found a significantly lower history of childhood asthma among the medical x-ray technologists (who had exposure to potential respiratory irritants in x-ray film processing and development).

There may be greater difficulty for adult-onset asthmatics who have already chosen their career path. They may have the option of primary prevention of work-related aggravation of asthma by moving to work in a relatively clean environment with moderate temperatures and exercise requirements as discussed above. If not, then second-

ary measures such as an adjustment in asthma control medications such as inhaled steroids and long-acting bronchodilators during work weeks in addition to short-acting bronchodilators as needed may prevent work-related exacerbations of asthma. Such patients should also be educated as to the likelihood of increased effects of workplace irritants at times of concurrent upper respiratory infections (at which time it may be appropriate for them to be off work or in modified duties until asthma control again improves), or at times after non-occupational allergen exposures.

SUMMARY AND CONCLUSIONS

Each year the number of causes of OA continues to increase, with new agents, or new occupational uses of previously recognized sensitizers. Prevalence rates of some of the causes have been studied in detail but rates for individual causes will vary with geographic region, depending on the local occupations, industrial practices, and industrial hygiene measures which will affect levels of exposure to respiratory sensitizers and irritants. As the prevalence of asthma in the general population has increased, more workers have asthma, thus increasing the population at risk for workplace aggravation of their asthma.

Work-related asthma should be considered in any adult with new onset or worsening asthma. Once the diagnosis of asthma is confirmed, investigations to clarify the presence and type of work-related asthma should be pursued. As objective a diagnosis as possible should be reached, as the management and prevention of sensitizer-induced, irritant-induced, and work-aggravated occupational asthma differ. Unfortunately there is no simple, readily available diagnostic test for occupational asthma. A careful occupational history is critical. Supportive or confirmatory investigations vary depending on the type of work-related asthma and, whenever possible, should be performed before the patient is removed from work. Improved preventive, surveillance, and diagnostic strategies are greatly needed. Ongoing research to better define the pathogenic mechanisms and host and exposure risk factors should lead to such strategies.

19.3 Byssinosis and Other Textile Dust-Related Lung Diseases

E Neil Schachter

For nearly 300 years, work in the textile industry has been recognized as an occupational hazard. In the early 18th century, Ramazzini described a peculiar form of asthma among those who card flax and hemp. The 'foul and poisonous dust' that he observed 'makes the workmen cough incessantly and by degrees brings on asthmatic troubles'.¹ That such symptoms did occur in the early textile industry has been illustrated by Bouhuys in his physiologic studies at Philipsburg Manor (a restoration project of life in the early Dutch colonies in North Tarrytown, New York).² In a primitive workshop where raw flax fiber was processed, this study documented objective lung function changes characteristic of those seen in modern textile workers.

The term byssinosis derives from a Greek (βυσσος) and a Latin (byssus) root first applied to the description of illnesses of textile workers by the Belgian public health physician Achille Adrien Proust in the late 19th century.³ Although numerous authors throughout the 19th and early 20th centuries in both Britain and Europe⁴⁻¹¹ described the respiratory manifestations of work-related illness in textile mills with increasing frequency, the disease remained essentially unrecognized in the United States until the 1960s when studies under the direction of Richard Schilling indicated that despite pronouncements to the contrary by both industry and government, characteristic byssinosis did occur in the US.¹²⁻¹⁶

From this modest beginning, through the efforts of epidemiologic and clinical investigations, the United States not only recognizes the important prevalence of this illness among its textile workers, but has, as a result of these findings, developed some of the most stringent environmental standards in the world. Additionally, these cotton dust standards are coupled with medical surveillance within the industry. This approach begun in the 1970s promises to reduce the prevalence of byssinosis in the United States, although residual disease in older and retired workers may persist. Moreover, shifts in the textile industry to other centers throughout the world and particularly to developing countries have recently confirmed that with inadequate control, byssinosis will continue to be a important occupational illness of international concern (Table 19.3.1).

Niven et al.¹⁴⁰ report that: 'similar prevalence rates of byssinosis as experienced in the UK in the 1950s and 1960s are now being experienced in the developing countries where production is increasing. Prevalence rates of byssinosis of 30% in Indonesia, 37% in Sudan, 40% in Ethiopia and up to 50% in India have been reported, although the same criteria for diagnosing byssinosis have not been used in all these studies. It thus appears that while the disease is disappearing from the UK as a result of both lower dust exposures and because of industrial recession, it is becoming epidemic in parts of the world where cheap labor can be exploited'.

THE TEXTILE INDUSTRY

Natural fibers are common in the vegetable world, particularly among plants structured with cellulose (e.g., cotton,

wood, straw); however, only a limited number of these natural fibers can be used for textile products based on their physical properties (e.g., length, strength, pliability, elasticity). The use of these vegetable fibers for the manufacture of textiles dates back to the third millennium BC. Cotton was processed in India, flax in Egypt, and silk in China. The manufacture of these textiles, however, remained relatively limited, and the processes for converting them to yarn and fabric were primitive until the Industrial Revolution, at which time the cleaning and spinning of textiles became automated and developed on a large scale. Despite a tremendous growth in the use of man-made fibers, natural fibers remain a major source of textiles.

Recent trends in the industry show that while worldwide consumption of cotton continues to grow in recent years, production in the US has stabilized or declined, as have exports of this commodity (Table 19.3.2). This trend is reflected by a drop in the current workforce, which is projected to continue, albeit at a slower rate, well into the next decade (Table 19.3.3).

Vegetable fibers are categorized according to the origin of the fiber within the plant (Table 19.3.4). The difficulty in physically separating cellulose fibers from other vegetable components explains in part why only a limited number of plants can be used for textile manufacture. Steps in the processing of the three major vegetable fiber groups are outlined in Table 19.3.5. The early phases of the process (e.g., opening, picking, carding) tend to be dustier and dirtier because during this phase, non-cellulose plant material is separated from the fibers to obtain a pure product. In this stage of processing, brittle components of the processed plant may be ground by the mechanical separator and disseminated in a fine dust that includes particles of respirable dimension. Inhalation of this material is associated with the clinical syndromes seen in textile workers. The description presented by Kay⁸ in 1831 is particularly vivid: 'In the production of yarn, cotton is subjected to various processes, during the different stages of which, considerable quantities of dust and small filaments escape, are driven into the air by the circular motions of the machinery. I have ascertained by inquiries which I prosecuted extensively amongst the population engaged in cotton spinning, that those employed in the early processes, and particularly in the card rooms, are more subject to those affections of the lungs which are vulgarly classed under the symptomatic denomination of coughs, than the workmen engaged in the latter operations'.

PATHOGENESIS AND ETIOLOGIC AGENTS

Despite studies of workers, as well as in-vivo and in-vitro models, etiologic agent(s) and pathogenesis of byssinosis remain unclear. Identification of a specific agent could lead

to technology that would eliminate such a toxin (either during the growing of cotton or the processing of textiles) before it is spread by dust in the workplace. The most common hypotheses about the pathogenesis of byssinosis include: (1) the release of mediators, (2) immunologic mechanisms, and (3) airway reactions to specific cotton dust components.

Release of mediators

The release of pharmacologic mediators either preformed (e.g., histamine, serotonin) or synthesized de novo (e.g., leukotrienes) has been proposed to explain the mechanism of the acute (across-shift) changes seen with exposure to cotton dust.^{16–24} The subacute changes have been associated with hyper-reactivity and sustained airway obstruction.

Source of fiber	Examples
Fibers originate from seeds or the inner walls of the fruit.	Cotton, kapok (kapok tree)
Each fiber is a single cell.	Coir (coconuts)
Fibers originate from the inner bast tissue of the plant stems. Each fiber consists of the overlapping cells.	Flax, hemp, jute
Fibers are part of the fibrovascular system of leaves.	Abaca, heneguen, sisal

Table 19.3.5 Schematic outline of some of the key steps in the processing of three major textile groups

In-vitro studies using both animal^{16,17,19,22,24} and human tissue^{20–23} demonstrate that exposure to cotton dust or extracts of cotton bracts (CBE) leads to the release of histamine and other mediators.¹⁹ Although cotton dust may itself contain histamine and other mediators, the quantity of these agents has generally been considered too small to explain the physiologic phenomena. Recent work in vivo with subjects not previously exposed to cotton dust demonstrates that CBE injected into the skin elicits a cellular reaction characteristic of non-immunoglobulin-related mediator release,²⁵ with the early appearance of mast cells, which degranulate, followed by prominent chemotactic effects. Similar findings of inflammation have been reported in the airways with the generation of mediators following CBE exposure.²²

Elevated levels of histamine have been reported in the blood of both cotton and flax workers.²⁶ Levels usually are significantly higher on the first day of re-exposure after an absence from work, and in some studies, the amount of histamine appears to be related to the level of dust exposure.²⁷ Individuals continuously exposed to cotton dust were reported to have lower blood levels of histamine than those with interrupted exposure.²⁸ The histamine metabolite 1-methylimidazole-4-acetic acid has been found to be elevated in 24-hour urine samples of normal individuals challenged with cotton dust. This finding suggests that endogenously formed histamine is released following exposure to cotton dust.^{29,30}

A host of other mediators have been associated with airway irritation due to cotton dust exposure. It has been suggested that a 5-hydroxytryptamine receptor agonist is released by cotton dust, an observation that may be related

to the finding that circulating platelets decrease over the work shift in textile workers.²⁴ When they are incubated with gram-negative bacteria isolated from cotton, neutrophils induce platelets to release serotonin, probably as a result of the generation of platelet-activating factor (PAF).³¹

Products of arachidonic acid metabolism, prostaglandins, leukotrienes, and thromboxane have all been demonstrated following cotton dust and bract stimulation of cells and tissue *in vitro*.^{32,33}

No single mediator can explain cotton dust-induced bronchial obstruction. Histamine, although ubiquitous in these reactions, in general is associated with only a short-lived airway response, and pretreatment with antihistamines has not consistently blocked byssinotic reactions.³⁴ In contrast, the mast cell stabilizer cromolyn blunts the response to CBE. Leukotrienes and PAFs may account for some of the delayed features of the response as well as the associated chemotactic phenomena. None of these mediators, however, explain the characteristic tachyphylaxis that occurs over the work week early in the course of the disease (see below).

Immunologic mechanisms

Immunologic mechanisms have been proposed to explain clinical findings in byssinosis. These include: (1) immediate hypersensitivity (immunoglobulin E [IgE] mediated), (2) immune complex formation, and (3) complement activation. In favor of an immune reaction is the relatively long period of time (usually years) required before workers begin to note symptoms, which could indicate sensitization. Clinical investigations, however, show that naive subjects develop airway obstruction when challenged with CBE,³⁵ as well as immediate and delayed skin reactions.²⁵ These lung function changes in naive subjects are, in general, not associated with symptoms, and the delayed onset of symptoms in workers may reflect slow progressive damage.

Studies of textile workers have suggested that IgE-mediated reactions might be involved in byssinosis,^{36,37} and found that exposure to dust in textile mills can raise IgE levels.³⁸ The presence of specific allergy to fungal antigens in cotton dust has been reported. However, other studies³⁹ have found negative RAST and skin test results for cotton dust extracts in byssinotic workers. Non-specific allergy, produced by other antigens or airway hyper-reactivity, may play a role in predisposing workers to byssinosis.^{40,41}

The early suggestions of an immune complex disease have not been borne out by subsequent investigations.^{42,43} Extracts of cotton dust have been shown to activate the complement cascade *in vitro*.⁴⁴ However, *in-vivo* measurements of complement during the work shift do not show signs of activation.³⁹

Specific cotton dust components

There are at least 50 biologically active components of cotton dust that could contribute to pathologic reactions. Two of these components have been extensively studied.

Endotoxin

Vegetable fibers are host to a variety of micro-organisms. Unopened cotton bales are sterile;⁴⁵ however, sterility quickly disappears after the bale opens, and bacterial contamination of baled cotton is widely recognized.⁴⁶ Of the bacterial flora that live on the plants processed by the textile industry, interest has focused on Gram-negative organisms. Measurements of airborne contamination in cotton mills suggest that concentrations of 10^2 to 10^5 organisms/m³ were present, with higher concentrations being found in cardrooms.^{47,48} Bacterial endotoxin is a biologically active organic constituent of the wall of Gram-negative bacteria and is now commonly measured in cotton dust as well as in the air of the mills.^{49,50} It has been hypothesized that these endotoxins promote inflammatory reactions in humans that account for many of the features of byssinosis.⁵¹

Endotoxin that is composed primarily of bacterial lipopolysaccharides (LPS) induces a variety of *in-vitro* and *in-vivo* reactions when studied in various animal and human models. Alveolar macrophages are activated by LPS and respond by secreting lysosomal enzymes and neutrophil chemotactic factors and by increasing phagocytosis.^{52,53} Platelets also are recruited in this response.^{54,55} Additionally, histamine release⁵⁰ and fever have been associated with exposure to LPS.

In a model cardroom, Castellan and coworkers⁵⁶ demonstrated a strong correlation between lung function decrements (over a 6-hour exposure) with levels of endotoxin (6–779 ng/m³), but not airborne dust concentrations (0.12–0.55 mg/m³). A similar study⁵⁷ demonstrated that washing cotton resulted in reduced declines in FEV₁, which correlated with endotoxin concentrations. A group of investigators have proposed a standard for airborne endotoxin.⁵⁸ While these guidelines may prove useful (they are as yet untested) their potential is already limited by the fact that between laboratories comparisons of standardized endotoxin preparations yield very different measurements.⁵⁹

In contrast, not all studies indicate that endotoxin is associated with bronchospasm.⁶⁰ Some of the exposure levels in these negative studies, however, were lower than may be necessary to produce bronchoconstriction.^{17,50,51,61,62}

Recently a series of clinical studies such as those of Nightingale et al.⁶³ and Michel et al.⁶⁴ indicate that in asthmatic, atopic, and even healthy individuals, the inhalation of endotoxin is associated with neutrophil inflammation and the release of interleukins (e.g., IL8 and TNF α) and other mediators. In some but not all individuals, Kline et al.⁶⁵ have demonstrated dose-related drops in lung function following challenge with inhaled lipopolysaccharide. Despite the plausible hypothesis that, as in asthma, chronic inflammation (in this case associated with endotoxin exposure) is the causative agent of chronic lung disease in the textile industry, epidemiologic studies of textile workers, such as that reported by Christiani et al.,⁶⁶ have not confirmed this. In their 11-year prospective study of cotton and silk workers in Shanghai, cumulative dust levels, but not endotoxin, were associated with a consistent 11-year loss in FEV₁ (after adjustments for

confounders). The authors conclude that cotton dust is more strongly associated with chronic airflow limitation than with endotoxin.

Taken together, these studies suggest that although the presence and quantity of endotoxin in cotton dust may be a good index of acute bronchoconstrictor responses, endotoxin alone is not the principal bronchoconstricting agent. The role of endotoxin in the development of chronic byssinosis disease remains to be determined.

Tannins

This group of biochemical substances is widely distributed among plants, particularly in their roots, leaves, and fruits. Tannins have been documented in mill dust and aqueous extracts of bracts. Soluble tannin was found to constitute 4.2% of unsieved mill dust and 5.1% of respirable mill dust in one setting.⁶⁷ Studies suggest that the biologic activity of these tannins may explain some of the physiologic observations seen with byssinotic reactions.^{24,68-75} Tannins have been shown to recruit neutrophils into the airways of different laboratory animals.^{68,69} In vitro, tannins cause aggregation of platelets with the release of a number of mediators, including serotonin and thromboxane A₂.²³ These inflammatory responses tend to mimic the time course of the acute response to CBE extracts. In addition to stimulating inflammatory cells, tannins may have a toxic effect on respiratory epithelial and endothelial cells.^{73,74}

Several additional interesting activities of tannins on airway cells have been described by Cloutier et al.^{76,77} In vitro, tannin inhibits chloride secretion of airway epithelium in part by inhibiting protein kinase c (PKC). Such inhibition could result in mucus retention and decreased mucociliary transport. Additionally this group has shown that cotton bract tannin can blunt isoproterenol-stimulated cyclic AMP (cAMP) accumulation by desensitizing tracheal epithelial cells to beta agonists. Ultimately this also could affect chloride secretion and mucous content in the airways, a phenomenon demonstrated by Marom et al.²²

Tannins, by contrast, do not produce direct airway smooth muscle contraction in animal models, as do extracts of cotton dust.^{24,74} Laboratory studies using guinea pigs to observe neutrophil recruitment and cotton textile workers to measure lung function changes across a shift failed to demonstrate a clinical effect of tannins.⁷⁵ Hence, although the biologic activity of tannins remains impressive in vitro, there is little evidence to support the theory that these agents contribute to clinical findings.

Other agents

Examination of the biochemical constituents of cotton dust has shown that this byproduct contains more than 50 biologically active substances, including tannins, terpenoids, primary amines, endotoxins, glucans (a major biochemical component of fungi), and lacinelenes, many with known toxic properties.^{19,67,78} Attempts to better define the nature of these active agents have met with varying degrees of success. An in-vivo assay with healthy human subjects was established by Buck^{79,80} to determine the bronchoconstrictor potential of various fractions of the

crude bract preparation. The majority of the extract activity was confined to low molecular weight substances (<1000 daltons). Removal of lacinelene and endotoxin activities in this analysis failed to significantly reduce the bronchoconstrictor activity of the extract. The active agent in this system was highly soluble in water (as the cotton washing trials suggest) and less so in organic solvents. This purified fraction contains glucose and possibly other hexoses as well as amino nitrogen, but the final identification of the active agent or agents remains elusive.

CLINICAL FEATURES OF TEXTILE WORKER'S DISEASE

Byssinosis is a disease of textile workers characterized by distinctive work-related respiratory complaints (often called Monday symptoms) as well as changes in pulmonary function. When they are processed to make textiles, many⁸¹⁻⁸³ but not all vegetable fibers may cause byssinosis (Table 19.3.6). The distinguishing feature of the clinical history in the patient with byssinosis is its relationship to the work week. The worker, typically after having worked a number of years in the industry, describes chest tightness beginning on Monday (or the first work day of the work week) afternoons. The tightness subsides that evening, and the worker is well for the remainder of the week, only to re-experience the symptoms on the following Monday. Monday dyspnea may continue unchanged for years or may progress with symptoms developing on subsequent workdays until tightness is present throughout the work week and ultimately while the person is away from work on weekends and vacation.

When the symptoms become chronic, dyspnea is described as effort dependent. At this stage, a non-productive cough may be present. Monday symptoms are accompanied by across-shift decreases in lung function. These decreases may be present on other work days even in the absence of symptoms, but the physiologic changes are not so marked (Fig. 19.3.1). Baseline (Monday pre-shift) lung function deteriorates as the disease progresses. The characteristic respiratory and physiologic changes seen in byssinosis workers have been standardized by Schilling^{79,80} into a series of grades (Table 19.3.7), which currently form the basis of most clinical and epidemiologic investigations. Symptoms other than chest tightness are frequent among textile workers, particularly cough and bronchitis. These symptoms probably represent variants of the airway irritation brought on by dust inhalation.

Byssinosis	Non-specific airway irritation
Cotton	Jute
Flax	Sunn: Indian hemp
Soft hemp	Henequen
Sisal	Mauritius hemp
	Manila hemp
	St. Helena hemp

Table 19.3.6 Vegetable dusts causing byssinosis

Figure 19.3.1: Forced expiratory volume in one second (FEV₁) during 5-day exposure of 25 carders classified according to symptoms of byssinosis. With permission from Merchant JA, Halprin GM, Hudson AR et al. Evaluation before and after exposure – the pattern of physiological response among cotton textile workers. *Ann NY Acad Sci* 1974; 221:38–43. © 1974 New York Academy of Sciences, USA.

Grade	Symptoms
Grade 0:	Normal – no symptoms of chest tightness or cough.
Grade 1/2:	Occasional chest tightness or cough or both on first day of working week.
Grade 1:	Chest tightness on every first day of the working week.
Grade 2:	Chest tightness on every first day and other days of the working week.
Grade 3:	Grade 2 symptoms, accompanied by evidence of permanent incapacity from ventilatory capacity.

Table 19.3.7 Grades of byssinosis

Many of the quoted epidemiologic studies note the high prevalence of bronchial irritability in workers with byssinosis. This finding tends to occur in older workers who frequently have a history of heavy smoking. Nevertheless, analysis of symptoms in non-smoking workers as well as pathologic findings suggest that chronic dust exposure is an independent risk factor for chronic bronchitis and, therefore, these symptoms are consistent with the diagnosis.

The prevalence of symptoms and lung function abnormalities is dose dependent and job dependent. For example, in a landmark study by Merchant et al.^{86,87} involving North Carolina cotton textile workers, non-smoking workers in the yarn and cotton preparation areas had a byssinosis prevalence (all grades) of approximately 5% when they were exposed to median dust levels of 0.1 mg/m³; this rate rose to nearly 15% when the dust levels were 0.5 mg/m³. Among smokers, the prevalences were approximately 15% and 35% for similar exposure levels.

In different textile industries (e.g., hemp, cotton, flax) reported prevalences of byssinosis have varied greatly, as they have within a single industry. In a study by Valic and Zuskin⁸⁸ byssinosis prevalences were highest among hemp and flax workers (44% and 43%) and lower in cotton workers (20%). No specific byssinotic symptoms were elicited among the sisal or jute workers, although these workers experienced high prevalences of other non-specific respiratory symptoms. The absence of precise exposure data (e.g., dust and endotoxin levels) makes interpretation difficult.⁸⁸

In addition to classic byssinosis, textile workers are subject to several other symptom complexes; in general, these problems are associated with fever and are not related to the initial day of the work week.

Mill fever (cotton fever, hemp fever) is associated with fever, cough, chills, and rhinitis that occurs with the workers' first contact with the mill or with return after a prolonged absence. Chest tightness does not appear to be associated with this syndrome. The occurrence of these findings is variable, from as low as 5%⁸⁵ of the workers to a majority of those employed.⁸⁹⁻⁹¹ Characteristically, symptoms subside after a few days despite continued exposure in the mill.

*Weaver's cough*⁹² is primarily an asthmatic condition characteristically associated with fever; it occurs in both new and senior workers. The symptoms (unlike mill fever) can persist for months.

The third syndrome associated with textile processing is *mattress makers' fever*.⁹³ In its original description, it was characterized as an acute outbreak of fever and constitutional symptoms, including retrosternal discomfort in workers using low-grade cotton.

In general, the febrile syndromes are believed to be clinical entities distinct from byssinosis. For example, in studies of 528 cotton workers by Schilling,⁸⁸ 38 gave a history of mill fever. The prevalence among workers with classic byssinosis was 10% (14:134) compared with 6% (24:394) among workers without byssinosis (not significantly different).

As defined by historical criteria, chronic bronchitis is very prevalent among textile workers,^{94,95} particularly among non-smoking textile workers.^{89,96,97} This finding is not surprising because the most characteristic histologic feature of this disease is mucous gland hyperplasia.⁹⁸⁻¹⁰⁰ The syndrome of chronic bronchitis should be distinguished carefully from the symptoms of classic byssinosis, although byssinotic and bronchitic complaints frequently overlap and are probably different pathophysiologic manifestations of airway inflammation in textile workers.

Pathologic studies of textile workers are limited, but reports have shown a consistent pattern of disease involving the larger airways but no evidence suggestive of destruction of lung parenchyma (e.g., emphysema).⁹⁹

CLINICAL COURSE

Acute versus chronic disease

Implicit in the Schilling grading system (Table 19.3.7) is a progression from acute Monday symptoms to chronic and essentially irreversible respiratory disease in workers with byssinosis. That such a progression occurs has been suggested in cross-sectional data beginning with the early studies of Lancashire cotton workers, which found a shift toward higher byssinosis grades with increasing exposure (Table 19.3.8). Similar findings have since been reported by others.¹⁰¹⁻¹⁰² Moreover, this progression may begin relatively soon after employment (e.g., within the first few years).¹⁰³

Cross-sectional data^{104,105} also have shown that other chronic respiratory symptoms such as wheezing or chronic bronchitis are much more prevalent in older cotton textile workers than in a similar control population. Table 19.3.9 shows the prevalence of chronic bronchitis in a population of cotton workers and in two control groups. In all cases, the cotton textile workers have more chronic bronchitis than do the controls, even when adjusting for sex and smoking status. Grade 3 byssinosis indicates that in addition to symptoms, textile workers demonstrate changes in respiratory function.

The progression from early byssinosis (grade 1) to late byssinosis (grade 3) is suggested by the association of lung function loss with the higher grades of byssinosis in cross-sectional studies of textile workers.^{102,106} Several studies have given support to the concept that across-shift changes in lung function (which correlate with chest tightness) are related to chronic irreversible changes.¹⁰⁷

Underlying the association between acute and chronic disease in textile workers is a dose-response relationship seen for acute symptoms. This relationship was first docu-

mented by Roach and Schilling¹⁰⁸ who found a strong linear association between biologic response and total dust concentrations in the workplace. Based on their findings, they recommended 1 mg/m³ gross dust as a reasonably safe level of exposure. This concentration, later adopted by the American Congress of Government Industrial Hygienists, was the value used as the threshold limit value (TLV) for cotton dust. The fine dust fraction (<7 µm) has been shown to account for practically all of the prevalence of byssinosis.^{101,109,110} Merchant et al.⁸⁷ confirmed the association between byssinosis prevalence (as well as decrements in expiratory flows) and concentrations of lint-free dust in a study of cotton and other textile workers.

The validation of progressive changes in respiratory function suggested by cross-sectional studies has come from a number of longitudinal investigations that complement and extend the results of the earlier studies. These studies have highlighted the accelerated loss of lung function in cotton textile workers as well as the high incidence of new symptoms.^{94,96,105,115,116}

Many authors have raised the potential confounding issue of cigarette smoking. Because many textile workers are cigarette smokers, it has been claimed that the chronic lung disease associated with exposure to textile dust can be attributed, in large part, to cigarette smoking. However, Beck et al.¹¹⁷ demonstrated that the effects of cotton dust and smoking on lung function were additive, that is, the amount of lung function loss due to one factor (smoking or cotton dust exposure) was not changed by the presence or absence of the other factor. In a related study, Schachter et al.¹¹⁸ demonstrated that using a parameter that described the shape of the maximum expiratory flow volume curve, angle beta, distinct patterns of lung function abnormalities could be shown for a smoking effect and for a cotton effect. Similar conclusions were also reached by Merchant.⁸⁶

More recent studies have confirmed an association between acute, across-shift changes in lung function and chronic loss of lung function in textile workers. Glindmeyer et al.¹¹⁹ found a significant association between acute and chronic effects of cotton dust extracts on lung function. While some shortcomings of this study have been pointed out by Becklake,¹²⁰ these observations are consistent with previous findings.

Mortality

Studies of cotton dust exposure on mortality rates have not consistently demonstrated an effect. Review of experience in the late 19th and early 20th centuries in England¹²¹ suggested a high rate of cardiovascular mortality in older textile workers. In contrast, review of the experience in New England and Georgia mills failed to demonstrate high rates of mortality.^{122,123} In contrast, a study of Dubrow and Gute¹²⁴ of male textile workers in Rhode Island using the proportionate mortality ratio (PMR), showed a significant PMR for non-malignant respiratory disease. These PMRs followed the trend of jobs with high dust exposure. An interesting finding of this and other studies^{123,125} is the low mortality rates from lung cancer among these workers,

Years of exposure	0	Byssinosis grades		Total byssinotic (1 + 2)
		1	2	
0-9	14 (67%)	4 (19%)	3 (14%)	7 (33%)
10-19	22 (47%)	18 (39%)	7 (15%)	25 (53%)
20-29	22 (35%)	22 (35%)	19 (30%)	41 (65%)
30+	17 (29%)	23 (39%)	19 (32%)	42 (71%)

‡ Compared with cotton textile workers $P < 0.1$.
§ Compared with cotton textile workers $P < 0.05$.

Table 19.3.9 Prevalence of chronic bronchitis by sex and smoking status in three populations of whites aged 45-74 years

which has been used to argue that smoking is not a major cause of mortality in these groups. Observations from a cohort in South Carolina¹²⁶ suggest that chronic lung disease is a major cause (or predisposing factor) for mortality in this population.

DIAGNOSIS

Unfortunately, there is no simple test to diagnose byssinosis. This diagnosis is made on the basis of worker symptoms and a consistent occupational exposure history. Although they are not always specific, lung function data may be helpful in establishing the diagnosis and in characterizing the degree of impairment.

History

Characteristic work-related symptoms found in the early stages of the disease (byssinosis grades 1/2, 1, and 2; Table 19.3.7) have served as a basis for establishing the clinical diagnosis. Chest tightness and breathlessness are associated with the first and possibly subsequent workdays following an absence from the workplace. These symptoms are characterized by substernal discomfort, which may be aggravated by exertion. The symptoms become progressively more prominent over the course of a work day, first being noted several hours after beginning work. The symptoms persist after leaving the mill but characteristically disappear by the evening. These grade 1 symptoms may persist for years or may advance rapidly to grade 2 symptoms.⁸⁵

Confounding the clinical diagnosis of byssinosis is the frequent co-existence of cough and chronic bronchitis. These symptoms may result from dust exposure in combination with other risk factors, such as cigarette smoking, and the progression to grade 3 disease.

The importance of occupational history in the diagnosis of byssinosis needs to be emphasized. The early phases of the processing of cotton in the mill are those most likely to be associated with symptoms. Workers employed in maintaining and cleaning machinery (such as carding machines) may be at a particular risk. Also of interest when assessing exposure is the age of the equipment (many modern machines have built-in pollution control devices) and the layout of the mill; if the mill is small with different processing areas contiguous in one open space, dust levels and content may be similar in different processing areas.

A misconception that occasionally arises, even among otherwise sophisticated medical personnel, is that individuals may develop byssinosis from the end-product (cloth products). There is no evidence that these contain any of the toxicants of cotton dust, and hence neither fabricators of finished products (e.g., seamstresses) nor the general public are at risk.

Probably the most difficult differential diagnosis is in the older worker with irreversible lung disease. These workers with a variety of respiratory symptoms may describe 'Monday dyspnea,' which presumably occurred decades earlier. A history of cigarette smoking may confuse the issue because symptomatic findings may be identical in chronic

smokers and workers with long exposures in the industry. Analysis of data from epidemiologic studies suggests that chronic exposures to cotton dust and cigarette smoke yield approximately equal physiologic impairment when measured by FEV₁.¹¹¹ A presumptive diagnosis should be made if the clinical, physiologic, and exposure data are consistent with byssinosis. This is particularly important in older workers with impairment of lung function in whom fixed symptoms are described and 'Monday dyspnea' may not be elicited.

Lung function

Monitoring of across-shift lung function changes and annual lung function testing are part of the mandated medical surveillance of workers in the United States.

In many workers with byssinotic symptoms lung function deteriorates over the Monday work shift. Characteristically, a 5% decrement or a loss of 0.2 liter of FEV₁ across a shift have been considered significant. More recently, the widespread availability of spirometric devices relating flow to volume has popularized the use of flow rates. Changes in flow rates at low lung volumes, such as the forced expiratory flow at 50% of the vital capacity (FEF₅₀ or Vmax₅₀), show proportionally greater changes from baseline over a shift and have been used by some investigators¹²⁰ to characterize lung function changes. Despite the usefulness of spirometry in characterizing 'Monday dyspnea', there is not always a correlation between lung function and symptoms so that the absence of across-shift changes in FEV₁ does not exclude the diagnosis.

In addition to across-shift changes in spirometry, accelerated loss of lung function also is associated with work in the textile industry.⁹⁴ One proposed classification of respiratory impairment is shown in Table 19.3.10.¹²⁷ Other lung function measurements such as arterial blood gases¹²⁸ and nitrogen washout have been used to characterize byssinotic responses, but are not practical for diagnosis. Static lung recoil pressures¹²⁹ do not change with exposure. The diffusing capacity is usually unaffected in patients with byssinosis, consistent with the pathologic observations that chronic airway changes rather than emphysema are associated with byssinosis.^{98-100,130} Overall, the physiologic picture suggests airways obstruction and, in particular, obstruction of smaller airways.¹³¹ In some workers, however, a restrictive or mixed pattern also may be seen.¹³²

Functional category	Across-shift change in FEV ₁	Reduction in baseline FEV ₁ *
F0	None (less than 5%)	None (>80%)
F1/2	Slight (6–20%)	None
F1	Definite (>20%)	None
F2		Slight/moderate (60–75%)
F3		Moderate/severe (<60%)

* As a % of predicted

Table 19.3.10 Classification of respiratory impairment by functional grades in byssinosis

Physical examination

Physical findings in workers with byssinosis are non-specific. In workers with advanced disease, the stigmata of chronic obstructive airway disease (e.g., hyperinflation, cor pulmonale) may be elicited.

Laboratory evaluation

In general, routine laboratory examinations are not useful in the diagnosis of byssinosis. With advanced disease, the findings of respiratory insufficiency and cor pulmonale may be noted. The chest x-ray study usually is normal but may show changes caused by hyperinflation.

Challenge testing

A number of studies suggest that individuals with underlying hyper-responsiveness may be at greater risk for byssinosis. Among exposed individuals, atopic patients have been found to have greater declines in FEV₁ than non-atopic patients.⁴⁰ In studies of non-exposed individuals, responsiveness to a water-soluble extract of CBE produced lung function changes and symptoms similar to those of grade 1 byssinosis.⁸⁰ Similarly, non-exposed subjects who respond to CBE have been found to have a lower threshold to methacholine and a greater response to metaproterenol than those who do not respond to CBE.⁴¹

Immunologic testing

Extracts of various cotton byproducts have been shown to produce an immediate as well as a delayed reaction to skin testing¹³³ but have not proven to be useful diagnostically. Immediate sensitivity to skin testing has not been associated with airway reactivity. This finding is not surprising because the typical airway response to CBE is not immediate but subacute.^{35,41} The delayed response on skin testing characterized by Schachter and colleagues,²⁵ may correlate with the airway inflammation and bronchoconstriction reported following airway challenge with CBE.¹³⁵ Skin testing and RAST testing for cotton dust have not been shown to be helpful in establishing the diagnosis of byssinosis.³⁹ Finally, workers with byssinosis do not have elevated levels of IgE.¹³⁶

Other diagnostic tests

Routine blood and urine tests, chest x-ray studies, and ECGs are not helpful in diagnosing byssinosis. However, they may be useful in characterizing the complications of chronic lung disease, such as respiratory infection, respiratory failure, or cor pulmonale.

Blood histamine levels have been reported to correlate with the days of the week and the level of dust exposure,^{26,27} but have not been used routinely to diagnose this disease.

Pathologic studies of textile workers are limited, but reports have shown a consistent pattern of disease involving the airways without evidence suggestive of destruction of lung parenchyma (e.g., emphysema). Histologic evalua-

tion is not indicated in the routine work-up of patients with suspected byssinosis.

Relatively little is known about the cellular constituents and inflammatory products associated with the airway disease of textile workers.¹³⁷ In a study of BAL in naive subjects prior to challenge with CBE, Merrill and coworkers¹³⁸ noted that the proportion of lymphocytes present in BAL correlated with the physiologic response. Subsequent studies by this group have demonstrated the inflammatory nature of the response to CBE¹²⁸ and the release of mediators. Experience is much too limited at present to advocate the use of this technique for either diagnosis or management.

Specific antigen inhalation tests have been used to characterize occupational lung diseases. Schachter and coworkers challenged seven senior textile workers with CBE¹³⁹ who all had severe impairment of respiratory function (mean FEV₁ 52% of predicted) and carried a presumptive diagnosis of byssinosis. Four of seven workers responded to the extract (20% or greater decrease in maximal expiratory flow, measured on the partial flow volume curve [MEF] 40% [P]). These findings suggest that with chronic established disease, challenge with CBE may not be a sensitive method of diagnosis, because at this stage of the disease, reactivity to CBE may have waned in some workers.

TREATMENT AND PREVENTION

Byssinosis displays many of the physiologic features of asthma and chronic bronchitis. Therefore, it is not surprising that the administration of bronchodilating agents such as beta-adrenergic drugs can prevent bronchoconstrictor responses to textile dust exposure.

Antihistamines have been shown to modify byssinotic symptoms and airway obstruction.^{18,34} This latter effect is not surprising given the histamine-releasing action of many textile dusts.^{16,17} Disodium cromoglycate³⁴ has been shown to be a potent agent in preventing acute and delayed responses to organic dusts. Induced airway obstruction through extracts of CBE as well as bronchoconstriction in workers has been significantly reduced by pretreatment with disodium cromoglycate.^{34,140} Finally, the administration of aerosolized steroids (e.g., beclomethasone) has proved beneficial.¹⁴⁰

A comprehensive approach to medical management for the worker with byssinosis has not been formulated. Based on clinical studies, it would appear that beta-agonists (e.g., albuterol) are among the most effective agents for the management of acute respiratory symptoms. If the sensitive worker knows he or she will be exposed to a particularly dusty environment, pretreatment is indicated. The role of long-acting β -agonists such as salmeterol is unknown but is likely to be useful given the effectiveness in asthmatic individuals with persistent symptoms. Because most studies suggest that chronic airway disease in byssinosis is the result of a chronic inflammatory state, the use of aerosolized steroids for workers with symptoms who continue in a dusty environment may have short-term as well as long-term benefits. Other agents such as disodium cromoglycate and

antihistamines also may play a role. To date, there are no controlled clinical trials indicating that long-term pharmacologic management alters the course of the disease.

Prevention of byssinosis is clearly preferable to medical management of the chronic condition. At present, recommended prevention strategies include: (1) dust abatement, (2) medical surveillance with transfer policies for affected workers, (3) treatment of raw cotton to eliminate toxic factors. Currently, preventive efforts are primarily directed at implementing the first two strategies. Pre-employment screening of workers to identify workers with airway hyper-reactivity or a pre-existing allergic condition has been considered but this has not been generally adopted. Finally, although a number of organic and biologic constituents of cotton dust have been implicated in byssinosis, this knowledge has not yet translated itself into an effective strategy for rendering the workplace less dangerous.

In view of the additive effect of cigarette smoking, smoking cessation should be promoted and a smoke-free workplace should be the norm, as recommended by NIOSH.¹⁴¹

Criteria for removal of the affected individual from the workplace, with or without transfer to less dusty areas, are not explicitly defined. Workers with a diagnosis of byssinosis, disabling symptoms, progressive lung function loss, or established obstructive airway disease should be considered for transfer or removal from high-risk areas.

COMPENSATION

Byssinosis was not commonly recognized as an occupational disease in the United States until the 1960s. In contrast, in Great Britain as early as 1927 governmental committees were set up to investigate the effects of dust in the cotton industry,¹⁴² and as a result of one such effort, the Byssinosis (Workmen's Compensation) Scheme became effective in 1941. Under this policy, to be considered disabled, workers had to be male, employed on or after the date of adoption of the Scheme, and working in specified areas. It also was required that these workers be employed in the industry for at least 20 years and be totally and permanently disabled. Over the succeeding years, the terms for compensation were liberalized to include women, cover degrees of disability less than total, reduce the length of exposure necessary for claims, abolish the specific job requirements, and extend the regulations to include flax workers. By 1979, a total of 5045 textile workers had been accepted for compensation at a time when the average annual size of the eligible workforce was 14,700 (this number increased by 7500 in 1974 because of further changes in standards for eligibility).

SURVEILLANCE AND DUST CONTROL

In June 1978, the United States Occupational Safety and Health Administration (OSHA) issued a new cotton dust standard, based on a NIOSH criteria document. This standard proposed reductions in dust levels in the workplace to

be implemented over a 4-year period. During this transition period, workers in high dust areas would wear respirators or masks. For those workers unable to wear respirators, the standard mandated transfer without loss of pay or seniority. In 1981, the United States Supreme Court upheld the more rigorous dust standards advocated by the Textile Worker's Union (ACTWU). At present, the principal provision requires that no more than 200 $\mu\text{g}/\text{m}^3$ respirable particles (measured over an 8-hour period as a time weighted average) be present in yarn manufacturing and cotton washing operations, and carding and spinning areas. For the textile mill waste house operations and lower grade washed cotton in the yarn manufacturing area, the level is 500 $\mu\text{g}/\text{m}^3$, and for slashing and weaving, 750 $\mu\text{g}/\text{m}^3$. The level is 1000 $\mu\text{g}/\text{m}^3$ for waste recycling and garnetting. Data are not readily available to confirm the common view that compliance is generally good.

The adequacy of the current standard has been challenged by the study of Glindmeyer et al.¹⁴⁷ indicating that exposure to dust concentrations below those specified by the current OSHA standard (i.e., <150 $\mu\text{g}/\text{m}^3$ in slashing and weaving areas) might be harmful, particularly in the case of workers who were smokers. They suggested that smokers be restricted from working in yarn manufacturing areas and that the feasibility of lowering allowable respirable dust levels for all yarn manufacturing be studied.

The OSHA standard mandates medical surveillance and specifies standards for the type of apparatus used, the measurement techniques, the interpretation of the tests, and the qualification of the personnel administering the tests. Current standards require that lung function tests be administered annually. If a worker's baseline is less than 80% of predicted or if the FEV₁ decreases by more than 5–10% over a work shift, retesting should be performed semiannually. If lung function is less than 60% of predicted, workers are referred to physicians for a complete examination. The consultant reports to the employer who then voluntarily initiates any necessary change in the employee's work status. Wage retention and transfer, however, are only guaranteed as specified by the employee's contract.¹³⁸ The standard does not address pre-existing airways disease. Recent studies suggest that prescreening workers with measurements of airway reactivity may be useful in identifying workers susceptible to byssinosis. Other studies suggest that airway hyper-reactivity may result from dust exposure.

The outcome of dust abatement on respiratory health in this country as a result of regulatory requirements is largely unknown. The one major study reported in the last decade which addresses this issue¹⁴⁷ indicates that overall byssinosis symptoms were less than 5% among the more than 2000 textile workers studied. There was nonetheless a significantly higher loss of lung function among textile workers due to dust exposure that was dose dependent. Despite clear-cut gains in worker safety in the United States, the problem of adequate and available medical, financial, and rehabilitative help for workers disabled by years of service in the textile industry remains to be resolved. Although the prevalence of byssinosis in developed coun-

tries has fallen, prevalence rates in the developing world remain high.

19.4 Chronic Obstructive Pulmonary Disease and Chronic Bronchitis

Susan M Kennedy

Patients with chronic obstructive pulmonary disease (COPD) and chronic bronchitis are commonly encountered in clinical practice. COPD ranked as the fourth leading cause of death in 2000 and the prevalence of COPD morbidity is estimated at 4% in the United States.¹ In a report released in April 2001, the Global Obstructive Lung Disease Initiative of the US National Heart, Lung, and Blood Institute and the World Health Organization identified the major risk factors for COPD as 'tobacco smoke, occupational dust and chemicals, and indoor/outdoor air pollution'.²

Chronic bronchitis is defined clinically as the presence of cough with phlegm at least 3 months of the year, for at least 2 years. COPD is defined as 'airflow limitation that is not fully reversible, . . . progressive and associated with an abnormal inflammatory response of the lungs to noxious particles or gases'. COPD and chronic bronchitis are the functional and symptomatic consequences of chronic or repeated exposure to inhalation of pro-inflammatory agents from the combination of all sources of polluted air to which the patient has been exposed. These include voluntary sources (i.e., tobacco smoke) and sources present in the work and home environment.

Defining *occupational* COPD and *occupational* chronic bronchitis requires a consideration of this multifactorial etiology. Patients are often exposed to more than one source of polluted air, and the relative contribution of each may be impossible to disentangle. Thus, occupational COPD or chronic bronchitis is best defined as 'COPD or chronic bronchitis in a patient with a history of chronic exposure to pro-inflammatory agents in workplace air'. This definition is useful for clinical management and public health prevention as it points to the potential for eliminating or modifying occupational risk factors for the disease. Additional challenges with defining occupational COPD for legal or compensation purposes will be discussed below.

EPIDEMIOLOGY

Prevalence and population burden

The population prevalence of COPD and chronic bronchitis from all sources increases with age and varies with the distribution of risk factors in the population and with the definitions used. In the third US National Health and Nutrition Examination Survey (NHANES III), a large survey of a representative sample of the US population, the prevalence of low lung function among adults of all ages was 6.8% overall, with about equal prevalence among men and women.³ The prevalence of COPD is increasing both in North America and worldwide, with the rate increasing fastest among women.⁴ The direct and indirect costs to society are large, because the disease is prevalent, chronic, and contributes to considerable loss of work and productivity.

COPD was ranked as the 12th leading cause of disability-adjusted life years lost worldwide in 1990 (including all childhood and adult diseases and accidents).

The general population prevalence of *occupational* COPD and chronic bronchitis is difficult to estimate due to the lack of occupational exposure information in most population-based studies. After reviewing all available published evidence from general population epidemiologic studies, an ad hoc committee of the American Thoracic Society recently estimated the contribution of occupational exposure to the overall population burden of COPD to be at least 15%.⁵ A recent study of 517 lifetime non-smokers referred to a hospital pulmonary function laboratory estimated the population attributable risk among non-smokers from occupational exposure to be 23.6% for bronchitis and 29.6% for obstructive lung disease.⁶

Specific occupational risk factors

Workplace-based studies can provide more precise estimates of the prevalence of occupational COPD and chronic bronchitis than population-based studies, due to more precise estimates of exposure. Occupations in which employees are more likely to develop occupational COPD and occupational chronic bronchitis are those associated with chronic or repeated exposure to organic particulate matter, bioaerosols, combustion products, mineral and/or metal particulate matter or fume, irritant gases and vapours, and combinations of these exposures. These exposures can be found in a wide variety of workplaces, including farming and food processing, wood and textile sector jobs, service occupations, and transportation, as well as the mining and metal processing jobs typically associated with occupational lung disease in the past.

Figure 19.4.1 shows prevalence rates for airflow obstruction (defined as FEV₁/FVC % below the age-adjusted lower 95% confidence limit) among non-smokers, aged 50 and over, from workplace-based cross-sectional studies, compared to a blue-collar 'control' population⁷ and to 'expected rates',⁸ from Canadian studies conducted by the UBC Occupational Lung Diseases Research Unit.⁹⁻¹¹ The sections that follow summarize some of the evidence showing work-relatedness of COPD in selected occupational groups.

Mineral particulate and fibers

Chronic or repeated exposure to mineral particulate matter is common in mining, tunnelling, mineral processing, excavating, and building and road construction. It can also be encountered in numerous other occupational settings such as cement work, stone carving, and even farming.¹² Patients with a history of chronic asbestos exposure are encountered in an even greater array of occupations

Figure 19.4.1: Prevalence rates for airflow obstruction (defined as FEV_1/FVC % below the age-adjusted lower 95% confidence limit) among non-smokers, aged 50 and over, exposed to mineral or organic dusts, or fumes, compared to a blue-collar 'control' population⁷ and to 'expected rates',⁸ from studies conducted by the UBC Occupational Lung Diseases Research Unit.^{10,11,72}

including construction and maintenance work in all sectors.

Prevalence rates for COPD among miners range from 6 to 20% among non-smokers, and up to 60% among smokers^{13–16} and the prevalence increases as exposure duration or intensity increases. Among non-smoking British coal miners, airflow obstruction was found in 10.5% of those exposed to low dust levels and 20.6% of those exposed to medium and high dust levels. Similarly, among non-smoking US underground coal miners the corresponding rates were 7.4% in the lower dust exposure category and 14.3% in the high dust exposure category.^{17,18}

Among miners exposed to higher silica content dust, even higher COPD rates are seen. Among South African gold miners, the estimated effect of dust exposure on airflow obstruction was approximately 10 times greater than that seen among coal miners.¹⁹ Increased mortality from bronchitis, emphysema, and asthma was associated with silica exposure among Norwegian smelter workers.²⁰

COPD has also been clearly demonstrated in association with asbestos exposure.^{21–24} From the evidence to date, airflow obstruction appears more pronounced among workers installing or handling asbestos products than among miners; however only few studies have looked specifically for airflow obstruction in these populations. Among miners and millers of wollastonite (another fibrous dust) significant dose–response relationships for cumulative dust and airflow obstruction were seen in both non-smokers and smokers.²⁵

COPD is also linked to particulate exposure (with and without crystalline silica) in other industries, such as quarrying and carbon black manufacturing.^{26,27}

Metal fumes, irritant gases, combustion products

Exposure to metal fumes, irritant gases, and combustion products appears to augment the effect of exposure to dust alone on COPD. This has been seen in mining and smelter workers,^{28,29} workers in rubber manufacturing,³⁰ welders,^{31–33} in tunnel workers,³⁴ and fire fighters.^{35,36} There is some evidence that the risk of airflow obstruction in welders and smelter workers may be higher among atopic workers, raising the possibility that at least some of the excess airflow obstruction seen in these groups may be related to asthma.

Organic dusts – wood, textiles, grain, food processing

Although organic dust exposure is frequently associated with asthma and hypersensitivity pneumonitis, there is increasing evidence that chronic bronchitis and COPD are associated with exposure to both 'allergenic' and 'non-allergenic' organic dusts. For example, a recent study of non-asthmatic cedar sawmill workers found that the annual decline in FVC was significantly related to cumulative dust exposure, even when the average dust exposure was well below the accepted limit.³⁷ Studies of sawmill and furniture workers exposed to wood dusts from species not currently known to cause asthma also show exposure-related airflow obstruction.^{38–40} Generally, in these studies, the excess airflow obstruction linked to dust exposure is similar among non-smokers and smokers.

There is also considerable evidence confirming a link between grain dust and COPD in both smokers and non-smokers, with consistent dose–response relationships found.^{41–43} Among retired grain workers, moderate to severe airflow obstruction was found in 40% of non-smokers and 50% of smokers. Increased risk for chronic bronchitis was seen among food processing workers and highly elevated risk for chronic bronchitis and airflow obstruction was seen among bakers in a New Zealand population-based study.⁴⁴

Textile workers exposed to cotton dust are also at risk for chronic bronchitis in addition to their increased risk for byssinosis (see Chapter 19.3). A large study of British cotton textile workers found about double the rate of chronic bronchitis among exposed workers, after taking into account the effects of smoking and age. The risk increased with longer exposure duration.⁴⁵

Similar results have been seen in population-based studies. A large European population-based study of young adults found significantly increased chronic bronchitis (but not airflow obstruction) among workers exposed to organic dusts in textiles, agriculture, and wood and paper industries.⁴⁶ The fact that no association was seen between occupational exposures and lung function may have been due to the relatively young age of the subjects studied. In Spain, exposure to 'biologic dust' was associated with both chronic cough and airflow obstruction in a similar study.⁴⁷

Agriculture

Agricultural exposures, including dusts from cereal grains, animal feed, and soils; gases and fumes, such as manure gases and fumes from disinfectants; and components from micro-organisms, such as endotoxin and fungal components, have all been suggested as potential initiators of the inflammatory process in the airways which may ultimately lead to chronic airway disease.

Mixed exposure to grains, other animal feeds, and animal by-products are found in animal confinement buildings and there is clear evidence of excess chronic bronchitis among farmers and workers in poultry and swine confinement buildings, with prevalence rates remarkably consistent across studies at about 25–35%.^{19,48–52} Evidence for non-asthmatic chronic airflow obstruction in this industry is mixed. Some studies have reported reductions in airflow associated with duration of exposure^{53,54} and accelerated decline in airflow over time among animal confinement farmers.⁵⁵

Two population-based studies of retired workers have also shown increased respiratory morbidity from COPD and chronic bronchitis among agricultural workers. In the Dutch study of residents of Zutphen, among 824 men aged 65–84, increased chronic bronchitis was seen in association with agricultural work.⁵⁶ Among a random sample of French residents over age 65 ($n = 3777$), the occupational groups with the highest prevalence rates for dyspnea grade 3 or greater were farmworkers (37% with dyspnea) and farm managers (32%), compared to 31% among unskilled blue-collar workers, 25% among skilled blue-collar workers, and 15% among teachers.⁵⁷

Environmental tobacco smoke in the workplace

There is growing evidence that exposure to tobacco smoke in the workplace contributes significantly to chronic bronchitis and COPD among non-smokers. A Scottish study of lifetime non-smokers revealed airflow obstruction (significantly reduced FEV₁ and FVC) among both men and women exposed to environmental tobacco smoke (ETS) at work compared to those not exposed at work;⁵⁸ similar results were found in a population-based study in China.⁵⁹ Occupational ETS exposure is particularly high among hospitality industry employees (e.g., waiters, bar tenders, casino workers) and hair levels of nicotine among non-smoking workers in these industries have been shown to be similar to those of active smokers.^{60,61}

COMPARING THE EFFECT OF CIGARETTE SMOKING AND OCCUPATIONAL EXPOSURES

A growing body of research confirms that occupational exposure plays a clinically important role in the development of COPD in exposed workers. Among aluminum smelter workers, the impact of a 30-year working career with particulate exposure at the permitted level was about the same as smoking 75 grams/week (or about 1/2 pack of cigarettes per day).⁶² Among tunnel workers exposed to

dust and diesel exhaust, the decline in FEV₁ associated with each year of tunnel work was twice that associated with each pack year of cigarette smoking. Among fire fighters, the cumulative impact of 'being a fire fighter' on longitudinal decline in FEV₁ was about half as strong as the impact of cigarette smoking.⁶³

Cigarette smoking and dust exposure appear to exert their effect on airways in a roughly additive fashion regardless of the dust type. There is a suggestion that the effect is more than additive in patients with marked airflow obstruction, and in the presence of high crystalline silica.⁶⁴

NATURAL HISTORY, PATHOGENESIS

Most research indicates that the natural history of COPD is similar regardless of the source of the polluted air. Some evidence suggests that a rapid decline in airflow rates due to occupational exposures early in life may be linked to more pronounced airflow obstruction later. This has been seen in British, US, and Italian⁶⁵ coal miners, and among workers exposed to asbestos⁶⁶ and grain.

The specific mechanisms responsible for chronic airflow obstruction due to organic dust exposures are unclear. Autopsy carried out on three grain workers who died as a result of their illness showed that the lungs were not only emphysematous, but also had diffuse granulomata with fibrosis,⁶⁷ suggesting that grain dust may induce changes in both the airways and the parenchyma. Several of the studies cited above found that exposure to both grain and wood dust induced changes in FVC equal to the reductions in FEV₁, suggesting the possibility of alveolar duct or parenchymal involvement. Furthermore, some of the wood dust studies have implicated exposure to visible mold as well as dust in dose-response analyses. Immunologic mechanisms for airflow obstruction should be ruled out where possible in individual cases. However, in the absence of evidence of hypersensitivity, there is no clear way to determine the mechanism for chronic airflow limitation in workers exposed to organic dusts in the clinic or in epidemiologic studies.

ASSESSMENT OF EXPOSURE

Exposures in previous jobs as well as those in the current job are relevant for assessing the occupational contribution to COPD and chronic bronchitis. Therefore, the best clinical tool for assessing exposure is a detailed occupational history, augmented by specific enquiry about exposures to dusts, gases, and fumes. In fact, research has shown that a positive response to the simple question 'have you been exposed to dusts, gases, or fumes at work?' is linked to a more rapid decline in FEV₁ and increased prevalence of chronic bronchitis and airflow obstruction, in population studies.^{68,69} Table 19.4.1 summarizes the results of population-based studies in which the exposure was assessed using a simple question about potential exposure to dusts, gases, or fumes in the usual or current job.

Country, year	Population	Measure of exposure	Risk estimate or effect
United States, 1987 ⁷³	Sample of residents from 6 cities, <i>n</i> = 8515	Job with exposure to dust and gas or fume	Airflow obstruction: OR*: dust: 1.7 OR: dust/fumes: 1.6
France, 1988 ⁷⁴	Residents from 7 cities (excluding 'manual workers'), <i>n</i> = 12,182	Exposed to dust, gases, chemical fumes in any job	Significant reduction in FEV ₁ /FVC ratio in exposed group
Poland, 1988 ⁷⁵	Random sample of residents of Cracow, 13 yrs follow-up	History of exposure to dusts, variable temperature, chemicals	More rapid decline in FEV ₁ in group with exposure to variable temperature, dusts, and irritating gases
Norway, 1991 ⁷⁶	Random sample of residents from one county	Job with airborne exposure†	Chronic symptoms plus airflow obstruction: OR: high exposure: 3.6
China, 1992 ⁷⁷	Residents of Beijing (not using coal heat), <i>n</i> = 1094	Exposure to dust, and gas/fume	Significant reduction in FEV ₁ /FVC ratio in exposed group
New Zealand, 1997 ⁴⁴	Sample of residents from 3 areas, <i>n</i> = 1132	Everyone working with vapors, dusts, gases, fumes	Chronic bronchitis and airflow obstruction OR: exposed: 3.1

* OR: odds ratio; †based on job history.

Table 19.4.1 Summary of results of community-based studies using a simple occupational history and 'exposure to dust, gases, fumes' as the measure of exposure

If possible, the occupational history should be reviewed by a professional with knowledge of the typical occupational exposures in the region. However, this is seldom possible in clinical practice and evidence has shown that the patient is usually a reliable source for information about his or her exposures, both their duration and intensity. For each main job, the patient should be asked what year the job began and ended (to estimate duration of exposure); whether or not there was noticeable dust, fume, or gas exposure; and if so, how often it was present (to estimate intensity of exposure).

Although it is not possible provide a clear answer to the question, 'How much exposure is necessary before one should suspect an occupational contribution to COPD?', most research indicates that the relevant exposure duration is measured in years (or even decades), not months or days. Many patients will have held more than one job, and exposure duration should be summed over all jobs with relevant exposures. Time spent in irregular work environments should also be considered (e.g., in the armed forces, in the informal sector, in prison, during extended periods of casual or temporary employment), as hazardous exposures are common in these situations.

Exposures among women should be explored equally as for men, as chronic bronchitis prevalence has been shown to be similar in both sexes and many of the studies cited above have found increased rates associated with occupational exposures in women and men alike. Dust and fume exposures are seldom present every day, all day, so patients should be asked whether exposure occurred most days, only a few times a month, or only seldom (i.e., a few days a year). Exposures occurring at least a few times a month should be considered relevant.

Clinicians should not assume that if workplace exposures were within 'safe' limits or 'below regulatory standards' they were not high enough to produce disease. Many of the studies discussed above found significant airflow obstruction among workers exposed at or below regulated allowable limits. It is useful to consider the example of

grain dust, which in many countries (including Canada and much of the United States) is still regulated with reference to the 'nuisance dust' standard, despite overwhelming evidence that this standard is unacceptable. The American Conference of Governmental Industrial Hygienists has adopted the term 'particulate not otherwise classified' rather than nuisance dust, to indicate 'that all materials are potentially toxic, to avoid the implication that these materials are harmless' and to emphasize that 'although these materials may not cause fibrosis and systemic effects, they are not biologically inert'.⁷⁰

MANAGEMENT AND COMPENSATION

The evaluation of a patient with COPD (whether a smoker or non-smoker) should include consideration of occupational exposures that may have contributed to the disease. Continued occupational exposure may contribute to a worsening of the disease (in the patient, or in others in that workplace), if no preventive action is taken. For the patient still exposed to particulate or irritant gases or fumes, a recommendation should be made to reduce or eliminate the potential for the exposure. For the patient no longer exposed (or no longer working), the disease should be labelled as 'potentially occupational' in order that public health officials can assess the role of the occupational exposure and use this information to direct future prevention activities in the workplace.

Whether or not a patient with occupational COPD is entitled to compensation or disability benefits will depend on the specific requirements of the compensation or insurance carrier. These requirements vary across jurisdictions. *Disability* evaluation should be carried out without reference to etiologic agent, as the level of disability or impairment is unaffected by the cause. The decision to attach the label 'possibly occupational' to the diagnosis should be based on the occupational history. Although requirements

vary among jurisdictions, it is the attending physician's role to raise the possibility of occupational etiology, not to make the final determination in law. General guidance can be found in the following statement from the Workers' Compensation Board (British Columbia, Canada) policy manual:⁷¹

'Since workers' compensation . . . operates on an enquiry basis rather than on an adversarial basis, there is no onus on the worker to prove his or her case. All that is needed is for the worker to describe his or her experience of the disease and the reasons why they suspect the disease has an occupational basis. Then it is the responsibility of the Board to research the available scientific literature and carry out any other investigations into the origin of the worker's condition which may be necessary.'

That said, unfortunately, physicians do find themselves called upon by legal tribunals, to quantify the relative contribution of occupational exposure to COPD. This can be extremely difficult, if not impossible, in the absence of detailed exposure information and the expertise to interpret it. A useful benchmark may be the research among smelter workers, discussed earlier in this section, that found the effect of working for 30 years at today's 'accepted' exposure concentration had an impact on airflow of about the same magnitude as 30 years of cigarette smoking.⁷²

PREVENTION

Some evidence suggests that a rapid decline in FEV₁ (but still in the 'normal' range) in young exposed workers may be associated with a worse prognosis. Therefore, although these workers are unlikely to seek treatment, if such a patient is encountered (e.g., as a result of routine screening or for other reasons) the index of concern should rise. The evidence is not strong enough to suggest that such a worker should be removed from exposure, but the patient should be made aware of his or her excess decline in lung function and the potential role of occupational exposure should be explored.

Global prevention of occupational COPD will require increased recognition of the disease (by physicians, by regulators, and by employers), and willingness by regulators and employers to act to reduce exposure to particulates and irritant gases and fumes in the work environment. Primary care and pulmonary physicians can play a major role in prevention by increasing the recognition of the disease, by reporting it, even if just as 'suspect' or 'possible' occupational COPD, to the local agency responsible for occupational disease prevention.

19.5 Acute Inhalational Injury

David A Schwartz

INTRODUCTION

The events in Bhopal, India, dramatically illustrate the potential consequences of acute exposure to toxic inhalants. In the workplace, toxic inhalants have been reported to cause a variety of clinical problems ranging from mild irritation of the upper airways to non-cardiogenic pulmonary edema (ARDS) and death. Exposure to toxic inhalants presents problems in clinical management for the following reasons:

1. exposures occur at infrequent, unpredictable intervals
2. exposures may involve large numbers of individuals
3. the exact toxic agent may not be known to the patient or physician
4. there are a broad range of acute clinical manifestations with a varying time of onset
5. the chronic effects of acute exposures have not been clearly characterized.

Despite these problems, knowledge of the basic principles underlying these acute parenchymal responses will allow the clinician to respond appropriately. Although many agents, such as asphyxiants (e.g., carbon monoxide and hydrogen cyanide), metal fumes (e.g., cadmium), and immunologically active inhalants (e.g., red cedar dust, animal dander, and grain dust), are potent mediators of acute lung injury, this chapter will focus attention on the agents which are capable of causing a toxic pneumonitis as well as inhaled toxins associated with systemic illnesses.

This discussion will focus on the perspective of a clinician who is faced with a patient with respiratory problems or concerns following exposure to a noxious agent. Importantly, many of the exposures that can result in acute toxic airway and parenchymal injury may also result in subacute and chronic abnormalities that can dramatically alter lung function. Although the long-term effects of acute inhalational injury are poorly understood, we will present this information since delayed effects from acute high-dose exposures regularly occur in the clinical setting. Specific agents are discussed further in Chapters 39 (metals) and 47 (toxic gases).

PROPERTIES OF IRRITANTS

Inhaled toxins exist in many forms and may be categorized by taking into account their physical properties. General categories include gases, vapors, fumes, aerosols, and smoke. Tables 19.5.1 and 19.5.2 summarize the physical properties of these inhalants. Table 19.5.3 lists selected agents that can cause acute inhalational injury to the lung. The initial pathologic responses to a harmful inhaled agent depend on a number of factors, including the concentration of the substance in the ambient air, the pH of the inhaled substance, the presence and size of particles, the relative water solubility of the inhaled agent, the duration of exposure, and whether the exposure occurs in an enclosed space versus an area with adequate ventilation and free circulation

of fresh air. In addition, an undetermined number of host factors, including age, smoking status, the presence of pre-existing pulmonary or extrapulmonary disease, and the use of respirators or other protective breathing apparatus all impact upon an individual's response to the inhalation of a toxic substance.^{1,2}

Inhaled gases with potential irritant effects manifest their actions at different anatomic locations in the respiratory system.^{1,2} In general, substances that are highly water soluble, such as ammonia, sulfur dioxide, and hydrogen chloride, can cause immediate irritant injury to the upper airway. The acute effects of highly water-soluble irritants on the upper airway, exposed skin, and other mucous membranes often produce such unpleasant symptoms that exposed persons quickly leave the area of exposure, and avoid continued inhalation of the harmful toxins. In contrast, inhaled toxins that have low water solubility, such as phosgene, ozone, and oxides of nitrogen, often have little or no acute effect on the upper airway, and instead produce irritant effects at the level of the terminal bronchiole and alveolus. Because agents of low water solubility do not produce immediately noticeable upper airway irritation (except in episodes of massive acute exposure), exposed persons may inadvertently remain in the area of exposure, and thus increase their duration of exposure to harmful inhalants. Agents that exhibit intermediate water solubility, such as chlorine, can have pathologic effects throughout the respiratory system. However, extreme exposure to any one of these irritants may result in upper and lower respiratory tract involvement. Furthermore, absorption of any one of these irritants on particulate matter may also alter the area of involvement.

In addition to solubility, the size of inhaled particle is important in the pathogenesis of the toxic inhalation injury.¹ Aerosols, dusts, fumes, and smoke can produce upper airway injury as well as parenchymal damage. The location and extent of injury depend on the size of the inhaled particles as well as the intensity of the exposure. Particles that are 5.0 μm or less in diameter have the ability to penetrate into the lower respiratory tract, and often produce significant injury at the level of the terminal bronchioles and alveoli. Zinc chloride (hexite) particles, for example, have an average diameter of 0.1 μm and it is estimated that up to 20% of the inhaled zinc reaches the bronchiolar level, with the remainder deposited in more proximal airways.³ The particles themselves may have direct toxic effects, or they may serve as vehicles for adsorbed gaseous agents that are carried more distally into the lungs and do harm when they interact with terminal bronchioles and alveolar cells.

Irritants directly injure cells through non-immunologically mediated mechanisms of injury and inflammation. Cell injury involves the deposition or formation of an acid (chlorine, hydrogen, chloride, oxides of nitrogen, phosgene, and sulfur dioxide), alkali (ammonia), or reactive oxygen species (ozone, oxides of nitrogen and possibly

Gas	a formless state of matter in which molecules move freely about and completely occupy the space of enclosure.
Aerosol	a relatively stable suspension of liquid droplets or solid particles in a gaseous medium.
Vapor	the gaseous form of a substance that normally exists as a liquid or solid and that generally can be changed back to a liquid or solid by either increasing ambient pressure or decreasing the temperature.
Fume	an aerosol of solid particles generally less than 0.1 μm in size that arises from a chemical reaction or condensation of vapors, usually after volatilization from molten materials.
Smoke	the volatilized gaseous and particulate products of combustion; the particles are generally less than 0.5 μm in size and do not settle readily.

Table 19.5.1 Definitions of types of inhaled substances¹

Irritant gas	Water solubility	Mechanism of injury
Ammonia	high	alkali burns
Chlorine	intermediate	acid burns, reactive oxygen species
Hydrogen chloride	high	acid burns
Oxides of nitrogen	low	acid burns, reactive oxygen species
Ozone	low	reactive oxygen species
Phosgene	low	acid burns
Sulfur dioxide	high	acid burns

Table 19.5.2 Physical properties and mechanisms of lung injury of gaseous respiratory irritants²

Chemical	Properties and pulmonary sequelae
Gases	Strong oxidizer, upper airway irritant, delayed ARDS
Acetaldehyde	Oxidizer, upper airway irritant, delayed ARDS
Acrolein	Alkali, water soluble, upper airway irritant
Ammonia	Water insoluble, upper airway irritant
Boranes	Oxidizer, pneumonitis, ARDS
Bromine	Intermediate solubility, upper and lower airway irritant
Chlorine	Water soluble, upper airway irritant
Hydrogen chloride	Irritating odor, upper airway irritant, ARDS
Hydrogen fluoride	Reactive chemical, irritant, airway reactivity
Isocyanates	Odorless, strong oxidizer, upper airway irritant
Lithium hydride	Water insoluble, pneumonitis, ARDS, bronchiolitis obliterans
Oxide of nitrogen (NO, NO ₂ , N ₂ O ₄)	Water insoluble, pneumonitis, ? ARDS
Ozone	Water insoluble, pneumonitis, ARDS
Phosgene	Water soluble, pneumonitis, ARDS, bronchiolitis obliterans
Sulfur dioxide	
Metals	Oxidizer, upper airway irritant
Antimony	Odorless, pneumonitis, ARDS
Cadmium	Oxidizer, irritant, dyspnea
Cobalt	Oxidizer, metal fume fever
Manganese	Odorless, pneumonitis, ARDS
Mercury	Musty odor, asthma, pneumonitis
Nickel	White aerosol, upper airway irritant, metal fume fever
Zinc	

Table 19.5.3 Selected agents known to cause acute pulmonary injury

chlorine).^{2,4} The primary injury is localized in airway epithelial tissues, but extensive damage may also occur in subepithelial and alveolar regions. Acid injury results in coagulation of the underlying tissue, while acute injury due to alkali results in liquefaction of the mucosa and deep penetrating lesions in the airways. Reactive oxygen species include oxygen-derived metabolites (such as hydrogen peroxide and hydrochlorous acid), and oxygen-derived free radicals (such as superoxide anions and hydroxyl radicals). These reactive oxygen species may injure tissues and cells through lipid peroxidation that can directly injure cells as well as lead to elaboration of inflammatory mediators that can perpetuate the initial damage.⁴ Regardless of the initial mechanism of irritant injury, inflammatory mechanisms that involve networks of pro-inflammatory cytokines may be subsequently initiated. The resultant inflammation may be important with regard to perpetuation of the acute injury as well as long-term sequelae. In addition, disruption and eventual repair of the airway epithelia may decrease the host's ability to defend against future inhaled infectious or irritant substances.

PATHOGENESIS AND CLINICAL PRESENTATION OF TOXIC INHALATIONAL INJURY

Inhaled toxic agents can cause a spectrum of airway and parenchymal pulmonary diseases that can be classified as acute disorders that occur within the first 1–2 days of exposure and chronic problems that develop weeks to months after the exposure (Table 19.5.4). This classification is clinically useful because it recognizes that the timing of the exposure in relationship to the onset of pulmonary disease is critical in assessing causality.

Upper airway

Acute injury

The potential for an inhaled substance to acutely injure the upper airway depends largely on that substance's irritant qualities. Water solubility and particle size, as well as duration and intensity of exposure, all influence the host response to a specific exposure. Upper airway injury due to the inhalation of toxic agents involves a number of pathophysiologic mechanisms. Irritants produce injury through

Acute (within 1–2 days of exposure)
Laryngeal edema
Airflow obstruction – asthma and bronchitis
Pneumonitis, pulmonary edema
ARDS
Persistent sequelae (weeks to months after the exposure)
COPD
Reactive airways dysfunction syndrome (RADS)
Bronchitis
Bronchiolitis obliterans
Bronchiolitis obliterans organizing pneumonia (BOOP)

Table 19.5.4 Classification of chemical injury to the lung

direct contact with the skin and mucous membranes. Tissue and cellular damage can result from the injurious effects of acid, alkali, or reactive oxygen species. Acidic substances or those that react to form acids coagulate the underlying tissue. In contrast, alkalotic substances cause liquefaction of the surface mucosa and lead to further penetrating injury of deeper structures.²

Reactive oxygen species are involved with a variety of cellular and tissue disruptions through lipid peroxidation.⁴ The cellular injuries that result from the actions of acids, alkali, and reactive oxygen species may include loss of epithelial cell layer integrity, influx of inflammatory cells and mediators, and leakage of interstitial fluid. The initial insult to the airway epithelium decreases its ability to function as a protective barrier between the environment and the subepithelial layers. Disruption of the epithelium by inhaled toxins exposes underlying inflammatory cells, nerves, muscles, and blood vessels. The resulting inflammation, edema, and stimulation of neuronal afferent receptors may all contribute to the clinical manifestations.

Individuals exposed to irritants that injure the upper airway often have associated injury to exposed mucous membranes and skin. Clinical presentations include burns of exposed skin and corneas, rhinitis, conjunctivitis, tracheobronchitis, and oral mucositis. Persons exposed to upper airway irritants may experience burning sensations of the eyes, nasal passages and throat; profuse lacrimation and copious sputum production may also occur. Coughing and sneezing may be prominent symptoms. Upper airway injury from irritant inhalants is generally acute and self-limited. Life-threatening upper airway obstruction due to mucosal edema, large amounts of secretions and sloughed epithelial cells, or laryngospasm can occur in cases of massive acute exposure. Hoarseness or stridor may warn of impending airway compromise, and patients presenting with either of these physical findings must be carefully observed and may require emergent management of acute upper airway obstruction.

Treatment is not specific for most inhaled substances, but instead addresses removal of the patient from the exposure. Basic principles of airway management are paramount because the most likely acute life-threatening manifestation of this injury is upper airway obstruction due to a combination of tissue edema, thick secretions, and laryngospasm. Frequent suctioning of secretions is often required. Provision of adequate supplemental oxygen is necessary if there is evidence of hypoxemia. Inhaled racemic epinephrine may be useful for patients with potential for upper airway obstruction, but should not substitute for or delay emergent airway management by endotracheal intubation or tracheotomy if necessary. Corticosteroids have not been conclusively shown to influence outcome, but are suggested in cases with extensive upper airway edema. Toxic substances that remain present on the skin or mucosal surfaces should be removed via irrigation with large amounts of water. Basic principles of burn management should be applied to skin and mucosal surface burns. Ophthalmologic consultation is recommended for management of injuries to the cornea or other eye structures.

Conducting airways

Acute injury

Inhaled irritants that penetrate to the conducting airways are capable of inducing immediate as well as long-lasting injury through a variety of mechanisms. The airway epithelium provides a barrier that protects inflammatory cells and submucosal structures (nerves, vessels, and muscle) from direct exposure to environmental agents. Disruption of the integrity of this protective barrier can be caused by a variety of environmental agents and, importantly, may result in edema, inflammation, direct smooth muscle contraction, and stimulation of neuronal afferent receptors. Moreover, this primary lesion in the airway epithelium can facilitate stimulation by subsequent agents that come in contact with the denuded epithelial surface.

The tight junction interface between epithelial cells appears to be the primary site of injury following exposure to a variety of gases and aerosols. For instance, cigarette smoke has been shown to damage the airway epithelium by primarily disrupting the tight junctions between epithelial cells, resulting in increased permeability to other unrelated irritants, such as horseradish peroxidase.⁵ Similarly, hamsters exposed to nitrogen dioxide gradually develop severe disruption of tight junctions between bronchial epithelial cells.⁶ Ozone⁷ has also been shown to increase airway epithelial permeability. Thus, damage to the airway epithelium, particularly at tight junctions, renders the respiratory mucosa permeable to other inhaled substances, which are then able to penetrate the subepithelial mucosal region. These agents may directly interact with effector cells in subepithelial mucosa. Thus, they may have direct smooth muscle bronchoconstrictive effects, and they may also stimulate parasympathetic sensory afferent nerve endings, resulting in extensive bronchoconstriction.⁸

Inhalation of irritant gases and aerosols may cause airway hyper-responsiveness by initiating a localized inflammatory response. Inhalation studies with allergens and specific environmental irritants have demonstrated that neutrophils and eosinophils are recruited within a few hours to the airway and alveolar surface, and this response has been shown to persist for at least 48 hours following this type of challenge.⁹ Moreover, the number of mast cells, eosinophils, and airway epithelial cells obtained by bronchoalveolar lavage following an aerosol challenge has been found to correlate strongly with the degree of airway hyper-reactivity in mild atopic asthmatics.¹⁰ Inflammatory cells such as neutrophils appear to be critical elements in the development of airway hyper-reactivity following exposure to ozone.¹¹

Damage to the airway epithelium and inflammation of the subepithelial mucosa may contribute to the development of airway disease in persons exposed to irritant gases and aerosols. Inhaled agents, either allergens or irritants, may primarily cause mucosal inflammation that subsequently results in increased epithelial permeability. The altered epithelial permeability exposes subepithelial irritant receptors, which are subsequently at risk of being stimulated by a variety of agents including cold air,

changes in humidity and temperature (exercise), and cigarette smoke. Damage to the airway epithelium by cigarette smoke is associated with increased epithelial permeability and an inflammatory reaction characterized by mucosal edema and infiltration of neutrophils.¹² In addition, direct damage to the airway epithelium may result in decreased production of epithelial-derived bronchodilating substances and neutral endopeptidases that would normally serve to reduce the effects of bronchoconstricting agents.¹²

The inflammatory response in the epithelial and subepithelial regions can result in chronic remodeling of the underlying airway architecture. Striking inflammatory changes, such as extensive collagen deposition beneath the epithelial basement membrane, eosinophil infiltration, and mast cell degranulation, are seen in transbronchial biopsy specimens obtained from asthmatic persons following aerosol challenges.¹³ Chronic bronchitis, an inflammatory state characterized by neutrophil infiltration, is strongly associated with airway hyper-responsiveness and has been demonstrated in animals following exposure to irritant gases.² Release of mediators, such as histamine, leukotrienes, prostaglandins, neutrophil chemotactic factors, platelet activating factor, tachykinins, cytokines, and growth factors, from a variety of structural and inflammatory cells in the airway and subepithelial region may significantly contribute to the chronic inflammatory response that has been well documented in asthma and in other forms of chronic airway disease.

Changes in the structure of the airways may significantly enhance the development of airway reactivity and contribute to the development of respiratory symptoms. Baseline airway caliber appears to be an important determinant of airway hyper-responsiveness.¹⁴ The airway caliber can be influenced by a variety of factors including the tone of the airway smooth muscle and the overall thickness of the subepithelial region. The thickness of the subepithelial region is influenced by edema and inflammation. Interestingly, inflammation and edema of the submucosal region not only may decrease airway caliber but also may alter airway smooth muscle mechanics, resulting in maximal contraction following stimulation of the airway smooth muscle. Similarly, chronic changes in the architecture of the basement membrane may also alter smooth muscle length-tension relations.

Lower airway injury resulting from irritant toxin inhalation can be manifested as transient or long-lasting intrathoracic airflow obstruction. The precise mechanism of the obstruction is not clear, but likely involves one or more inflammatory mechanisms. Exposed individuals who are cigarette smokers or who have pre-existing airway obstruction may be at increased risk for the persistence of toxin-induced airflow obstruction. Significant clinical manifestations of lower airway injury may not be initially recognizable, but may develop and worsen over the first 24–48 hours after exposure. Hospitalization for observation is indicated for initially asymptomatic exposed subjects who present with any objective evidence of respiratory compromise, such as decreased airflow, abnor-

malities of gas exchange, or an abnormal chest radiograph, or whose exposure history is suggestive of a relatively intense exposure. In addition, individuals who report respiratory symptoms including dyspnea or chest tightness should be hospitalized, followed closely with objective measures of respiratory function, and treated symptomatically, even in the absence of objective abnormalities.

Spirometry may initially be normal, but in some cases progressive airflow obstruction develops, and thus a case can be argued for obtaining baseline airflow indices and following the exposed individuals with spirometry over the first 24–48 hours after exposure. For individuals without significant decrements in airflow but with symptomatic chest tightness or wheezing, inhaled steroids are essential and bronchodilators may be useful. In cases that demonstrate airflow obstruction (FEV₁ of 80% or less than predicted, or 10% or less than the patient's initial baseline), a short course of systemic corticosteroids may be beneficial in addition to the use of inhaled steroids and bronchodilators. However, there is no definitive evidence that treatment with parenteral corticosteroids substantially improves the airflow obstruction or prevents the onset of bronchiolitis obliterans.

Chronic injury

Obstructive airway disease. Previously healthy individuals who experience acute toxin inhalation may go on to develop clinical and pathologic features of chronic obstructive pulmonary disease (COPD). Inhaled irritants most often implicated in the development of chronic bronchitis, emphysema, or reversible airflow obstruction include chlorine¹⁵ and sulfur dioxide.¹⁶ However, definitive evidence that demonstrates a causal relationship between a toxin exposure and resultant chronic respiratory disease is frequently difficult to elicit. This is often because of the frequent concomitant presence of potentially confounding factors, most prominently cigarette smoking, that independently increase any individual's risk for the development of COPD.

Nevertheless, there is some growing evidence that acute exposure to a number of inhaled irritants may produce conditions in the conducting airways that lead to a complex interaction of inflammation, smooth muscle activity, and neuronal inputs that are involved in the creation and perpetuation of varying degrees of fixed and reversible airflow obstruction. The initial irritant insult to epithelial cells appears to be central to subsequent abnormal function and continuing injury processes that involve the epithelium as well subepithelial structures. Repair of the acute injury may also contribute to resultant chronic airflow obstruction via scarring and other mechanical factors. Disruption of normal protective structures and mechanisms may also predispose exposed individuals to chronic pulmonary infections. In addition, damage to and destruction of functional alveoli may also involve ongoing inflammatory and repair processes that have been initiated by the acute irritant exposure.

The development of irritant-induced COPD appears to be dependent on the intensity of the exposure. In addition, underlying host factors, including cigarette smoking and pre-existing pulmonary disease, may increase an individual's likelihood of developing or worsening COPD. It is extremely difficult to accurately assess the potential contribution of acute irritant inhalation to chronic lung disease in individuals who smoke cigarettes. Baseline measures of pulmonary function can help determine the presence of pre-existing disease, but unfortunately this information is often unavailable, especially in cases of accidental acute exposure. Evaluation of possible irritant-induced COPD includes a thorough history, physical examination, radiographic evaluation, and objective measures of pulmonary function, including spirometry, measurement of lung volumes, determination of diffusing capacity, and assessment of gas exchange. Frequent measurement of spirometry may help determine progression or regression of airflow abnormalities. Treatment is as for COPD due to causes other than acute irritant exposure and includes bronchodilators, corticosteroids, smoking cessation, and supplemental oxygen if necessary. Occupational COPD and chronic bronchitis are discussed further in Chapter 19.4.

Reactive airways dysfunction syndrome (see also Chapter 19.2). The persistence of airway reactivity following acute exposure to respiratory irritants has been termed reactive airways dysfunction syndrome (RADS).¹⁷ A variety of inhaled irritants have been associated with this syndrome, including sulfuric acid, chlorine, ammonia, household cleaners, and smoke. Most often, the initial inhalation injury is due to a single, acute, high-intensity exposure. Symptoms of airflow obstruction, including cough, dyspnea, and wheezing, are reported immediately or several hours after the end of the exposure, and may persist for months to years. Previous exposure or sensitization to the toxic agent does not appear to be necessary. By definition, individuals who develop RADS have no history of respiratory illness. Pulmonary function tests may be normal, or they may demonstrate airflow obstruction. Individuals with RADS have persistent, positive responses to methacholine challenge testing, even in the presence of normal pulmonary function tests. Non-specific bronchial reactivity may persist for months to years following the initial inhalation injury.

Bronchial biopsies of patients with RADS demonstrate an inflammatory response characterized by epithelial desquamation and mucus cell hyperplasia. The exact mechanisms of the pathophysiology of RADS are unclear, but implicated mechanisms include altered neural tone and vagal reflexes, modified beta-adrenergic sympathetic tone, and influences of a number of pro-inflammatory mediators. The direct irritant injury may expose and damage subepithelial irritant receptors. Subsequently, repair mechanisms which are not fully understood may result in alteration of the irritant receptor threshold and lead to airways hyper-reactivity. Changes in epithelial permeability may also contribute to the resultant hyper-reactivity. None of these proposed mechanisms is completely understood at this time.

Treatment of RADS includes the use of corticosteroids to help minimize inflammatory mechanisms, and bronchodilators to reverse bronchospasm. There is limited, mostly anecdotal, evidence for the efficacy of corticosteroids. Bronchodilators may only partially reverse airflow obstruction, especially in later, chronic stages of the syndrome.¹⁸ Despite treatment with corticosteroids and bronchodilators, many exposed individuals may be left with persistent asthma-like symptoms, airflow obstruction, and non-specific bronchial hyper-reactivity.

Pulmonary parenchyma

Acute injury

Toxic inhaled agents that have relatively low water solubilities, such as phosgene, ozone, and nitrogen oxides, produce most of their irritant damage distal to the upper airway. Because of the relatively low solubilities of these substances, inhalation does not typically result in upper airway irritation and its associated symptoms. As a result, subjects may endure continued exposure to the toxic gases and thus increase the total time and resultant dose of exposure. In addition, massive acute inhalation of gases and aerosols that have intermediate (chlorine) or high water solubilities (ammonia, sulfur dioxide) can overwhelm the absorptive capacity of the upper airway and injure more distal structures. Damage may be particularly severe when particulates form part of the inhaled substance. The reasons for this are not fully understood, although it is possible that particle deposition in the alveoli might provide a nidus for ongoing inflammation and subsequent severe injury. Respirable particles with diameters in the 0.3–0.5 μm range can bypass the upper airways and deposit in the more distal airways and alveoli.¹

The clinical consequences of these injuries include diffuse bronchiolar inflammation and obstruction as well as alveolar filling (pulmonary edema). Atelectasis may result from destruction or disruption of the surfactant layer. Individuals who have sustained an initial toxic insult to the lower airways and lung parenchyma may be more susceptible to subsequent pulmonary infections because of damage to inflammatory cells, including alveolar macrophages, that provide host defense against infectious agents.

The lower respiratory tract and alveoli are susceptible to injury from many inhaled toxins. In general, the extent and severity of acute lung injury due to a toxic inhalant appear to be dose related. The clinical and histopathologic features of toxin-associated pulmonary edema and ARDS are not unique to any particular inhalant. Instead, many different inhaled toxins can damage the pulmonary parenchyma via what appear to be common pathways that are identical or at least qualitatively similar to those that cause acute lung injury secondary to causes other than toxin inhalation. However, unlike some focal processes that progress to ARDS, the initial inhalation of toxins is more likely to produce a diffuse, relatively homogeneous acute lung injury.

Regions of the lower respiratory system that are susceptible to toxin injury include the airway epithelium, subepithelial mucosa, alveolar lining cells, and vascular endothelium. Alveolar type I epithelial cells seem particularly susceptible to acute injury from inhaled substances. Some of the mechanisms involved in the general epithelial injury described in the previous section also apply to injury to the epithelia of the lower airway and alveoli. Damage can result in focal and confluent areas of edema with protein-rich fluid in the alveolar spaces, hyaline membrane formation, and denudation of the alveolar epithelium. Mucous membranes of the bronchial and bronchiolar walls may be destroyed or denuded.

Pulmonary parenchymal injury that results from inhalation of irritant substances runs the spectrum of acute lung injury and includes pneumonitis, pulmonary edema, and the acute respiratory distress syndrome (ARDS). Pneumonitis is the most frequent parenchymal manifestation of inhalation injury. Clinical features include dyspnea, productive or dry cough, hypoxemia, mild restriction of ventilation, decreased alveolar gas diffusion, and diffuse bilateral infiltrates on the chest radiograph. Generally, pneumonitis caused by toxic inhalation is a self-limited process, with clinical improvement mirrored by rapid clearing of infiltrates seen on the chest x-ray. Treatment is supportive, usually includes supplemental oxygen, and may require mechanical ventilation. The use of corticosteroids has not been shown to be of significant benefit in the treatment of pneumonitis secondary to the inhalation of irritant gases such as chlorine, ozone, and phosgene, but may be indicated in cases of known inhalation of some metal fumes such as mercury, cadmium and zinc – all of which have been reported to progress to severe and sometimes fatal acute lung injury. As it is for toxic pneumonitis, the treatment of toxin-induced pulmonary edema and ARDS remains largely supportive, and may include hemodynamic monitoring and mechanical ventilation.

Chronic injury

Bronchiolitis obliterans. Bronchiolitis obliterans, an inflammatory reaction with obliteration of the small airways, can occur as a late consequence of the inhalation of several toxins. Exposures to ammonia, mercury, oxides of nitrogen, and sulfur dioxide have been associated with bronchiolitis obliterans.^{19–22} High-intensity inhalation exposures can be followed by acute pulmonary edema and ARDS. Survivors of the acute lung injury may experience a relatively asymptomatic period that is followed by the development of irreversible airflow obstruction that often presents one to three weeks after the initial injury. Early inspiratory crackles are a characteristic physical exam finding. The appearance of the chest radiograph is variable, and may be associated with the degree of clinical severity. Mild cases can have normal chest x-rays, while more severely affected individuals may demonstrate hyperinflation. Infiltrates are generally absent. Pulmonary function tests typically demonstrate airflow obstruction that may

in some cases also be associated with restrictive defects. The histologic picture is characterized by the presence of granulation tissue plugs within the lumina of small airways and occasionally alveolar ducts, as well as by the destruction of small airways with obliterative fibrous scarring.

The pathophysiology of bronchiolitis obliterans due to toxin inhalation is not well understood. The predominance of neutrophils in the bronchoalveolar lavage fluid of some patients with bronchiolitis obliterans clearly identifies an active inflammatory process, but the exact mechanisms involved are not currently well defined. The process may not respond to treatment with corticosteroids; however, a 6-month trial of corticosteroids should be given. Bronchodilators may be efficacious in some symptomatic individuals, although clear-cut evidence of this potential benefit is not available.

Bronchiolitis obliterans organizing pneumonia (BOOP). Bronchiolitis obliterans organizing pneumonia (BOOP), a proliferative bronchiolitis with inflammation of the distal lung parenchyma, is an uncommon delayed consequence of the inhalation of toxic substances such as ammonia, mercury, and sulfur dioxide.^{23,24} The clinical presentation is characterized by a persistent, non-productive cough, fever, sore throat, and malaise. The lung exam typically reveals late inspiratory crackles but no wheezes; many patients have no abnormalities on physical exam. The characteristic chest x-ray findings include bilateral, patchy, 'ground glass' densities which start as focal lesions but may coalesce with time. In contrast to patients with bronchiolitis obliterans, those with BOOP present with restrictive ventilatory physiology and decreased diffusing capacity.

The histology of BOOP includes the presence of granulation tissue in the small airways and alveolar ducts, as in bronchiolitis obliterans. In addition, however, the granulation tissue extends into the alveoli and may result in interstitial scarring. This distinction between the histologic features of BOOP and those of 'pure' bronchiolitis obliterans (without organizing pneumonia) may reflect different host responses to similar inhaled toxins.²⁴ Examination of the granulation tissue plugs from patients with BOOP demonstrates temporal uniformity in a patchy distribution with the preservation of background architecture. Bronchoalveolar lavage fluid demonstrates a neutrophilic alveolitis; lymphocytes may also be prominent. These findings suggest that the pathological process results from an initial insult (e.g., an inhaled toxin) with subsequent inflammatory and reparative processes.

Treatment of BOOP with corticosteroids often results in dramatic clinical improvement. Pulmonary function abnormalities can improve considerably, and in some cases may rapidly normalize. The radiographic abnormalities also rapidly clear. A small number of patients may not respond to corticosteroid therapy and may develop progressive fibrosis. Duration of therapy is generally at least 6 months but should be guided by the rate and extent of the clinical response.

CLINICAL COURSE AND EVALUATION

The development of a toxic pneumonitis indicates that the epithelia in the terminal bronchioles and alveoli have been acutely damaged and are no longer able to prevent fluid, inflammatory mediators, and cells from accumulating in the airways and alveoli. Importantly, the spectrum of disease is dependent on the extent and location of injury to the airway and alveolar epithelia. While brief exposures to soluble agents may result in only mild tracheal-bronchial irritation, more extensive exposure to insoluble aerosols and gases can cause diffuse alveolar injury and may present as acute respiratory distress syndrome (ARDS). Thus, the clinician should be aware of this spectrum in evaluating patients following exposure to potentially hazardous inhaled agents.

Among those surviving the acute symptomatic exposure, persistent airway hyper-reactivity and bronchiolitis obliterans have been reported in a few individuals. The term reactive airway dysfunction syndrome (RADS) has been applied to the persistence of airway reactivity following acute exposure to respiratory irritants. Although somewhat speculative, persistent airway hyper-reactivity is believed to result from continued epithelial cell inflammation, which causes either an increase in epithelial cell permeability or a decrease in the conduction threshold for subepithelial vagal afferent receptors.

BOOP is characterized by persistent respiratory symptoms and recurrent patchy infiltrates which wax and wane for several months prior to diagnosis. Although this represents an unusual manifestation of an inhalational injury, it should be included in the differential diagnosis given the proper clinical setting. The chest x-ray demonstrates areas of focal hyperinflation and, additionally, often has multiple patchy densities which appear as ground glass infiltrates. Physiologically most patients present with restrictive lung function and diminished diffusing capacity; however, occasionally airflow obstruction may also be present in this disease process. Lung biopsies, which are needed to definitively diagnose this condition, demonstrate extensive granulation tissue in the airways, alveolar ducts, and alveoli. Of note, organizing fibrosis is clearly identified in the peribronchial region and is typically of uniform age, suggesting a time-limited environmental or infectious insult. Corticosteroids appear to be effective in reversing the underlying inflammatory process in approximately 65% of the cases.

History

The medical history should take precedence and, given the potentially fatal outcome, initial attention should focus on the extent and pace of the parenchymal injury. Dyspnea is the most common symptom following inhalation of detrimental gases or aerosols. It is essential to grade the degree of dyspnea (at rest, with minimal exertion, or with extensive exertion) to both establish a new baseline and also determine the extent of the parenchymal injury. Clearly, the rate of change in dyspnea and specific signs of

pulmonary disease are key features used to guide the clinical management. Other symptoms that have been observed in these patients include chest tightness and burning, a cough that may or may not be productive of sputum, and wheezing. Patients with dyspnea at rest and a cough with or without pink, frothy sputum should be assumed to have extensive parenchymal injury and are at high risk of developing (or having) ARDS. Other acute symptomatology may include asthma and bronchial inflammation or bronchitis.

Importantly, weeks to months after the exposure, individuals may first develop symptoms of asthma, bronchitis, or even bronchiolitis obliterans. These subacute symptoms will primarily develop from the delayed onset of airflow obstruction. Symptoms of airflow obstruction include wheezing, dyspnea with exertion, and cough with or without sputum production. However, unlike the acute symptomatology, these symptoms commonly develop 4–6 weeks following the exposure and may worsen over time.

The environmental or occupational history is critical since the clinical presentation can be confused with other more common forms of asthma, bronchitis, pneumonia, or ARDS. However, in many cases where symptoms develop acutely following exposure, the exposure history will be clearly evident. If questioned properly, patients can usually recall the specific exposure or event that was associated with the onset of symptoms. In most cases, there is a clear temporal relationship between exposure and symptom onset. However, with less soluble agents, such as nitrogen dioxide and phosgene, the onset of symptoms may occur hours to days after the exposure. In addition, the delayed or subacute symptomatology (asthma, bronchitis, and bronchiolitis obliterans) may take weeks to months to develop. Thus, clinicians need to aggressively pursue an occupational/environmental history in cases of non-bacterial pneumonia, adult onset asthma or bronchitis, and all cases of bronchiolitis obliterans and focus on relatively high exposures to the agents listed in Table 19.5.3.

Physical examination

Acutely following the exposure, the clinician needs to assess the pace and extent of the parenchymal injury. Given the potential life-threatening consequences of these exposures, the initial examination needs to be directed toward essential measures of cardiopulmonary function, such as gas exchange, pulmonary edema, and hemodynamic stability. In addition, if significant injury has occurred to the airway, signs of upper airway edema and stenosis along with generalized airflow obstruction may be present. Elevated temperatures are usually not part of the clinical picture; however, this may be present when diffuse parenchymal injury has occurred.

Weeks to months after the exposure, patients may present with signs of asthma, bronchitis, or even bronchiolitis obliterans. Thus, wheezing and rhonchi with patchy areas of rales are not infrequently observed. Since the onset of subacute airway and parenchymal disease can be quite insidious, the clinical evaluation should maintain a relatively low threshold for pursuing these delayed complications.

Substance	Acute clinical manifestations			Chronic clinical manifestations		
	Onset	Upper airway irritation	Pneumonitis, ARDS	Bronchiolitis obliterans, BOOP	Obstructive lung disease	RADS
Irritant gases						
Ammonia	minutes	severe	+	+	+	+
Chlorine	minutes to hours	moderate	+	–	+	+
Hydrogen chloride	minutes	severe	+	–	–	–
Oxides of nitrogen	hours	mild	+	+	+	+
Ozone	minutes to hours	mild	+	–	–	–
Phosgene	hours	mild	+	–	+	–
Sulfur dioxide	minutes	severe	+	+	+	+
Metals						
Cadmium	hours	mild	+	–	+	–
Mercury	hours	mild	+	+	–	–
Zinc chloride	minutes	mild	+	–	–	–
Zinc oxide	hours	mild	+	–	–	–

+ = exposure reported to be associated with clinical entity
 – = exposure as yet not reported to be associated with clinical entity

Table 19.5.5 Pulmonary manifestations of toxin inhalation

Laboratory evaluation

Immediately following exposure, the clinician needs to be concerned with gas exchange and the extent of the parenchymal injury. Arterial blood gases (ABG) can adequately assess gas exchange and the chest radiograph will be helpful in determining the overall extent of the pulmonary injury. Since certain chemicals, particularly the less soluble ones, may have between 12 and 24 hours of delay between exposure and the full development of the lung injury, it is not unreasonable to observe patients for at least 12 hours following the exposure. Symptomatic patients should be hospitalized for a minimum of 24 hours, regardless of the initial chest radiogram and ABG. In the first 24–48 hours following exposure, pulmonary function tests are not needed and the results may be misleading. However, several days to weeks following the exposure, pulmonary function tests can be used to identify problems with airflow obstruction, restrictive lung function, or abnormal gas exchange. While airflow obstruction would be indicative of asthma or bronchitis, restrictive lung function with or without abnormal gas exchange (i.e., low diffusing capacity) would be most consistent with bronchiolitis obliterans.

Several weeks after the exposure, all patients should have a complete set of pulmonary function tests (spirometry, lung volumes, and diffusing capacity) to either document a return to baseline function or identify subclinical changes in lung function that may be related to the exposure. Occasionally methacholine challenge may be indicated to assess airway lability (RADs, for example). Rarely, an open lung biopsy is needed to establish the diagnosis of bronchiolitis obliterans in patients with patchy involvement of the lung parenchyma several months following the exposure.

Treatment

The treatments in the acute phases of these exposures are largely supportive. Specific attention needs to be directed

toward bronchodilator therapy, adequate oxygenation, and the treatment of the non-cardiogenic pulmonary edema. Supplemental oxygen, intubation in severe cases, and ventilatory support with the use of positive expiratory pressure are the mainstays of treatment. If the patient has severe nasopharyngeal or pharyngeal edema, a tracheotomy may be needed. If bronchospasm is present, bronchodilators should be used and parenteral corticosteroids should be considered. In the absence of bronchospasm, the role of corticosteroids in the acute phase of pulmonary edema has not been definitively established and may place the patient at further risk for the complications of ARDS. Prophylactic antibiotics have not been proven to be helpful and should be reserved for those patients with evidence of overt infection. Beyond the acute phase, inhaled corticosteroids should be considered to diminish the local inflammation in the airway. Bronchodilators should only be used in patients with clinically significant airflow obstruction. Corticosteroids are clearly indicated in the treatment of bronchiolitis obliterans but have not been evaluated in effectively preventing the onset of this or any other late complication.

Prevention

Most toxic inhalational injuries occur as a result of accidental overexposures. Preventive measures can be taken to reduce the risks of such overexposures, such as better industrial hygiene and engineering controls, regular maintenance of equipment, and proper worker training. In addition, a comprehensive plan to handle accidents and emergencies is necessary, including appropriate evacuation plans and availability of necessary emergency provisions such as air supplying respirators, showers, and oxygen. Workers should be educated regarding potential risks, warning symptoms and the accident action plan, and regular practice drills be instituted.

EFFECTS OF SPECIFIC INHALED TOXINS ON THE RESPIRATORY SYSTEM

The following sections address the pulmonary effects of selective specific inhaled toxins. Table 19.5.5 summarizes the acute and long-term manifestations. Specific agents are discussed further in Chapters 39 (metals) and 47 (toxic gases).

Ammonia

Ammonia is a highly water-soluble substance that is extensively used in the manufacturing, chemical, and agricultural industries. Its uses are many, and include the manufacture of explosives, cyanides, synthetic fibers, and plastics. It also has applications in petroleum refining, as a cleaning agent and refrigeration system coolant. Its high nitrogen content makes ammonia a commonly used soil fertilizer; it can be applied in its liquid form, or as ammonia dissolved in water. Most inhalation exposures are the result of accidental releases, including tank leaks and transportation mishaps.^{22,25,26}

Exposure to ammonia gas or vapors causes immediate irritation of the mucosal surfaces of the eyes, skin, nasopharynx, oropharynx, larynx, and trachea. Ammonia reacts with water that is present on mucosal surfaces to form ammonium hydroxide, which in turn forms hydroxyl ions. This exothermic reaction contributes to thermal burns that form part of the initial injury. In addition, chemical injury results from alkali burns that are deeply penetrating and result in tissue liquefaction. Cutaneous burns, which may be disfiguring, are deepest in areas with the highest moisture content. Burn injuries to the eyes may result in permanent visual impairment and include damage to the corneal endothelium, corneal stroma, iris, and lens; these burns are often more severe than those caused by other alkalis because of ammonia's ability to deeply penetrate tissues. Initial injury to the mucosa of the oropharynx may result in edema, hemorrhage, and sloughing of tissue and can result in fatal upper airway obstruction.

The severity of ammonia-induced injury depends on the concentration and duration of exposure. Lower airway and pulmonary parenchymal injury can occur acutely with high intensity exposures. It is characterized by pulmonary edema, hemorrhage, and atelectasis. A biphasic pattern of pulmonary response to ammonia inhalation has been reported, characterized by initial, acute pneumonitis that may clear over the next 2–3 days, followed in some individuals by the gradual development of airway obstruction and respiratory failure.²⁵ Bronchopneumonia due to superinfection with bacterial organisms is common. Bronchiectasis and focal bronchiolitis obliterans have been associated with this late phase.

Initial treatment of individuals exposed to ammonia gas or vapors includes immediate irrigation of all exposed surfaces, especially eyes, with copious amounts of water. The airway must be secured. Treatment of pulmonary

involvement is supportive, and includes supplemental oxygen and mechanical ventilation if indicated. The use of corticosteroids is controversial, and prophylactic antibiotics have not been shown to clearly improve outcome.

Chlorine, chloramine, and hydrochloric acid

Chlorine (Cl_2) is a highly reactive gas that is widely found in industrial, environmental, and home settings. Its uses include as a bleaching agent in the textile and paper industries, and as part of water purification processes at swimming pools and sewage systems. Currently, episodes of toxic inhalation exposure are most often the result of accidental releases and spills.^{27,28} Common settings for chlorine exposure are secondary to transportation accidents, accidental industrial releases or spills, and accidental spills or releases at swimming pools and sewage treatment facilities.^{27,28}

Chlorine reacts with water to form hydrochloric acid (HCl) and hypochlorous acid (HOCl). These products, as well as elemental chlorine itself, exert various irritative effects on the respiratory system. Chlorine has intermediate water solubility, and its inhalation can therefore result in irritation of the upper and lower respiratory tracts. Its mechanism of cellular injury appears to involve the generation of oxygen free radicals. Hydrochloric acid and hypochlorous acid, on the other hand, are highly water soluble, and thus exert significant irritative effects on the mucous membranes of the upper respiratory tract and ocular conjunctivae. Lower respiratory irritation is less common with these acids, although it has been reported following acute, high-intensity exposures. Hydrochloric acid is an irritant and acts to coagulate underlying tissues.

The clinical manifestations of the inhalation of chlorine and its derivatives are similar to those of other inhaled gases that have similar solubility profiles. Because chlorine has intermediate water solubility, its irritant effects are manifested throughout the respiratory system, and include immediate rhinitis, conjunctivitis, and skin irritation, as well as cough, dyspnea, and chest tightness.

In addition to the toxic effects of chlorine and its derivatives discussed above, a significant number of toxic inhalation exposures involve the products that result from the mixing of chlorine compounds and other substances. Many of these exposures occur in the household setting and involve various cleaning agents.²⁹ Chloramine gas is formed when chlorine or hypochlorous acid are mixed with ammonia. Chloramine gas, in turn, decomposes to ammonia and hypochlorous acid or hydrochloric acid when it comes into contact with water. Ammonia, hypochlorous acid, and hydrochloric acid are all highly water soluble, and therefore have primarily upper respiratory tract irritative effects. Household bleach (which contains hypochlorous acid, or hypochlorite) reacts to form chlorine gas when it is mixed with phosphoric acid or hydrochloric acid. The resultant chlorine gas subsequently produces irritative symptoms throughout the respiratory tract.

Chlorine gas was one of several chemical warfare agents used in the First World War. Several follow-up studies of exposed military personnel report long-lasting pulmonary impairments, including chronic bronchitis and airflow obstruction, in some individuals. Others, however, apparently fully recovered from similar degrees of chlorine gas exposure. Total dose of exposure is probably the most significant determinant of long-term adverse respiratory effects following acute chlorine inhalation.¹⁵

Sulfur dioxide

Sulfur dioxide is a heavy, colorless gas that is widely used in many industrial processes, including mining, ore smelting, and the bleaching of wool and wood pulp.

Sulfur dioxide is highly water soluble and hydrolyzes to sulfuric acid upon contact with water on mucous membranes. While the acid injury to cellular components is not fully understood, it appears to involve direct damage via irritant mechanisms. In addition, subacute inflammation may contribute to long-term respiratory sequelae. Individuals who experience acute, high-intensity exposure report the immediate onset of symptoms that include burning of the eyes, nose, and throat, rhinorrhea, tearing of the eyes, dyspnea, chest tightness, and cough. Extremely high-intensity acute exposures can lead to death within minutes from respiratory failure due to a combination of alveolar hemorrhage and edema, possible reflex vagal stimulation, and the asphyxiating effect of high concentrations of sulfur dioxide.¹⁶

Significant extrapulmonary injuries include corneal injuries that can range in severity from superficial burns that resolve completely in days to weeks to permanent opacification; these injuries appear to be dose dependent. Less intense acute exposures can produce a broad range of upper and lower respiratory tract injury that also appear to occur in a dose-dependent manner. Acute pneumonitis can progress to ARDS. Survivors of the acute lung injury may experience a relatively asymptomatic period that is followed several weeks later by the onset of irreversible airflow obstruction due to bronchiolitis obliterans.³⁰ Other individuals may demonstrate immediate, persistent airflow obstruction and non-specific bronchial hyper-reactivity that is consistent with RADS.¹⁷

Treatment of inhalation injury due to sulfur dioxide and sulfuric acid is supportive and includes supplemental oxygen, maintenance of a patent airway, and mechanical ventilation if necessary. Corticosteroids have not been shown to alter the course of ARDS due to this toxic inhalation, and rarely provide significant benefit for patients who have developed bronchiolitis obliterans. However, a trial course of corticosteroids is not unreasonable. Bronchodilators may be helpful for those patients with symptomatic airflow obstruction.

Nitrogen oxides

Nitrogen oxides are major components of air pollution. In addition, accidental releases of nitrogen oxide gases can

occur in occupational settings and result in high intensity exposures. Oxides of nitrogen are present in a number of industrial settings, including mining, acetylene welding, and explosives manufacturing. These gases can also be present in closed or poorly ventilated areas in which engines are operated. Perhaps the best recognized occupational exposure to nitrogen oxides occurs in agricultural workers ('silo filler's disease') who are exposed to silo gas that is formed via the decomposition of organic matter.³¹

Clinical manifestations of toxicity include signs and symptoms of a chemical pneumonitis, the severity of which is dose dependent and is influenced both by the time and concentration of the exposure. Severe cases progress to ARDS and sometimes lethal acute lung injury, while less severe cases can completely resolve or result in varying degrees of chronic airway obstruction and RADS. Bronchiolitis obliterans can be a late sequela and may develop following a relatively asymptomatic period after the resolution of ARDS.

The mechanism of injury due to the inhalation of nitrogen dioxide involves the production of nitric acid from the hydrolysis of nitrogen dioxide and water; this acid production occurs at the levels of the terminal bronchioles and alveolar membranes. Nitric acid can subsequently dissociate to nitrates and nitrites that can cause tissue injury through direct local cytotoxicity and inflammation, as well as via the formation of free oxygen radicals that can be involved with the peroxidation of lung lipids, with resultant disruption of cellular membranes. This constellation of toxin damage may explain the clinically recognized pulmonary edema and lower airway obstruction that often result from nitrogen oxide inhalation.

The treatment of the acute lung injury is supportive and includes supplemental oxygen and mechanical ventilation. In addition, awareness of the potential for the development of obstructive lung disease, including bronchiolitis obliterans, several weeks after initial apparent recovery is important. Individuals who survive the acute lung injury are at risk for these later complications and should be followed closely with serial assessment of pulmonary mechanics and gas exchange. Asymptomatic hypoxemia or decrements in airflow should be closely monitored since those individuals may also go on to develop bronchiolitis obliterans. Corticosteroids may be helpful in preventing or decreasing the severity of progressive airflow obstruction, and should be considered in asymptomatic individuals who demonstrate spirometric or gas exchange abnormalities.

Prevention of exposure includes the provision of adequate ventilation and appropriate respiratory protective equipment in all environments in which nitrogen oxides may be encountered.³¹ Agricultural workers should be aware that the hazard from oxides of nitrogen in silos is greatest during the first week to 10 days after green ensilage has begun fermenting. Engineering controls can reduce the accumulation of harmful nitrogen oxides. Poorly ventilated silos should not be entered unless adequate respiratory protection is available.

Phosgene

Phosgene, another gaseous toxin that has relatively low water solubility, is perhaps most notorious for its role as a war gas. Its use in the First World War reportedly led to as many as 80% of all the gas deaths during that conflict. In modern times, phosgene is used to catalyze a number of industrial reactions including the production of polyurethane resin, toluene diisocyanate, pesticides, pharmaceutical products, and dyes. In addition, it is produced via heat decomposition of various solvents, paint removers, dry cleaning fluids, and methylene chloride.³²

As for other inhaled toxins that have low water solubilities, phosgene produces its most recognized clinical effects through injury to the lower airway and lung parenchyma. A clinical picture of pneumonitis that can progress to the adult respiratory distress syndrome (ARDS) results. Phosgene is hydrolyzed to hydrochloric acid, and injury may occur via direct cytotoxicity or enzymatic poisoning. Phosgene is a colorless gas that at a concentration of one ppm has the odor of newly mown hay or grass. At higher concentrations it has a more pungent odor and can be mildly irritating to the upper airway. Concentrations of 5–10 ppm inhaled for as few as 5–10 seconds can cause immediate cough, lacrimation, and mucosal irritation. A latent period of 30 minutes to 8 hours can precede the onset of symptoms of lower airway and parenchymal irritation. The duration of the latent period is inversely proportional to the severity of exposure and is also thought to be inversely proportional to the subsequent severity of disease.

Clinical manifestations of the lower airway and parenchymal effects include dyspnea, chest tightness, and increasing respiratory distress. Physical exam may reveal cyanosis and rales. Chest radiograph can show diffuse bilateral infiltrates consistent with pulmonary edema. Treatment is supportive, and may include mechanical ventilation and supplemental oxygenation. Individuals that survive the acute injury can be left with chronic bronchitis or emphysema, although others may experience no long-lasting adverse clinical sequelae.³²

Ozone

Ozone is recognized as a major constituent of environmental smog, and is also present as a naturally occurring gas in the upper atmosphere, where it has a protective effect against ultraviolet radiation from the sun. It is a colorless, odorless gas that has relatively low water solubility. Chronic and acute adverse health effects from the concentrations of ozone (0.05–0.8 ppm) that are commonly found in ambient air have been well described and include many respiratory symptoms as well as evidence of upper and lower airway irritation, inflammation, and airflow obstruction.⁷ In the occupational setting, ozone has been implicated as a toxic inhalant in airplane cabins during high altitude flight, in industries where it is used as an oxidizing agent, and in arc welding where it can occur in association with oxides of nitrogen.³³

Cadmium

Cadmium (Cd) is a highly corrosion-resistant metal that has many industrial applications. It is used in solder and brazing rods as well as in the manufacture of batteries, alkaline accumulators, and steel alloys. It is commonly used to electroplate or galvanize metal surfaces. In addition, cadmium-containing pigments are used widely including in paints, plastics, printing inks, leather, glass, and enamels.³⁴

Most toxic exposures have been reported following exposure to cadmium vapors in enclosed spaces or poorly ventilated areas. Heating of cadmium-containing materials can release vapors and cadmium oxide fumes. The typical clinical presentation is similar to that for metal fume fever (see below), and includes an initial asymptomatic period that lasts several hours and is followed by fevers, chills, and myalgias. Unlike uncomplicated metal fume fever, after Cd exposure, these constitutional symptoms are often accompanied by or shortly followed by respiratory distress, including cough, chest tightness, and dyspnea. The chest x-ray reveals bilateral infiltrates consistent with pneumonitis. Initial pulmonary function tests can show a restrictive ventilatory defect and decreased diffusion. Fatal cases have been remarkable for initial pneumonitis that progresses to ARDS and eventual death from respiratory failure.³⁵ Individuals who survive the acute lung injury may be left with persistent ventilatory restriction.

The mechanisms involved with the acute lung injury due to cadmium inhalation are not well defined. Postmortem examinations of individuals who died after accidental acute inhalation exposure have revealed tracheobronchitis, consolidated lungs, denuded bronchial epithelium, intra-alveolar hemorrhage, and the presence of macrophages in the alveolar spaces.³⁵

Treatment of acute lung injury due to the inhalation of cadmium fumes is supportive and common to treatment for other forms of acute lung injury and ARDS. Corticosteroids may help improve outcome, but their efficacy is not well established. Elevated blood and urine cadmium levels may help establish cadmium as the likely etiologic agent in cases in which the nature of the exposure is not clear. Blood levels may reflect acute exposure, while urine levels better reflect the total body burden. Monitoring of blood or urine levels during treatment has not been shown to influence the clinical outcome.³⁴

Mercury

Acute mercury vapor inhalation occurs in occupational settings, including metal reclamation processing, fur and felt hat making, and dentistry. In addition, high exposures have occurred in the home during amateur attempts to extract precious metals from amalgams that also contain mercury.^{36,37} Common to episodes of toxic mercury inhalation are settings that involve vapor generation in closed spaces or poorly ventilated areas.

Mercury vapor has little or no immediate upper airway or mucosal surface irritant effects, and as a result exposed

individuals may inadvertently remain in an area where the harmful vapors are present. Typical clinical presentations include symptoms of cough, dyspnea, and respiratory distress that develop 12–24 hours post-exposure. These initial symptoms are sometimes accompanied by fever, nausea, vomiting, diarrhea, and a metallic taste in the mouth, similar to what is often experienced by individuals with metal fume fever. Symptoms of mercury vapor inhalation do not, however, spontaneously resolve in a pattern similar to that for metal fume fever. Instead, the pneumonitis may progress to ARDS. Death due to progressive respiratory failure may ensue; pneumothorax has been reported to be a preterminal event in several cases.

The severity of the injury appears to depend on the intensity of exposure and, possibly, the size and age of the exposed individual. Children and small household pets seem especially vulnerable to life-threatening acute lung injury after the inhalation of mercury, but death due to respiratory failure has also been reported in exposed adults.³⁷ Adults who survive the acute lung injury usually experience resolution of their symptoms from 2 to 7 days following onset, although longer courses of resolution have been reported for those who have sustained more severe injury.

The acute effects of inhaled mercury are usually confined to the respiratory system, although renal involvement with acute tubular necrosis has been reported.²⁰ The acute gastrointestinal and renal injuries that are seen after mercury ingestion are not typical of acute inhalation exposure. Chronic, low-intensity inhalation exposure may be associated with central nervous system and systemic symptoms and injury similar to that observed after ingestion.

Treatment of mercury inhalation is supportive and common to treatment for acute lung injury and ARDS. Corticosteroids have no proven benefit. Chelating agents, such as dimercaprol and d-penicillamine, frequently used

to increase the rate of mercury excretion after ingestion, have not been shown to affect the outcome of the acute lung injury.³⁷

Smoke bombs (zinc chloride)

Zinc chloride (ZnCl_2 , or hexite) is a major ingredient of smoke bombs.^{3,38} Oxides and chlorides of zinc and chloride are formed by the ignition of hexachlorethane, zinc oxide, and calcium chloride and are produced by some of the smoke-generating devices used by the military, in firefighter training, and for the generation of special effects in the entertainment industry. Toxic inhalations have occurred in settings where individuals have breathed in smoke in confined spaces (Fig. 19.5.1), in most instances without functional protective breathing apparatus. The smoke effect tends to contribute to the duration of exposure by obscuring vision, sometimes resulting in directional disorientation and the inability to quickly escape the area of exposure.

Zinc chloride is a hygroscopic, caustic salt that forms hydrochloric acid and zinc oxychloride upon contact with water on mucous membranes and other surfaces. The severity of injury appears to be related to the intensity of the exposure, and depends both on the duration of exposure and the concentration of zinc chloride in the smoke. Irritation and burning of the eyes, skin, and mucous membranes result. Zinc chloride is present in particulate form and the average size has been reported as $0.1\ \mu\text{m}$. This size makes it possible for relatively large amounts of the inhaled hexite to penetrate into the lower respiratory tract, and as much as 20% of the total may reach beyond the level of the respiratory bronchioles, while the remainder settles throughout the tracheobronchial tree. Deposition of particles in the lungs and subsequent forma-

Figure 19.5.1: Chest CT scan and pulmonary function tests obtained from an individual following an inhalation injury after a smoke bomb was ignited in an underground cave. The CT scans were obtained 1 week and 12 weeks after the accident and demonstrated the extensive interstitial lung disease that resolves radiographically. The pulmonary function tests obtained 1, 3, and 12 weeks after the exposure demonstrated marked restrictive lung function and abnormal gas exchange that also resolves within 3 months of exposure.

tion of hydrochloric acid may primarily be responsible for the diffuse lung injury.³⁸

Signs and symptoms of tracheobronchitis and pneumonitis are common following inhalation of smoke that contains zinc chloride. Initial chest radiographs can be normal, but can also show diffuse bilateral infiltrates that are consistent with pneumonitis. Hypoxemia may not be present initially, but can develop over a course of several days after the exposure. Progression to ARDS following an initial period of clinical stabilization or partial resolution has been reported. Pneumothorax is a frequent complication of the acute lung injury due to subpleural emphysema.

The treatment of zinc chloride inhalation includes oxygen supplementation and mechanical ventilatory support if indicated. Corticosteroids have been used but it is unclear whether they alter the clinical course. N-acetylcysteine may minimize oxidant-induced lung injury, but it is not clear whether this influences the clinical outcome.³ Exposed individuals who survive may have persistent ventilatory and diffusion defects.

Mace and tear gas

Chloroacetophenone (CN, or 'mace') and orthochlorobenzaldehyde (CS) are crowd control agents commonly used by the military and law enforcement agencies. These inhaled agents, often referred to as 'tear gas', have immediate, profound, irritant effects on exposed mucous membranes and lacrimal glands and are used to incapacitate individuals. Exposure to either of these agents produces acute rhinorrhea, oral mucositis, conjunctivitis, and lacrimation. The severity of the effect is apparently dose related. Initial physical examination performed within hours of the inhalation exposure demonstrates findings consistent with irritant injury to mucous membranes and lacrimal glands, but no evidence of lower airway or parenchymal damage.

Several case reports describe varying degrees of pneumonitis and pulmonary edema, typically developing hours to several days after the inhalation exposure. The cases reported involved individuals who were exposed to tear gas for prolonged periods of time in poorly ventilated structures.^{39,40} Controlled animal studies have also demonstrated delayed-onset pulmonary parenchymal injury and respiratory failure, with postmortem findings of pulmonary edema as well as hemorrhagic and atelectatic lungs following exposure to high concentrations of tear gas.⁴¹

Treatment of inhalation injury due to tear gas is supportive and includes management of the immediate mucous membrane irritant effects, with particular attention to maintenance of a patent upper airway with frequent suctioning if necessary. Infants and small children may be at particular risk for acute airway obstruction due to copious oral and nasal secretions. Corticosteroids have not been shown to be efficacious in this situation. Awareness of the potential for delayed evidence of acute lung injury is essential.

SYSTEMIC ILLNESS FROM INHALED TOXINS

A number of inhaled substances can cause extrapulmonary illness and injury. Metal fumes, fumes composed of heat-degraded fluorocarbons, and organic dusts have been implicated as causative agents in self-limited systemic syndromes (metal fume fever, polymer fume fever, and the organic dust toxic syndrome) that are notable for influenza-like illness with complete resolution within hours to days of exposure.⁴²⁻⁴⁴ While some exposed individuals experience only constitutional symptoms, there appears to be a continuum of illness that extends to include significant pulmonary parenchymal injury in some exposed subjects. The mechanism or mechanisms of these syndromes are currently unknown, although recent human exposure-response studies have implicated cytokine-mediated inflammation as central to the pathogenesis of metal fume fever⁴⁵ and the organic dust toxic syndrome.

Metal fume fever

Metal fume fever is a self-limited syndrome characterized by the delayed onset of fever, chills, myalgias, and generalized malaise following exposure to fumes that contain metal oxides. The syndrome has acquired a number of names over time, including brazier's disease, spelter shakes, brass chills, zinc chills, welder's ague, copper fever, and foundry fever. Metalworkers with the syndrome sometimes describe their symptoms as being 'galvanized'. Welders are the workers most often reported to experience metal fume fever, although a variety of other metalworking occupations, including soldering, brazing, cutting, metallizing, forging, melting, and casting have been associated with exposures to metal fumes that are responsible for the syndrome.

A common scenario is that of exposure to metal oxide fumes generated by welding in a closed space or poorly ventilated area. Zinc oxide is often implicated as the toxic agent responsible for metal fume fever; however, fumes composed of oxides of copper, cadmium, mercury, aluminum, antimony, selenium, iron, magnesium, nickel, silver, and tin have also been implicated.⁴²

Constitutional symptoms are often preceded or accompanied by complaints of dry throat and a sweet or metallic taste in the mouth. The characteristic fever, chills, and myalgias, which are sometimes accompanied by headache and nausea, usually develop 4-8 hours after exposure to metal fumes, and spontaneously resolve over the next 24-48 hours. Laboratory findings are remarkable for transient leukocytosis. Tachyphylaxis appears to occur in some individuals who are repeatedly exposed to metal oxide fumes, usually in occupational settings. These workers often report recurrent 'Monday fever' after returning to the workplace following weekend or vacation absences. Metal fume fever has been mistaken for influenza, atypical or community-acquired pneumonia, and a malaria-like illness because of overlapping presenting symptoms.

Some, but not all, individuals also complain of chest tightness, cough (usually non-productive), and varying degrees of dyspnea. The chest x-ray is typically normal, but in individuals with respiratory symptoms, a radiographic picture consistent with pneumonitis has been reported. Pulmonary function tests are usually normal, although in those with symptomatic and radiographic evidence of pneumonitis, obstructive and restrictive defects, as well as abnormalities of diffusion, have been reported. Human studies that have examined the systemic and pulmonary responses to exposure to zinc oxide fumes generated by welding in an environmental chamber suggest that cytokine-mediated inflammatory mechanisms are involved.⁴⁵ There appears to be a continuum of clinical severity that ranges from exposed persons who experience the classic, self-resolving, constitutional symptoms of metal fume fever, to those who also develop transient pulmonary impairment, to a group that experiences more severe, sometimes even life-threatening pulmonary injury.

The predisposition to developing these more serious manifestations of metal fume exposure appears to be related to the duration and concentration of the inhalation exposure, and also is most frequently reported after episodes involving fumes from zinc, mercury, and cadmium. The treatment of metal fume fever is supportive, and includes antipyretics and analgesics. Prevention involves provision of adequate ventilation, fume removal devices and respiratory protection for workers in environments where metal oxide fumes are generated.

Polymer fume fever

Polymer fume fever is a syndrome with many clinical similarities to metal fume fever. It results from the inhalation of pyrolysis products of fluoropolymers, the most often reported of which is polytetrafluoroethylene (PTFE, or Teflon).⁴³ In addition to their popularly recognized use as non-stick coatings on cooking equipment, fluorocarbon polymers are widely used in industrial settings as mold-release sprays, lubricants, and fabric or leather treatments. Heating of fluoropolymers to high temperatures results in the production of fumes composed of a vapor phase that can contain or ultimately produce carbonyl fluoride, perfluorinated alkanes, hydrofluoric acid, and carbon dioxide. Respirable particles may also contribute to the toxic elements in the heat-generated fumes.⁴³ The fumes produced may lead to the systemic and pulmonary toxicities through mechanisms that are not currently well understood.

The clinical presentation of polymer fume fever includes initial, sometimes immediate symptoms of upper airway irritation: dry throat, rhinitis, chest tightness, and conjunctivitis. Typically, constitutional symptoms consisting of fever, chills, and myalgias occur 4–8 hours after exposure and spontaneously resolve over the next 24 hours. Laboratory features include a transient leukocytosis. There is no consistent pattern of pulmonary function studies. However, individuals with pre-existing obstructive lung disease may experience worsening obstruction after recur-

rent exposures to polymer fumes.⁴⁶ Cough and dyspnea that are associated with wheezing and sometimes radiographic evidence of parenchymal consolidation can occur. Pneumonitis accompanies constitutional symptoms more often than is reported in cases of metal fume fever but is usually self-limited. The reasons for this difference are unknown, but may relate to the release of hydrofluoric acid. Unlike the decline in the severity of metal fume fever symptoms that is observed with frequent, repeated exposures to metal fumes, tolerance does not appear to develop in individuals repeatedly exposed to pyrolyzed fluoropolymers, implying possible qualitative differences in the mechanisms of injury and host response in these two syndromes.⁴⁶

Exposure to pyrolyzed fluoropolymers occurs in home and industrial settings, often in poorly ventilated areas. Humans as well as animals may suffer the effects of this form of toxic inhalation; several case reports of polymer fume fever in humans also mention the sudden deaths of pet birds that were similarly exposed. Many workers who experience symptoms consistent with polymer fume fever are cigarette smokers, some of whom have reported the abrupt onset of symptoms immediately after smoking tobacco products. Several reports have suggested that these workers may have directly contaminated their smoking products with inert fluoropolymers that are subsequently pyrolyzed and inhaled in concentrated form along with the tobacco smoke. Alternatively, cigarette smoking may independently predispose individuals to the development of polymer fume fever and associated acute lung injury.

Treatment of polymer fume fever is supportive and similar to that for metal fume fever. Prevention includes provision of adequate ventilation. In addition, workers should adhere to strict hand-washing habits after handling products containing fluoropolymers, should not eat, drink, or smoke in the work environment, and should not carry smoking materials into the work setting.

Organic dust toxic syndrome

Organic dust toxic syndrome (ODTS), also referred to as silo unloader's syndrome, atypical farmer's lung, or pulmonary mycotoxicosis, is a self-limited illness characterized by fever, chills, myalgias, dry cough, headache, and dyspnea that occur 4–8 hours after exposure to large amounts of organic dusts.⁴⁴ These symptoms, although uncomfortable and sometimes transiently debilitating, usually spontaneously resolve over the next 36–48 hours with no long-term adverse sequelae. The etiologic agent or agents have not been fully characterized, but likely include substances that are present in moldy organic material, including fungal spores, actinomyces, bacteria, endotoxin, and other components of grain dusts. These air-borne substances are often encountered after uncapping silos that contain hay or corn silage, during the removal of layers of spoiled animal feed, or when working in swine confinement facilities. Agricultural workers are understandably at the highest risk for the development of ODTS, but others who are exposed to environments where large amounts of grains, hay, straw, or wood chips are present can also present with this

syndrome. Although prior sensitization does not appear to be a characteristic feature in individuals who develop ODS, those who have a history of atopy may manifest more severe symptoms compared to non-atopics.⁴⁷

The physical exam in patients with ODS is usually normal but can show the presence of bibasilar crackles and scattered wheezes. Laboratory studies reveal a neutrophil-predominant leukocytosis. Mild hypoxemia and infiltrates on chest x-ray have been reported. Bronchoalveolar lavage performed early in the course of the illness may reveal a predominance of neutrophils; with time, lymphocytes may dominate the BAL cellular population.⁴⁴ Open lung biopsy in ODS reveals multifocal areas of acute inflammation with neutrophils and macrophages in terminal bronchioles, alveoli, and interstitial areas, but no evidence of granulomas. Human exposure-response studies have reproduced the characteristic symptoms and laboratory abnormalities, and have also demonstrated transient airflow obstruction.^{48,49}

The initial symptoms of ODS are sometimes confused with those of hypersensitivity pneumonitis. However, unlike hypersensitivity pneumonitis, ODS is transient, can occur in previously unexposed individuals, and requires a relatively intense exposure. Bronchoalveolar lavage consistent with an acute neutrophilic alveolitis is different from the BAL lymphocytic predominance that has been reported in hypersensitivity pneumonitis. In contrast to what is often found in cases of hypersensitivity pneumonitis, serum allergic precipitins are usually negative in individuals with ODS.⁴⁴

The course of ODS is benign, with spontaneous resolution of symptoms as well as laboratory and radiographic abnormalities within days of the exposure. Treatment is symptomatic. Steroids are not recommended. Long-term sequelae of repeated high-intensity exposures that lead to recurrent episodes of ODS may be associated with chronic bronchitis and decrements in airflow, but these have not been clearly established. Prevention involves education of agricultural workers and other potentially exposed subjects regarding specific practices related to the handling of moldy hay, grains, and other organic materials. In addition, individuals who engage in activities known to produce large quantities of potentially harmful air-borne organic substances, such as weighing of swine and the intense handling of moldy grain, hay, straw, or wood chips, should be advised to wear respiratory protection.

Smoke inhalation

Inhalational injury due to smoke inhalation is the primary cause of morbidity and mortality in fire-exposed persons. The thermal and chemical content of the inhaled smoke accounts for the type and degree of respiratory injury. Direct thermal burns are usually limited to the supraglottic region because the nasopharynx, larynx, and trachea are effective in cooling the hot, dry air. However, inhalation of steam and respiratory aspiration of hot liquids, which have a greater heat capacity, can cause direct pulmonary injury.

Toxic inhalant	Thermodecomposition source
Acrolein	Cellulosics and polyolefins
Ammonia	Inorganic combustion, melamine, nylon, silk and wool
Carbon monoxide	Incomplete combustion of hydrocarbons
Halogenated acids	Fire-retardant materials containing bromine and fluorinated resins and films
Hydrogen chloride	Chlorinated acrylics, polyvinyl chloride, and fire retardant-treated materials
Hydrogen cyanide	Acrylonitrile, nylon, polyurethane paper, silk and wool
Isocyanates	Urethane and isocyanate polymers
Nitrogen dioxide	Cellulose nitrites, and fabrics
Phosgene	Chlorinated acrylics, polyvinyl chloride, and fire retardant-treated materials
Sulfur dioxide	Combustion of compounds containing sulfur

Table 19.5.6 Toxic inhalants commonly encountered in fires

Of greater concern in fire victims is the large number of toxic gases and chemicals that can be generated in the fire environment. The particulates present in smoke are generally cleared by the respiratory tract. The toxic gases and chemicals resulting from the combustion of the numerous different materials and products that can be present in the fire environment are the major inhalational toxins. These gases and chemicals will vary from fire to fire as the materials that are burning differ in each fire. Major toxic inhalants commonly encountered in fires are listed in Table 19.5.6. The chemicals released in a fire fall into two broad categories – irritants and chemical asphyxiants. Irritants include acrolein, ammonia, chloride, hydrogen chloride, phosgene, and sulfur dioxide. The major chemical asphyxiants are carbon monoxide, produced by incomplete combustion of carbon-containing materials without adequate ventilation, and cyanide. Cyanide, produced by the combustion of materials such as polyurethanes, acrylics, and nylon, binds to mitochondrial cytochrome oxidase, resulting in anaerobic metabolism and lactic acidosis.

Smoke inhalation can result in a spectrum of clinical manifestations, depending on the toxic gases and chemicals present, and extent of exposure. The major acute effects are upper airway obstruction, bronchitis, and bronchospasm. Pulmonary edema and ARDS are less common. Recent studies of New York City fire fighters have shown persistent cough and bronchial hyper-responsiveness related to acute irritant exposures following the World Trade Center collapse.

Evaluation of those exposed to excessive smoke should proceed in a systematic fashion. Information about the fire environment, including potential combustion products, should be obtained. Risk factors predictive of clinically significant smoke inhalation include steam exposure, exposure in a closed space, exposure to plastic fumes, singed facial hair, oropharyngeal burns, altered consciousness, respiratory symptoms, an unexplained lactic acidosis, and a carboxyhemoglobin level higher than 20%. Initially, all smoke-exposed individuals should be treated with high concentrations of oxygen, and the carboxyhemoglobin level and serum pH should be measured.

Carbon monoxide poisoning can be assayed directly from the carboxyhemoglobin level, whereas an unexplained

acidosis should raise the suspicion of cyanide intoxication. Upper airway burns are a marker of significant thermal injury and, under some circumstances, are an indication for early endotracheal intubation. In the event of clinically significant smoke inhalation, the patient should be hospitalized for at least 24 hours and observed for the potential delayed complications of chemical fume exposure. Symptomatic individuals should be hospitalized and treated supportively. Early treatment with steroids or prophylactic antibiotics has not been shown to be beneficial and generally is not recommended.

SUMMARY

Acute inhalation exposure to a number of substances produces a spectrum of pulmonary and systemic injuries. Physicians and other healthcare professionals may encounter individuals who have experienced acute inhalation exposure to unknown types or doses of toxic substances. Treatment is generally supportive and is not specific to any individual exposure. This chapter has described typical presentations of injury resulting from a number of inhaled toxins. Awareness of the patterns of presentation and potential consequences of irritant induced inhalation injury can help guide initial and subsequent management. Since the clinical course of these accidental inhalations are often unpredictable, it is prudent to carefully monitor, follow, and have a low threshold for hospitalization when managing these patients. Materials safety data sheets (MSDS) can furnish concise information about specific substances or products. Additional information is also available through computerized library search tools and online information services.

19.6 Hypersensitivity Pneumonitis

Craig Glazer, Cecile S Rose

INTRODUCTION

Hypersensitivity pneumonitis (HP), also known as extrinsic allergic alveolitis, refers to a constellation of granulomatous, interstitial, bronchiolar and alveolar-filling lung diseases caused by repeated exposure and subsequent sensitization to a variety of organic and chemical antigens. Diagnosis relies on a constellation of findings including antigen exposure, characteristic signs and symptoms, pulmonary function abnormalities, radiologic abnormalities, and frequently, characteristic histologic findings.¹

ETIOLOGY

The extensive list of agents known to cause hypersensitivity pneumonitis can be organized into three main categories: microbial agents, animal proteins, and low molecular weight chemicals (Table 19.6.1). Regardless of the antigen, typically only a minority of exposed and/or sensitized individuals will develop hypersensitivity pneumonitis.²

Microbial agents

As a group, various bacteria and fungi represent the most common causative agents.¹ Among bacteria, multiple species of thermophilic actinomyces are the most frequently reported. Thermophilic actinomyces contaminate decaying vegetable matter and are causally associated with farmer's lung (the prototypical example of HP), bagassosis, and composting (including mushroom worker's lung).³⁻⁶ They may also contaminate ventilation systems and humidifiers, and cause disease through these exposure routes as well.⁷ Other bacteria, including *Bacillus*, *Klebsiella*, and *Epicoccum*, have been causally associated with HP.¹ More recently, non-tuberculous mycobacteria contaminating hot tubs and metal working fluids have been implicated as a likely cause of hypersensitivity pneumonitis.⁸⁻¹¹

Multiple fungi have been shown to cause hypersensitivity pneumonitis including various species of *Aspergillus*, *Mucor*, *Penicillium*, *Basidiospores*, and *Trichosporon*. Summer-type hypersensitivity pneumonitis, the most common form of

Antigen	Exposure	Syndrome
Bacteria		
Thermophilic bacteria		
<i>Micropolyspora faeni</i>	Moldy hay	Farmer's lung
<i>Thermoactinomyces vulgaris</i>	Moldy sugarcane	Bagassosis
<i>T. sacchari</i>	Mushroom compost	Mushroom worker's lung
<i>T. candidus</i>	Heated water reservoirs	Humidifier lung
		Air conditioner lung
Non-thermophilic bacteria		
<i>Bacillus subtilis</i> , <i>B. cereus</i>	Water	Humidifier lung
	Detergent	Washing powder lung
Fungi		
<i>Aspergillus</i> sp.	Moldy hay	Farmer's lung
	Water	Ventilation pneumonitis
<i>Aspergillus clavatus</i>	Barley	Malt worker's lung
<i>Penicillium casei</i> , <i>P. roqueforti</i>	Cheese	Cheese washer's lung
<i>Alternaria</i> sp.	Wood pulp	Wood pulp worker's lung
<i>Cryptostroma corticale</i>	Wood bark	Maple bark stripper's lung
<i>Graphium</i> , <i>Aureobasidium pullulans</i>	Wood dust	Sequoiosis
<i>Merulius lacrymans</i>	Rotten wood	Dry rot lung
<i>Penicillium frequentans</i>	Cork dust	Suberosis
<i>Aureobasidium pullulans</i>	Water	Humidifier lung
<i>Cladosporium</i> sp.	Hot tub mist	Hot tub HP
<i>Trichosporon cutaneum</i>	Damp wood and mats	Japanese summer-type HP
Amebae		
<i>Naegleria gruberi</i>		
<i>Acanthamoeba polyphagia</i>	Contaminated water	Humidifier lung
<i>Acanthamoeba castellanii</i>		
Animal proteins		
Avian proteins	Bird droppings, feathers	Bird breeder's lung
Urine, serum, pelts	Rats, gerbils	Animal handler's lung
Wheat weevil (<i>Sitophilus granarius</i>)	Infested flour	Wheat weevil lung
Chemicals		
Toluene diisocyanate (TDI)	Paints, resins, polyurethane foams	Isocyanate HP
Diphenylmethane diisocyanate (MDI)	Paints, resins, polyurethane foams	Isocyanate HP
Hexamethylene diisocyanate (HDI)	Paints, resins, polyurethane foams	Isocyanate HP
Trimellitic anhydride	Plastics, resins, paints	TMA HP
Copper sulfate	Bordeaux mixture	Vineyard sprayer's lung
Sodium diazobenzene sulfate	Chromatography reagent	Pauli's reagent alveolitis
Pyrethrum	Pesticide	Pyrethrum HP

Table 19.6.1 Selected agents reported to cause hypersensitivity pneumonitis (HP)

HP in Japan, is caused by *Trichosporon asahii* (formerly *T. cutaneum*).¹² Rhizopus, Pullaria, Penicillium, Aspergillus, and Alternaria have all been implicated as causative agents in woodworker's HP.^{13,14} In addition, both Aspergillus and Penicillium have been implicated in cases of farmer's lung disease.^{15,16} Amebae such as *Acanthamoeba polyphaga* have been implicated in humidifier lung.¹⁷

Animal proteins

Avian antigens are the most common animal proteins associated with hypersensitivity pneumonitis. Interestingly, exposure to live birds is not required, as cases have been reported related to use of a feather duvet and with exposure to feather decorations.^{18,19} Other implicated animal proteins include wheat weevil, rat, and gerbil proteins, and dust from mollusk shells.⁵

Low molecular weight chemicals

Isocyanates, reactive chemicals widely used in the production of polyurethane foams, elastomers, adhesives, and paints, are the most common cause of occupational asthma in developed countries.²⁰ In addition, these low molecular weight chemicals are known to cause hypersensitivity pneumonitis.²¹ Acid anhydrides, another group of reactive chemicals widely used in industry, also cause an HP-like syndrome frequently accompanied by anemia.²² In both circumstances the chemicals are thought to combine with endogenous proteins to form complete antigens.⁵ Other rare chemical causes of HP include the pesticide pyrethrum, Pauli's reagent (sodium diazobenzene sulfate), and copper sulfate.¹

EPIDEMIOLOGY

With the challenges of accurate diagnosis and disease reporting, reliable estimates of incidence and prevalence of hypersensitivity pneumonitis remain elusive and it is likely that hypersensitivity pneumonitis is more common than reported. Most studies have focused on farmer's lung, and estimates of incidence and prevalence vary significantly by region. In one study, the prevalence of farmer's lung in Scotland ranged from 23 to 86 per 1000 depending on the region investigated.²³ In Wyoming, the prevalence among dairy and cattle ranchers was found to be 3%, while in Wisconsin dairy farmers, prevalence rates as high as 12% have been reported.^{24,25} The annual incidence of farmer's lung in Finland is 44 per 100,000.²⁶

The prevalence of HP among bird hobbyists ranges from 0.5% to 21% depending on the study.²⁷ Among isocyanate workers, the prevalence of HP is approximately 1%.²¹

Importantly, attack rates in HP outbreaks may be significantly higher. Ganier et al reported an attack rate of 52% among office workers exposed to a contaminated humidification system.⁷ Similarly, Rose et al described attack rates of 27% and 65% in sequential HP outbreaks among lifeguards at an indoor swimming pool.²⁸ Thus, hypersensitivity pneumonitis may be quite common in some high-risk settings.

PATHOGENESIS

Immunology

HP is characterized by the presence of activated T lymphocytes in bronchoalveolar lavage (BAL) and an interstitial mononuclear cell infiltrate on lung biopsy. The pathogenesis involves repeated antigen exposure leading to immunologic sensitization and subsequent immune-mediated lung inflammation. The mechanisms underlying this series of events appear primarily to involve cell-mediated immunity. Passive transfer of cultured lymphocytes from sensitized animals, including guinea pigs,²⁹ rats,³⁰ rabbits,³¹ and inbred mice³² to unexposed, non-sensitized animals results in disease similar to human HP when the naïve animals subsequently are challenged with inhaled or infused pulmonary antigens. More recent animal experiments have shown the specific cells responsible to be activated T-helper memory cells with Th1 differentiation.^{33,34} Type 1 (Th1) cells are defined according to the primary cytokines secreted, interferon γ and IL-2,³⁵ and are the primary cells involved in cell-mediated immunity.

Data on the cytokines required for the manifestations of hypersensitivity pneumonitis confirm the importance of the cell-mediated immunity. Gudmundsson et al, using interferon γ knockout mice, proved that interferon γ is required for the development of HP in animals.³⁶ Overexpression of IL-12, a potent inducer of interferon γ production, modulates the expression of HP in various mouse strains.³⁷ Lymphocytes from BAL of patients with HP have been shown to overproduce interferon γ and to express high affinity IL-12 receptor, confirming the importance of these cytokines in human disease.³⁸

Viral infection leads to activation of the cell-mediated immune system and may alter host susceptibility to HP. This is suggested by the clinical observation of a viral prodrome often preceding HP. Viral infections have been shown to enhance HP in animal models leading to both a more intense alveolitis and an increased granulomatous inflammatory response on pathologic specimens.³⁹ In addition, viral proteins have been found in the lower airways of patients with HP.⁴⁰

The sequence of cellular and humoral events occurring in HP has been characterized using BAL. In a sensitized host, the initial response to antigen exposure is an influx of neutrophils.⁴¹ This is followed by a T lymphocyte-predominant alveolitis, often with 60–70% lymphocytes.⁴² Other cells found in increased numbers include natural killer cells and mast cells.^{43,44} Alveolar macrophages play a pivotal role throughout this process. They act as antigen presenting cells and secrete a variety of cytokines which function to both enhance the inflammatory response and recruit lymphocytes into the lung.^{45,46} In addition, activated macrophages release mediators of fibrosis including fibronectin and other matrix proteoglycans.⁴⁷

Host factors

Although many people are exposed to environmental antigens associated with HP, typically only a small percentage

develop disease. This suggests that host susceptibility or resistance factors may influence individual responses to inhaled antigens. Smoking is one such factor as multiple studies have shown that HP occurs more frequently in non-smokers.^{48,49} However, smokers who do develop disease appear to have a worse prognosis than non-smokers. In one study, smokers with farmer's lung disease had lower vital capacities, more frequent clinical recurrences, and a poorer 10-year survival than non-smokers with farmer's lung disease.⁵⁰

Other factors associated with differences in host susceptibility remain unclear. Despite multiple investigations, no association with HLA haplotypes and risk for HP has been discovered.^{51,52} However, more recent work suggests polymorphisms in the tumor necrosis factor- α (TNF- α) gene may be associated with disease. A polymorphism at position 308 is associated with higher constitutive and inducible levels of TNF- α and was found more frequently in patients with pigeon breeder's disease than controls.⁵³ In addition, patients with the disease and the 308 polymorphism were younger, had increased mean lymphocyte percentage in BAL, and a reported shorter antigen exposure duration than those patients without the polymorphism.⁵³

Exposure factors

Seasonal and geographic variations seen in most of the commonly recognized forms of HP indicate the importance of various exposure factors. Environmental risk factors such as antigen concentration, duration of exposure before symptom onset, frequency and intermittency of exposure, particle size, antigen solubility and potency, use of respiratory protection, and variability in work practices may influence disease prevalence, latency, and severity. Farmer's lung disease is most common in regions with heavy rainfall where feed is likely to become damp, and in harsh winter conditions where this damp hay is used to feed cattle in indoor barns with minimal ventilation. Pigeon breeder's lung is most common during the summer sporting season when exposures are at their highest.⁵⁴

Indirect and apparently trivial antigen exposures may be important with some antigens. Bird breeder's lung has occurred in spouses of pigeon hobbyists exposed to dusty laundry and in individuals whose only known exposure was to down comforters or feather decorations.^{18,19,55}

CLINICAL FEATURES

Signs and symptoms

Historically, the clinical presentation of hypersensitivity pneumonitis has been divided into acute, subacute, and chronic forms. However, significant overlap exists between these categories. In acute HP, systemic symptoms of fever, chills, and myalgias occur, along with respiratory symptoms of cough and dyspnea. These symptoms typically occur 4–12 hours after heavy exposure to the inciting antigen. Physical findings include fever and rales, and laboratory evaluation frequently reveals a peripheral leukocytosis. Recurrent acute symptom episodes should

prompt consideration of HP and a careful historical search for relevant exposures.

The subacute and chronic forms typically present with an insidious onset of respiratory symptoms often with non-specific systemic symptoms such as malaise, fatigue, or weight loss. Usually, the temporal relationship between symptoms and exposure is difficult to elicit. A high degree of clinical suspicion is required to confirm the diagnosis and initiate appropriate management. In a case series from Japan, the most frequent symptoms in chronic HP were cough and dyspnea.¹² Fever (low-grade) occurred in only half of the patients. Physical examination may be normal or reveal basilar crackles. Wheezing may occur and thus should not be used to exclude the diagnosis. Cyanosis and right-sided heart failure are found in end-stage disease. Depending on the clinical presentation, the differential diagnosis of HP can be extensive and includes inhalation fevers, other granulomatous disorders such as sarcoidosis, immunologic diseases such as asthma, infections, and fibrotic lung diseases such as idiopathic pulmonary fibrosis.

Precipitating antibodies

The finding of specific IgG precipitating antibodies in the serum of a patient with suspected HP is a helpful diagnostic clue but is neither sensitive nor specific and is no longer considered a hallmark of HP. Serum precipitins are found in 3–30% of asymptomatic farmers, and in up to 50% of asymptomatic pigeon breeders.^{56,57} Precipitins are thus a marker of exposure sufficient to generate a humoral immune response. However, they have no role in disease pathogenesis.

In addition, false-negative results can be common. In one study, 30–40% of patients with proven farmer's lung disease had no detectable precipitins to commonly tested antigens including *Saccharopolyspora rectivirgula*, *Aspergillus* species, and *Thermoactinomyces vulgaris*.⁵⁸ False-negative results may occur because of poorly standardized antigens, improper quality controls, insensitive techniques, the wrong choice of antigen, or underconcentrated sera.⁵⁹ They may also occur because serum precipitins may disappear over variable periods of time after cessation of exposure.³

Other laboratory studies

Mild elevations in erythrocyte sedimentation rate, C-reactive protein, and immunoglobulins of IgG, IgM, or IgA isotypes are occasionally evident, reflecting acute or chronic inflammation. Serum angiotensin-converting enzyme concentrations may be increased in patients with recurrent acute symptoms.⁶⁰ Antinuclear antibodies and other autoantibodies rarely are detected. Skin tests for both immediate and delayed-type hypersensitivity reactions are unhelpful in diagnosis. Recently, researchers have begun to investigate the utility of in-vitro lymphocyte proliferation tests to suspected antigens, with some success.^{12,61} However, standardization of both methods and results interpretation awaits further investigation.

Physiology

There is no single characteristic pattern of pulmonary function abnormalities in hypersensitivity pneumonitis. The original descriptions emphasized restriction as the primary abnormality. Although this remains true in acute disease, more recent studies stress the importance of airways obstruction in subacute and chronic HP. Lalancette et al found obstructive abnormalities in 42% of farmers after six years of follow-up.⁶² Others have confirmed the high prevalence of airways obstruction, even after accounting for the effects of smoking.^{63,64} Methacholine challenge showing increased non-specific bronchial hyper-reactivity has been demonstrated in both acute and chronic disease.^{65,66} Thus, patients with HP may exhibit obstructive, restrictive, or mixed patterns on pulmonary function testing. In early disease, normal values on spirometry and lung volumes are not uncommon.⁶⁷ Measures of gas exchange, particularly during exertion, are the most sensitive physiologic indicators of early HP abnormalities.^{21,67}

RADIOGRAPHIC FEATURES

Standard chest radiographs

The radiographic findings of acute HP include diffuse ground glass opacification and a fine nodular or reticulonodular pattern, often with lower lung field predominance. Consolidation is rarely seen.⁶⁸ The reticulonodular pattern becomes more prominent in the subacute phase.⁶⁹ In chronic HP, fibrosis with upper lobe retraction, reticular opacity, volume loss, and honeycombing may be seen.^{12,70} However, due to increasing awareness of disease preva-

lence and improved diagnostic techniques (especially fiberoptic bronchoscopy), the sensitivity of the chest radiograph has declined.⁷¹ In fact, the sensitivity in recent population-based studies is only about 10%.^{72,73} The sensitivity of high-resolution computed tomography (HRCT) is significantly better than plain radiographs.⁷⁴⁻⁷⁶

Computed tomography

A variety of HRCT patterns have been described in hypersensitivity pneumonitis, including ground glass, centrilobular nodules, fibrosis, and emphysema, discussed in more detail below.^{77,78} Most of these patterns have been correlated with histologic findings and some with pulmonary function abnormalities.⁷⁷ In addition, up to 50% of patients have mediastinal lymphadenopathy.⁷⁹ However, the adenopathy typically is not diffuse and the enlarged nodes are almost always smaller than 20 mm (short axis diameter).⁷⁹

Ground glass

Ground glass is defined as the presence of hazy increased opacity of the lung without obscuring underlying bronchial and vascular margins.⁸⁰ Ground glass is most common in acute hypersensitivity pneumonitis but may also be seen in subacute and chronic HP, especially if there is ongoing exposure (Fig. 19.6.1).⁸¹ The ground-glass opacification may be patchy or diffuse and some authors report a middle lung zone predominance.⁸² Ground-glass opacification may resolve with removal from exposure.⁷⁶

Histologically, ground-glass opacification is thought to represent either active alveolitis or fine fibrosis.^{76,83} This is

Figure 19.6.1: High-resolution (1.5 mm this section) CT images through the lungs of two patients with hypersensitivity pneumonitis show diffuse nodular densities in one (a) and generalized increase in attenuation of lung parenchyma with ground-glass opacification in the other (b).

consistent with the observed association with restriction and impaired gas exchange on pulmonary function testing.⁸⁴ Ground-glass opacification is frequently found in association with other radiographic abnormalities.

Centrilobular nodules

The nodules seen in hypersensitivity pneumonitis are round, poorly defined, and less than 5 mm in diameter (Fig. 19.6.1).⁶⁸ They are typically centrilobular⁷⁶ and profuse throughout the lung, but a middle to lower lung zone predominance has been variably reported.⁸² A patchy or unilateral distribution is more consistent with infection than hypersensitivity pneumonitis.⁸⁵ In several series, centrilobular nodules are the most frequent HRCT finding in HP.^{68,74,75,82} They are often found in association with ground-glass opacification, and the combination is highly suggestive of HP (Fig. 19.6.1).⁷⁷ As with ground glass, the nodules may regress with removal from exposure.^{75,76}

Centrilobular nodules are the radiographic equivalent of the cellular bronchiolitis frequently seen on histology. Unlike ground-glass findings, centrilobular nodules have not been correlated with pulmonary function abnormalities.^{76,84}

Airspace consolidation

Airspace consolidation differs from ground-glass opacity in that the underlying bronchial and vascular margins are obscured. Consolidation has only been reported in acute hypersensitivity pneumonitis,^{68,75} but is uncommon.^{76,85} When present, consolidation is the first abnormality to resolve with treatment.⁷⁵

Fibrosis

The irregular linear opacities, traction bronchiectasis, and honeycombing that may be seen in hypersensitivity pneumonitis all signify fibrosis.⁷⁷ These changes are most often found in the chronic stage of HP,⁷⁵ and occasionally in subacute HP. They would be distinctly unusual in acute disease.⁶⁸ Fibrotic changes may spare the apices and the costophrenic angles.⁸² In the transverse plane, the fibrotic changes are randomly distributed but a subpleural predominance has been described in some patients.⁸² Honeycombing has been found in up to 50% of chronic bird fancier's lung⁷⁶ but may be less common in chronic HP of other etiologies.¹² In farmer's lung, radiologic emphysema may be more common than fibrosis.^{78,81} Unfortunately, the presence and location of fibrotic changes remain non-specific, and HRCT cannot reliably distinguish chronic HP from idiopathic pulmonary fibrosis.⁸⁶

Emphysema

Radiographic evidence of emphysema in patients with chronic HP was first noted by Barbee et al in 1968.³ This finding was largely ignored until the early 1990s when Remy-Jardin et al noted emphysematous changes on HRCT in 50% of chronic bird fancier's HP.⁷⁶ In addition,

Lalancette et al reported that emphysema occurred more commonly than fibrosis in chronic farmer's lung.⁶² A more recent study by Cormier et al confirmed that emphysema is more prevalent than fibrosis in chronic farmer's lung, even after accounting for the effects of tobacco abuse.⁸¹ Another study showed an increased prevalence of emphysema in farmer's lung patients compared to control farmers matched for age, sex, and smoking status.⁷⁸ In that study, 13 of the 20 farmer's lung patients with emphysema were never smokers.

These findings indicate that hypersensitivity pneumonitis should be considered in the differential diagnosis of radiologic emphysema. While mechanisms for the development of emphysema in HP remain unclear, the bronchiolar inflammation and obstruction seen on pathologic examination are probably related.²

Mosaic pattern

High-resolution CT scans with a mosaic pattern display a patchwork of regions of differing attenuation.⁸⁰ In HP, this pattern is due to either patchy areas of ground glass or air-trapping. Air-trapping is best seen as a failure of an area to increase in attenuation on an expiratory scan.⁸⁷ A mosaic pattern is common in hypersensitivity pneumonitis. Nineteen of 22 patients in a series by Hansell et al displayed this finding.⁸⁴ Likewise, 15 out of 20 patients in Small et al's series had this pattern.⁸⁷ Thus, a mosaic pattern and air-trapping provide supportive evidence for the diagnosis of HP, especially when they occur in association with previously described abnormalities.⁷⁷

Air-trapping does not have a proven histologic correlate but is probably associated with bronchiolitis.^{84,87} HRCT evidence of air-trapping does correlate with evidence of obstruction on pulmonary function testing.^{84,88}

Specific inhalation challenge

The use of specific inhalation challenge in the diagnosis of HP is limited by the lack of standardized antigens and methods. Inhalation of an aerosolized antigen suspected to be causative is most helpful when acute symptoms and clinical abnormalities are part of the disease presentation and occur within hours after exposure.⁸⁹ In experienced laboratories, provocative testing may be useful in discriminating chronic HP induced by avian antigens from other interstitial lung diseases.⁹⁰ In some patients with acute symptoms, exposure to the suspect environment with postexposure monitoring of symptoms, temperature, leukocyte count, spirometry, diffusing capacity, and chest radiograph may be preferable to laboratory challenge. Interpretation of results is often difficult, and routine inhalation challenge is not recommended in most patients with suspected HP.⁹¹

Histopathology

The classic histopathology of hypersensitivity pneumonitis features the triad of cellular bronchiolitis, lympho-

Figure 19.6.2: Photomicrograph (40 ×) of a hematoxylin and eosin-stained transbronchial lung biopsy from a patient with hypersensitivity pneumonitis shows interstitial pneumonitis containing ill-defined epithelioid macrophage aggregates involving a respiratory bronchiole at left (star in lumen) and a non-necrotizing interstitial granuloma at right.

plasmacytic interstitial infiltrate, and poorly formed non-necrotizing granulomas (Fig. 19.6.2).⁹² Unfortunately, the complete triad is not always present and pathologic features may vary with disease stage. A fibrotic pattern very similar to usual interstitial pneumonitis (UIP) is frequently seen in chronic HP.⁹² In addition, granulomas are only seen in 60–70% of acute cases and in less than 50% of chronic HP.^{12,93} Giant cells, either alone or in clusters, airspace foam cells, and bronchiolitis obliterans with organizing pneumonia (BOOP) may also be seen.⁹² Recently, Katzenstein et al added non-specific interstitial pneumonitis (NSIP) to the histologic spectrum of hypersensitivity pneumonitis.⁹⁴ In the original series describing NSIP, 18% of patients had exposures consistent with HP. Katzenstein et al concluded that a thorough search for exposures should be conducted upon diagnosis of NSIP.⁹⁴ The varied pathologic findings of HP have prompted multiple authors to conclude that histologic features are not pathognomonic, and additional clinical and radiologic data are needed to confirm the diagnosis.^{1,5,91,92}

DIAGNOSTIC APPROACH

The diagnosis of HP remains challenging due to its varied presentation, wide spectrum of occupational and environmental exposure settings, and lack of a simple ‘gold standard’ and can include a large differential diagnosis (Table 19.6.2). The diagnosis should be considered in patients with both recurrent, more acute respiratory symptoms, as well as patients with insidious non-specific symptoms such as fatigue and weight loss. The differential diagnosis of HP includes a number of diseases. The following diagnostic studies are recommended on all patients with suspected HP: (1) *detailed* clinical history; (2) physical examination; (3) chest high-resolution computed tomography (unless the standard chest radiograph is clearly abnormal); (4) complete PFTs, including lung volumes, pre- and post-bron-

Inhalation fevers	Humidifier fever Organic dust toxic syndrome Pontiac fever (non-pneumonic legionellosis)
Granulomatous disorders	Sarcoidosis Beryllium disease Drug-induced pneumonitis Granuloma-vasculitis syndromes Lymphatoid granulomatosis Eosinophilic granuloma
Immunologic diseases	Asthma Collagen-vascular diseases Allergic bronchopulmonary aspergillosis Eosinophilic pneumonias
Infections	Viral and mycoplasma pneumonias Psittacosis Fungal infections Mycobacterial infections
Fibrosing lung diseases	Idiopathic pulmonary fibrosis Bronchiolitis obliterans from other causes Inorganic dust pneumoconioses

Table 19.6.2 Differential diagnosis of hypersensitivity pneumonitis

chodilator spirometry, and DLCO; and (5) fiberoptic bronchoscopy, usually with BAL and transbronchial biopsies.

The cornerstone of diagnosis and exposure prevention is a detailed history of symptoms plus occupational and environmental exposures. A clinical history suggesting a temporal relationship between symptoms and certain activities is often the first clue to the diagnosis of HP, although such a pattern may not occur in subacute or chronic forms of disease. The work history should include a chronology of current and previous occupations, with a description of specific work processes and exposures. Other important items in the work history include a list of specific chemicals, dusts, and other aerosol exposures, presence of persistent respiratory or constitutional symptoms in exposed coworkers, and whether respiratory protection was used. Review of Material Safety Data Sheets (MSDS) and any available industrial hygiene evaluations may supplement the work history.

The environmental history should explore exposure to pets and other domestic animals (especially birds); hobbies such as gardening and lawn care, which may involve sensitizing chemical exposures like pyrethrins; recreational activities, for example, use of hot tubs and indoor swimming pools from which microbial bioaerosols can be generated; use of humidifiers, cool mist vaporizers, and humidified air conditioners, which can be sources of microbial bioaerosols; moisture indicators such as leaking, flooding, or previous water damage to carpets and furnishings; and visible mold or mildew contamination in occupied spaces.

In patients whose detailed history is suggestive for HP but whose resting physiology is normal, exercise physiology can be helpful in detecting early abnormalities of gas exchange. Exercise testing can also help define impairment and guide treatment decisions, including the need for supplemental oxygen. Methacholine challenge does not distinguish asthma from HP and is generally not necessary. Serum precipitins are helpful when positive in supporting

the diagnosis of bird breeder's lung, and in other circumstances in which the putative antigen has been identified.⁹⁵ However, negative precipitins should not be used to exclude the diagnosis, and positive precipitins can occur in exposed unaffected individuals.

DIAGNOSTIC CRITERIA

Although there are multiple published diagnostic criteria, none have been validated. Cormier proposes that all of the following features are required for diagnosis: appropriate exposure, dyspnea on exertion, inspiratory crackles, and lymphocytic alveolitis,⁹⁶ but that lymphocytic alveolitis is not required provided at least two of the following criteria are present: recurrent febrile episodes, infiltrates on chest radiograph, decreased DLCO, precipitating antibodies to causative antigens, granulomas on lung biopsy, or improvement away from the exposure.

A few points about these criteria deserve further emphasis. Unlike earlier criteria, precipitating antibodies are not essential for diagnosis due to limited sensitivity and specificity. Lymphocyte subset ratios are also not included as diagnostic criteria. Initial studies suggested a lymphocytic alveolitis with reduced CD4:CD8 ratio was diagnostic of hypersensitivity pneumonitis. Although lymphocytic alveolitis is common, more recent studies show that the CD4:CD8 ratio varies with phase of disease,⁹⁷ inciting antigen,⁹⁸ and time since last exposure,⁹⁹ limiting its utility as a diagnostic test.

Acute and subacute HP suspected from a careful history can usually be confirmed based on the radiographic features, physiology, and findings on bronchoscopy noted above. The diagnosis of chronic HP can be more challenging, and open lung biopsy may be indicated when the diagnosis remains uncertain.

NATURAL HISTORY AND PROGNOSIS

The clinical course of HP is variable but permanent sequelae may include persistent bronchial hyper-responsiveness, emphysema, or progressive interstitial fibrosis. An accelerated decline in lung function with continued antigen exposure has been demonstrated for most forms of HP, underscoring the importance of cessation of exposure. However, the clinical course of HP is variable even with antigen avoidance. Acute HP generally resolves without sequelae.¹⁰⁰ However, progressive impairment may occur with recurrent attacks or with a single severe attack.^{3,101}

The subacute or chronic forms of HP present with insidious symptoms and more subtle clinical abnormalities, and are frequently recognized later in the disease course. The causative antigen cannot always be identified. As a result, these patients often have a poorer prognosis than those with acute disease. Symptomatic pigeon breeders monitored for 18 years showed a fourfold average rate of decline in pulmonary function in comparison with the expected rate.¹⁰² Four children and five adults with chronic avian HP were monitored for up to 10 years after standard treatment

consisting of removal from exposure and corticosteroids. Four had persistent symptoms, three had persistent functional abnormalities, and one died after unsuccessful lung transplant.¹⁰³ In subacute and chronic HP, some patients may experience disease progression despite exposure avoidance while others do not, even with ongoing exposure.^{99,104}

Long-term mortality rates for patients with chronic HP range from 1% to 10%.^{105,106} Prognostic factors include age, duration of exposure after onset of symptoms, and time of exposure prior to diagnosis.^{63,107} The specific antigen may also be important as some studies have shown prognosis is worse in avian HP than farmer's lung, with 5-year mortality rates approaching that of idiopathic pulmonary fibrosis (IPF).¹⁰⁸ Other potential prognostic factors include the ability to identify and thus avoid the relevant antigen and the presence of honeycombing.^{108,109} BAL findings do not appear to predict prognosis.^{110,111}

TREATMENT

The cornerstone of therapy for HP remains removal from exposure. Elimination of the antigen is the preferred approach and has the added benefit of preventing disease in other exposed individuals. For example, maple bark disease and bagassosis are now rare in the United States because changes in the handling of material resulted in diminished opportunity for microbial growth. Removal of damaged and colonized areas, disinfection, and elimination of conditions leading to seasonal mold contamination are effective in preventing recurrence of summer-type HP in Japan.¹¹² There are also numerous reports of patients with HP from other etiologies improving with removal from exposure alone.

In cases of home humidifier and hot tub-related HP, removal of the contaminated source is usually straightforward; however, on-site investigation of the work and home environments by an experienced industrial hygienist may be helpful in cases in which the exposure history is uncertain, particularly when disease is progressive. For fungal contaminants, both area and personal spore sampling and indirect immunofluorescence testing for spore-specific IgG have been used to assess indoor air quality and individual mold sensitization.¹¹³ However, quantitative bioaerosol sampling for indoor microbial antigens is time consuming, expensive, and not readily available to most clinicians, and requires an experienced industrial hygienist and analytical laboratory. Even when properly performed, results are often difficult to interpret and the sensitivity is such that negative results should not be used to disprove disease or exposure.¹¹⁴

Unfortunately, antigen abatement may not always be feasible,¹¹⁵ and removing the patient from the implicated environment may be necessary. In these cases, the social consequences and economic disruption to the affected individual may preclude strict abstinence from exposure. A long-term follow-up study of farmers found 70% had returned to farming by 15 years from diagnosis.¹⁰⁵ Respirators have been used when removal from exposure

was impossible. Kusaka et al found that negative pressure respirators prevented recurrent episodes of acute HP in 20 of 21 farmers.¹¹⁶ Nuutinen et al described the use of powered air-purifying respirators to protect farmers during indoor cattle feeding.¹¹⁷ Although respirators may provide protection during inhalation challenge tests or in circumstances with limited exposure periods, verification of their efficacy in preventing new onset or recurrent HP awaits further investigation.^{118,119} Moreover, respirators are difficult to wear for extended periods, require adequate fit testing and maintenance, and non-compliance with their use remains a significant problem.¹²⁰

Oral corticosteroids are frequently used to supplement antigen avoidance in severe or progressive disease. In cases in which pulmonary function abnormalities are minor and spontaneous recovery is likely with removal from exposure, steroids are probably unnecessary. When used, doses typically begin at 40–60 mg/day of oral prednisone and continue at this level until significant symptomatic and objective functional improvement is seen. Pulmonary function should be monitored within the first 4 weeks after initiation of treatment.⁶⁵ If there is objective improvement, a gradual taper to minimum sustaining doses should follow; otherwise, steroids should be tapered and discontinued.

Corticosteroids may shorten the duration of acute illness but they have not been shown to affect long-term prognosis.^{65,121} In patients suffering from acute HP, 2 months of corticosteroids therapy was compared to placebo; despite a more rapid resolution of functional and radiographic abnormalities in the steroid-treated group, long-term follow-up revealed no differences.¹²¹

Additional therapy includes supplemental oxygen in hypoxemic patients and other supportive measures. Inhaled steroids and β -agonists may be helpful in patients with airflow limitation.¹²² In refractory cases, cytotoxic agents including cyclophosphamide and azathioprine have been used. As in IPF, regular monitoring for side effects and adverse reactions from these immunosuppressive agents is essential. The authors typically maintain cytotoxic therapy, if tolerated, for at least six months to assess functional improvement and efficacy in preventing disease progression. Prophylaxis for pneumocystis pneumonia, appropriate viral and pneumonia vaccination and prompt treatment of intercurrent infection are recommended.¹

PREVENTION

Recognition of an index case of hypersensitivity pneumonitis may have considerable public health importance, since others exposed to the same environment are at risk for disease. Each case represents a sentinel health event, indicating the need for further investigation of the implicated environment where others may be at risk and where opportunities for prevention may be identified. Interventions may include control of moisture problems by preventing leaks and eliminating aerosol humidifiers or hot tubs. Dilution of contaminants can be affected by increasing the amount of outdoor air in a building, and high-efficiency filters can be added to the ventilation system.¹¹⁴

Altering work practices to reduce the prevalence of farmer's lung include efficient drying of hay and cereals before storage, use of mechanical feeding systems, and better ventilation of farm buildings.¹²³

PEDIATRIC HYPERSENSITIVITY PNEUMONITIS

There have been several case reports and case series of HP occurring in children. The illness has been reported in all pediatric age groups from infant to adolescent.^{124–127} Household birds are the most frequently reported antigenic exposure.^{125,126,128,129} However, agricultural exposures, contaminated humidifiers, and mold damaged homes are also reported etiologies in children.^{130–133} The clinical appearance of HP in children is similar to that of adults. Most reports describe repetitive episodes of acute disease that is often misdiagnosed as community acquired pneumonia, and clinical manifestations can be severe.¹³⁴ Children may also present with persistent unexplained respiratory symptoms.¹²⁹ Reported pulmonary function abnormalities include restriction, obstruction, and abnormal gas exchange.^{125,131} Chest radiographs usually feature ground glass and reticulonodular infiltrates; HRCT findings are similar to those reported in adults.¹³⁵ Most reported childhood cases have improved with removal from exposure, but long-term functional abnormalities and lung fibrosis have been reported.^{125,130} Fiberoptic bronchoscopy is usually not performed in children.

SUMMARY

Increasing recognition of the ubiquity of environmental antigen exposures and improved diagnostic tools, particularly HRCT and fiberoptic bronchoscopy, have led to increasing recognition of cases and outbreaks of HP in a wide variety of occupational and non-occupational settings. HP remains a diagnostic challenge because of the wide and varied spectrum of clinical findings and the lack of a simple 'gold standard' for diagnosis. The diagnosis depends on the combination of a strong clinical index of suspicion with a careful exposure history, and a constellation of radiographic, physiologic, and histopathologic findings. HP is both treatable and preventable but unrecognized disease may lead to permanent sequelae including asthma, emphysema, and interstitial fibrosis.¹² Confirmation of the diagnosis often generates broader public health implications regarding the potential risks from ongoing antigen exposure to others sharing the environment. Diagnosis of HP should prompt a search for additional cases in the shared environment as well as initiation of measures to eliminate further exposure.

19.7 Chronic Beryllium Disease and Cobalt-Related Interstitial Lung Disease (Hard-Metal Disease and Diamond Polisher's Lung Disease)

John R Balmes

Both beryllium and cobalt are relatively light metals that appear to have the potential to cause pulmonary toxicity through host immune responses because only a small percentage of exposed workers develop disease and relatively low level exposures can cause disease. Genetic susceptibility to interstitial lung disease from environmental exposure to these metals may involve either immunologically mediated sensitization (beryllium and possibly cobalt) or response to oxidant injury (possibly cobalt). Although much more is understood of host responses to inhaled beryllium than to inhaled cobalt, the interstitial lung diseases that result from chronic occupational exposure to these metals are important models of idiopathic sarcoidosis and giant cell interstitial pneumonitis, respectively.

BERYLLIUM DISEASE

Two different types of pulmonary disease can result from the inhalation of beryllium fumes or dust, or both. Short-term, high-intensity exposure ($\geq 25 \mu\text{g}/\text{m}^3$) can cause acute lung injury that is clinically and pathologically indistinguishable from toxic pneumonitis caused by the inhalation of other chemically irritating materials (see Chapter 19.5).¹ Exposure to lower concentrations of beryllium in workplace air over months to years can lead to the development of a chronic granulomatous disease that is similar to sarcoidosis.

Acute toxic pneumonitis due to beryllium is now rare, at least in developed countries, because the primary production industry is aware of the metal's toxic potential and has taken steps to prevent massive exposures. However, many thousands of workers in the United States and elsewhere remain at risk for the development of chronic beryllium disease (CBD) because of relatively low-intensity exposures in industries involved in the fabrication and machining of beryllium-containing alloys. Because acute beryllium pneumonitis can be considered with other forms of toxic pneumonitis, this section is restricted to a discussion of CBD.

Epidemiology

It has been estimated that up to 800,000 persons in the United States have current or past occupational exposure to beryllium.² The reported prevalence of CBD in exposed workers ranges from 2% to 16%. For perspective, the reported prevalence of sarcoidosis is much lower in the general population.³ That beryllium exposure can lead to granulomatous lung disease was established through investigation of an epidemic of sarcoidosis in the fluorescent lamp industry in Massachusetts during the 1940s.⁴ Removal of beryllium from fluorescent lamp manufacture eventually ensued. Reports of cases of CBD among non-

occupationally exposed residents of a neighborhood around a beryllium plant soon followed. The setting of an occupational exposure standard of $2 \mu\text{g}/\text{m}^3$ by the US Atomic Energy Commission in 1952 led to a reduction of cases due to beryllium production, but continued use of the metal in the aerospace, electronics, nuclear energy/weapons industries, metal recycling, and other high-tech industries has continued to generate new cases of CBD in the subsequent decades.⁵

Several conclusions can be drawn from the epidemiological database on CBD. It is clear that host susceptibility is an important factor because most exposed workers never develop clinically manifest lung disease. The form of beryllium to which workers are exposed also is important because exposure to beryllium oxide or fine fumes from heated metal is associated with higher rates of disease than exposure during cold processing.⁶ In addition to host susceptibility and the form of occupational exposure, there appears to be some relationship between dose of beryllium exposure and incidence of lung disease. Machinists of beryllium-containing materials in both the ceramics and nuclear weapons industries appear to have especially high rates of CBD.^{7,8} Recent data suggest that genetic and exposure-related factors contribute independently to risk of CBD.⁹

Pathogenesis

The pathological hallmark of CBD is the formation of non-caseating granulomas, which are identical to those seen in sarcoidosis. These granulomas are typically confined to the lungs but also may be found in other organs such as the skin, liver, spleen, lymph nodes, heart, kidneys, and salivary glands. In addition to granulomas in the lungs, there usually is a coexistent diffuse mononuclear cell alveolitis.

The salient feature of CBD is its association with delayed hypersensitivity to beryllium salts. This delayed hypersensitivity can be demonstrated by the in-vitro response of cultured T lymphocytes from either bronchoalveolar lavage (BAL) fluid or peripheral blood and by skin patch testing. The concept that CBD represents a disorder of cell-mediated immunity is not a new one, but it is only in recent years that it has been fully appreciated. In addition to the presence of delayed hypersensitivity to beryllium, support for this concept comes from the following evidence:

1. a usual history of exposure to beryllium for months to years before the disease develops,
2. data from multiple animal models indicating that beryllium exposure can lead to a beryllium-specific cell-mediated immune response,¹⁰
3. proliferation and accumulation of beryllium-specific CD4⁺ (helper) T lymphocytes in the lungs of patients with the disease,¹¹

4. dependence of beryllium-induced proliferation of lung helper T cells on the presence of major histocompatibility complex (MHC) class II antigens,¹²
5. susceptibility to CBD is associated with particular human leukocyte antigen (HLA)-DP alleles (especially substitution of a glutamic acid in position 69 of the beta chain),¹³ and
6. the finding of a limited subset of T-cell receptors in the lungs of patients with the disease.¹⁴

On the basis of this evidence, it is clear that CBD represents a cell-mediated hypersensitivity reaction to beryllium.

A plausible pathogenic sequence for chronic beryllium disease starts with phagocytosis of beryllium particles by alveolar macrophages, with beryllium acting as a hapten bound to some carrier protein (possibly even HLA-DP itself), followed by presentation of this new beryllium-induced antigen to T lymphocytes, which, in turn, leads to local clonal proliferation of sensitized CD4⁺ T cells. In response to subsequent inhalation of beryllium and further recognition of antigen, these helper T cells with memory for beryllium become activated and release various cytokines and chemokines consistent with a T-helper 1-type cytokine response (IFN- γ , TNF- α and IL-2). These mediators drive macrophage and other immune effector cell recruitment, giant cell and epithelioid cell formation, and ultimately, the creation of granulomas and surrounding fibrosis. Because the older term 'berylliosis' suggests a similarity to the mineral dust-induced pneumoconioses that are not characterized by an antigen-specific, cell-mediated immune response, the use of CBD is preferred.

Diagnosis

Patients with CBD typically present many years after initial exposure with respiratory symptoms of dyspnea and non-productive cough. Systemic complaints of weight loss, fatigue, and arthralgias also are frequent. The most common physical finding is inspiratory crackles at the bases, although skin lesions, hepatosplenomegaly, lymphadenopathy, and clubbing occasionally can be found.

The typical chest radiographic findings of chronic beryllium disease are diffuse interstitial infiltrates and mild bilateral hilar adenopathy, but can vary from normal to diffuse fibrotic changes. Hilar adenopathy is seen less impressively and frequently than in sarcoidosis (approximately 40% of cases) and rarely occurs in the absence of parenchymal changes (Fig. 19.7.1). The chest radiograph is an insensitive test for CBD. High-resolution computed tomography (HRCT) is more sensitive.¹⁵

Pulmonary function testing may demonstrate a restrictive pattern, an obstructive pattern, or a mixed restrictive-obstructive pattern. Occasionally, there may be an isolated impairment in diffusing capacity, especially in cases detected early. Mild hypoxemia is common. Pulmonary exercise testing is the most sensitive indicator of physiologic impairment in CBD, and an increased alveolar-arterial oxygen difference with exercise appears to have the greatest predictive value for the presence of the disease.¹⁰

Figure 19.7.1: Chest x-ray study of a 40-year-old metal refiner exposed to beryllium fumes for 6 years.

The primary diagnostic challenge is to distinguish CBD from sarcoidosis, because virtually every clinical manifestation of sarcoidosis, with the exception of uveitis and erythema nodosum, has been reported with CBD.¹⁶ A history of exposure is the most obvious clue, although patients may not be aware of exposure due to the fact that beryllium often is present in low percentage in alloys with copper or aluminum. There also may be a long latent period (from a few months to over 30 years) between beryllium exposure and clinical manifestations of disease, which can add to the difficulty of recognition of past exposure.

The histopathology of CBD is essentially identical to that of sarcoidosis so that transbronchial lung biopsy specimens showing non-caseating granulomas support either diagnosis (Fig. 19.7.2). Similarly, increases in the percentage of T lymphocytes and the ratio of helper to suppressor T cells on differential cell counting of BAL fluid are characteristic of both diseases. The results of other tests which may be used to help confirm a diagnosis of sarcoidosis, such as serum angiotensin-converting enzyme level and gallium scanning also do not distinguish chronic beryllium disease from its idiopathic counterpart.

Diagnostic criteria were developed for the US Beryllium Case Registry in 1952 to establish that a given patient had CBD.¹⁶ These criteria consist of the following: (1) evidence of significant beryllium exposure; (2) presence of beryllium in lung tissue, lymph nodes, or urine; (3) a clinical picture consistent with beryllium disease; (4) radiologic evidence of a pulmonary interstitial inflammatory process; (5) pulmonary function abnormalities (restrictive or obstructive ventilatory defects, or impaired diffusion); and (6) histopathologic evidence of non-caseating granulomas in lung or lymph node tissue. These criteria have been replaced by a diagnostic approach informed by a greater understanding of the beryllium-specific cell-mediated immune response.

The current diagnostic approach to CBD involves demonstration of a beryllium-specific immune response

Figure 19.7.2: Open lung biopsy from patient in Figure 19.7.1, showing intense lymphocytic alveolitis and non-caseating granulomas.(H & E stain, low power.)

and histopathologic evidence consistent with CBD (non-caseating granulomas or mononuclear cell alveolitis).¹⁷ The oldest test for beryllium hypersensitivity, the skin patch test, cannot be recommended because the test itself can induce beryllium sensitization in previously unsensitized individuals. Several groups of investigators have shown that the in-vitro proliferation of peripheral blood or BAL lymphocytes in response to beryllium salts is a specific test for beryllium hypersensitivity.^{18,19} The test is called the beryllium lymphocyte proliferation test (BeLPT) and is available in a limited number of medical centers. The basic principle underlying the test is that T lymphocytes that have memory for beryllium antigen will proliferate when exposed to beryllium salts in cell culture. This beryllium-specific cellular immune response is quantitated based on cell uptake of radio-labeled DNA precursors.

The BeLPT using peripheral blood lymphocytes is both sensitive for beryllium sensitization and reasonably specific for CBD. The BeLPT using mononuclear cells obtained by bronchoalveolar lavage may be more sensitive. Virtually all patients with CBD have a positive BeLPT test using peripheral blood or bronchoalveolar lavage sample, and patients with other granulomatous diseases do not. Beryllium-exposed persons can have a positive BeLPT but no evidence of pulmonary disease on lung biopsy and are said to be 'beryllium sensitized'. Longitudinal follow-up of exposed populations has shown that such persons remain at risk for progression to CBD in the future.²⁰

Fiberoptic bronchoscopy with multiple transbronchial biopsies is usually the best way to obtain adequate lung tissue to look for non-caseating granulomas and mononuclear cell infiltrates. The diagnosis of CBD can be confirmed in approximately 90% of patients with CBD by transbronchial biopsy, if a sufficient number of samples are taken,¹⁰ similar to the yield in sarcoidosis. In patients for whom bronchoscopy is considered overly risky, the diagnosis of CBD can be made by chest imaging findings consistent with sarcoidosis/CBD in the setting of a positive BeLPT and a history of beryllium exposure.

Prognosis

The natural history of beryllium sensitization and chronic beryllium disease is under active investigation. In the past, when workers tended to be exposed to beryllium under poorly controlled conditions, it appeared that most persons who developed the disease progressed to pulmonary fibrosis. Spontaneous remission was believed to occur much less frequently than in idiopathic sarcoidosis, and the response to corticosteroids was characteristically poor. The mortality rate was noted to be as high as 35%.²¹

More recently, with generally lower levels of workplace exposure and the ability to detect beryllium-sensitized workers who have not developed clinical disease, evidence has emerged that challenges the traditional view of the natural history of CBD. First, some workers with the disease have improved after removal from further exposure.²² Second, the clinical spectrum of CBD may be wider than previously recognized because in a report of a case series, in which the diagnosis was based on the results of BAL lymphocyte transformation testing and trans-bronchial biopsy, patients with disease were identified who were remarkably free of clinical manifestations.²³ Third, in most of the animal models of beryllium hypersensitivity reported to date, the inflammatory response resolves after cessation of exposure. These lines of evidence have prompted some investigators to call for the elimination of the usual modifier 'chronic' from the name given to the disease, as the disease may not become chronic in all workers, especially those detected early and with less beryllium exposure.

Although beryllium sensitization and CBD involve genetically mediated immune responses, there are exposure-related risks that suggest that improved industrial hygiene may decrease the likelihood of disease. The current OSHA standard of 2 $\mu\text{g}/\text{m}^3$ (8-hour TWA) does not prevent CBD.²⁴ Continued vigilance to reduce beryllium contamination of workplace air to the lowest possible level, combined with careful medical surveillance using the BeLPT for early detection of sensitization, is required to prevent CBD.

Management

The cornerstone of treatment of CBD is prompt removal of the affected person from further exposure. As noted earlier, this intervention alone may lead to remission. In all other aspects, treatment should be modeled after that used for idiopathic sarcoidosis. Systemic steroid therapy clearly has a role in symptomatic patients with documented pulmonary physiologic abnormalities and in those rare patients with extrapulmonary disease involving vital organs. If steroid therapy is initiated, objective parameters of responses, such as chest radiographs, HRCT scans, and pulmonary function test results, should be serially monitored in order to adjust appropriately the dose and duration of treatment. Because beryllium is considered a probable lung carcinogen (see Chapters 30.2 and 39.3) and because

of the potential for superimposed chronic obstructive pulmonary disease, cessation of smoking should be strongly encouraged.

Surveillance

As noted above, the blood BeLPT has high sensitivity and specificity for beryllium sensitization. Screening of beryllium-exposed workers with the blood BeLPT is recommended (see also Chapter 39.3). The test is a bioassay with some inherent variability, and a positive test is usually repeated to confirm sensitization. Because of the relatively low sensitivity of chest radiographic and pulmonary physiologic abnormalities for CBD, it is currently recommended that all sensitized individuals who have no contraindication undergo bronchoscopy for BAL and transbronchial biopsy.¹⁰

The results of population-based studies of beryllium-exposed workers that have employed blood BeLPT in conjunction with fiberoptic bronchoscopic diagnostic techniques suggest that such testing may prevent impairment due to CBD by identifying workers with subclinical disease. However, there is some evidence that progression to CBD may eventually occur in most sensitized workers. It has been recommended that beryllium-sensitized workers be re-evaluated (and considered for repeat bronchoscopy) every 1–3 years.¹⁰ However, further longitudinal study of the natural history of beryllium sensitization without evidence of disease is necessary before this approach can be definitively supported. The genes which may modify risk of beryllium sensitization and CBD are under investigation. However, there currently is no clinical role for genetic testing for markers of CBD susceptibility.

COBALT-RELATED INTERSTITIAL LUNG DISEASE (HARD-METAL DISEASE AND DIAMOND POLISHERS' LUNG DISEASE)

One of the most intriguing causes of occupational lung disease is hard metal, a cemented alloy of tungsten carbide with cobalt (although other metals such as titanium, tantalum, chromium, molybdenum, or nickel may be added). Workers exposed to cemented tungsten carbide dust are at risk for the development of an interstitial lung disease, so-called hard metal disease. The use of this term tends to obscure the probable etiologic role of cobalt in the disease process. Workers in the diamond industry who were exposed to cobalt-containing dust from polishing disks have also developed interstitial lung disease identical to hard-metal disease, thereby confirming the likely role of cobalt.

A more prevalent occupational respiratory disorder than interstitial lung disease among hard metal workers is occupational asthma. Cobalt, which appears to induce specific sensitization of the airways, also is the etiologic agent of

occupational asthma associated with exposure to hard metal dust. Because occupational asthma due to cobalt is similar to other types of occupational asthma (see Chapter 19.2), this section focuses on interstitial lung disease due to cobalt dust.

Epidemiology

Production of hard metal occurs worldwide. Exposure to hard metal is not confined to primary production workers; grinding of finished hard metal in the tool manufacturing industry is an important source of exposure. Thousands of workers in the United States have current or past exposure to tungsten carbide.²⁵ Despite the relatively large number of exposed workers, interstitial lung disease due to hard metal dust remains relatively rare. Only four (0.6%) of 700 employees at a Japanese production plant were found to have radiographic evidence of interstitial lung disease during a survey conducted from 1981 to 1990.²⁶ The prevalence of radiographic abnormalities suggestive of interstitial lung disease was somewhat higher (2.6%) in a cross-sectional study of 1039 hard metal production workers from 22 plants in the United States.²⁷ In fact, in one United States plant with extremely high cobalt dust concentrations, nine (6%) of 150 employees with heavy exposure had interstitial infiltrates.²⁸

Workers are also exposed to cobalt dust alone, such as in the diamond polishing industry in Belgium which involves exposure to cobalt in the absence of tungsten carbide. Cobalt-induced lung disease has been reported in less than 1% of a workforce of approximately 5000 diamond polishers in Belgium.²⁹ A cross-sectional survey of 195 polishers working in 10 plants, however, did show a dose-response relationship for level of cobalt exposure and decrements in lung function.³⁰ Interstitial lung disease also has been recognized among dental technicians exposed to cobalt-chromium-molybdenum alloys.³¹

Pathogenesis

The most characteristic histologic features of cobalt-induced interstitial lung disease are those of giant cell interstitial pneumonitis, with interstitial mononuclear cell infiltration and the accumulation of large, vacuolated mononuclear cells, as well as multinucleated giant cells in the alveoli.³² In fact, a retrospective review of Liebow's original collection of 31 giant cell interstitial pneumonitis cases revealed that 27 had worked in the hard-metal industry.³³ Therefore, the finding of giant cell interstitial pneumonitis on lung biopsy strongly suggests exposure to hard metal or other cobalt-containing compounds. Electron microscopy has revealed that the giant cells can be either macrophages or type II alveolar epithelial cells. BAL fluid from patients with hard-metal disease may show a relative increase of other cells (lymphocytes, neutrophils, or eosinophils), but it is the presence of multinucleated giant cells that is the characteristic finding.

The relative proportions of desquamative alveolitis and interstitial fibrosis can vary from case to case, and if lung

tissue is obtained late in the course of this disease or at autopsy, only the non-specific changes of end-stage fibrosis may be found.^{32,34} In some cases of hard-metal disease, features of bronchiolitis obliterans also are observed. Most reported analyses of biopsied or autopsied lung tissue from hard-metal workers have demonstrated tungsten-containing particles but not cobalt accumulation. This lack of retained cobalt has been attributed to its solubility in body fluids and presumed rapid clearance from the lungs.

Animal toxicological studies conducted during the 1940s demonstrated that the intratracheal administration of either metallic tungsten or tungsten carbide dust produced little histologic change.³⁵ Similar studies demonstrated that the administration of a 10:1 mixture of tungsten carbide and cobalt induced acute pneumonitis and bronchiolitis.³⁵ Cobalt alone, whether administered by intratracheal injection or by inhalation, causes, in high concentrations, acute pulmonary edema or, in low concentrations, a granulomatous pneumonitis with progression to fibrosis.³⁶ More recent studies in rats have confirmed that the pulmonary toxicity of intratracheally administered cobalt is enhanced in the presence of metallic carbides such as tungsten carbide.³⁷

The results of in-vitro studies have shown that cobalt and metallic carbides can interact to produce reactive oxygen species capable of causing oxidant injury.³⁸ The enhanced pulmonary toxicity of tungsten carbide-cobalt mixtures may be due to the ability of tungsten carbide to act as a conductor of electrons from cobalt to oxygen. It has even been suggested that genetically determined differences in antioxidant defense mechanisms may underlie the variable host susceptibility.³⁹

To date none of the animal models have been shown to develop giant cell interstitial pneumonitis, the pathological hallmark of hard metal disease. Because cobalt is well documented to cause contact dermatitis via a type IV delayed hypersensitivity mechanism, a cell-mediated immune response has been suspected. Positive cobalt patch tests have been reported in hard-metal workers, and blast transformation of peripheral blood lymphocytes from sensitized individuals has been demonstrated with in-vitro culture in the presence of cobalt salts.⁴⁰ Moreover, susceptibility to develop cobalt-related interstitial lung disease among a group of exposed workers was associated with the same genetic polymorphism in the HLA-DP B1 alleles (Glu 69) associated with risk of CBD.⁴¹

Giant cell interstitial pneumonitis, however, is histologically distinct from granulomatous lung diseases involving cell-mediated immune responses such as hypersensitivity pneumonitis and CBD. Nonetheless, hard-metal disease must involve more than an acute chemical pneumonitis or a chronic dust accumulation mechanism because relatively low-level exposures can cause the disease and only a small number of exposed workers ever develop it. The possibility of an autoimmune process is suggested by the report of the recurrence of giant cell interstitial pneumonitis after lung transplantation in a patient with hard-metal disease.⁴²

Any lingering debate over the primary etiologic role of cobalt in the interstitial lung disease seen among hard-metal workers would seem to be put to rest by reports from the Belgian diamond polishing industry. Both interstitial lung disease and occupational asthma have been described in workers using high-speed grinding tools with a polishing surface of microdiamonds cemented in very fine cobalt. No tungsten carbide is present in the dust generated by the diamond polishing process. The histologic findings on lung biopsy of diamond polishers with interstitial lung disease are identical to those of hard metal disease, including the virtually pathognomonic multinucleated giant cells.

Diagnosis

Workers who develop respiratory illness associated with occupational exposure to hard metal or other cobalt-containing dust present in several different ways.^{10,25} A typical occupational asthma syndrome, characterized by decrements in expiratory flow rates during or after the work shift, is the most frequent occupational pulmonary disorder seen among hard metal workers. Positive specific inhalation challenges to either aerosolized cobalt powder or tungsten carbide powder containing cobalt have been reported. Interstitial lung disease, or classic hard-metal disease, may be associated with either rapidly progressive dyspnea or a slow, insidious course. Non-productive cough is common.

Constitutional symptoms such as fever and anorexia have been described and when these occur in association with interstitial infiltrates on chest radiographs, the diagnosis of an atypical pneumonia is suggested. However, when such acute or subacute episodes of pneumonitis recur in a worker exposed to grinding dust, the presence of hard-metal disease should be suspected. Some cobalt-exposed workers present with features of both asthma and interstitial lung disease.

On physical examination, crackles may be heard during acute episodes of interstitial pneumonitis or during late-stage fibrosis. Chest radiographs may be normal early in the course of the disease but typically show a diffuse reticulonodular pattern (Fig. 19.7.3). Pulmonary function tests usually show a restrictive ventilatory impairment with reduced diffusing capacity and increased elastic recoil. These abnormalities may be present even if the chest radiograph appears normal. If cobalt-induced asthma also is present, a mixed obstructive-restrictive picture may be noted. If the disease is allowed to progress, severe hypoxemia may develop, which, in turn, can lead to pulmonary hypertension and cor pulmonale.

As with other relatively rare occupational disorders, the key to the diagnosis is a high index of suspicion. Because the clinical features of cobalt-related interstitial lung disease are not particularly distinctive, the diagnosis usually is based on the history of exposure plus supportive laboratory data (Figs 19.7.3 and 19.7.4). BAL and lung biopsy are helpful if the characteristic multinucleated giant cells are revealed. However, if these procedures are

Figure 19.7.3: Chest x-ray of a 33-year-old grinder exposed to tungsten carbide dust for about 2 years.

performed at a late stage in the disease process, non-specific findings are more likely to be demonstrated.

Although transbronchial biopsy specimens obtained via fiberoptic bronchoscopy may be adequate to show giant cell interstitial pneumonitis (Fig. 19.7.4), open lung biopsy has a greater yield.¹⁰ Scanning electron microscopy with energy dispersive x-ray analysis typically demonstrates the presence of tungsten if the exposure has been to hard-metal dust, but cobalt usually is not found.

Prognosis

Once the diagnosis of hard-metal disease is made, the patient should be removed from further exposure. The natural history may vary from complete recovery to continued progression. Disabling pulmonary impairment can result from hard metal disease. Severe relapses on return to work with renewed exposure to cobalt-containing dust have been described in patients who initially recovered with removal from exposure. It seems likely that early diagnosis and removal from exposure leads to an improved prognosis, although there are limited data available to support such a statement.

Management

The primary treatment of cobalt-related interstitial lung disease is removal of the affected person from further exposure. Although some workers improve with cessation of cobalt exposure, others continue to worsen. The risk factors for continued progression are unclear. Corticosteroid therapy has been used successfully to treat persistent or severe disease in addition to removal from exposure, but there have been no controlled clinical trials of the efficacy of this treatment. There are also anecdotal reports of therapeutic success with cytotoxic agents such as cyclophosphamide in patients who do not respond to corticosteroids.²⁵

Surveillance

Lower dust levels in modern hard-metal production facilities may have reduced the risk of classic hard-metal disease compared with past conditions in the industry,⁴³ but surveys in various settings have documented cases of both interstitial lung disease and occupational asthma when measured cobalt dust concentrations were below the current US OSHA threshold limit value time-weighted average of 50 $\mu\text{g}/\text{m}^3$.^{27,28,30,44,45} These cross-sectional surveys have also shown that although cases of hard-metal disease with severe impairment are rare, increased interstitial markings on chest radiographs and lung function abnormalities occur in exposed workers who are asymptomatic. Medical surveillance using chest radiographs, review of respiratory symptoms and pulmonary function testing is recommended and may prove useful in preventing cases of severe interstitial fibrosis by leading to the removal of workers with early-stage disease or excessive cobalt exposure.

19.8 Asbestosis and Asbestos-Related Pleural Disease

Carl A Brodtkin, Linda Rosenstock

Asbestos is a term applied to a heterogeneous group of naturally occurring asbestiform minerals, characterized as hydrated silicates, with variable magnesium content. Asbestiform minerals have a fibrous structure, and tend to separate into distinct fibers, with length at least three times greater than width. Fibers are classified structurally, with serpentine fibers (i.e., chrysotile asbestos) representing curved structures, and amphibolic fibers (e.g., amosite, crocidolite, anthophyllite, actinolite, and tremolite asbestos) representing straight structures arranged linearly.^{1,2} Fibers may also be classified by length, with fibers of greater than five microns in length identifiable by phase contrast microscopy (used in regulatory standards).

These six fibrous silicates are commonly referred to as asbestos, including the three most common commercial forms: chrysotile, or white asbestos; amosite, or brown asbestos; and crocidolite, or blue asbestos. Chrysotile is the most commonly used asbestos in North America, and accounted for more than 98% of asbestos consumption in the United States in the early 1990s.³ Although some differences in biologic potency have been observed among various fiber types, from the point of view of the clinician, it should be recognized that the three main commercial types have been associated with all of the major malignant and non-malignant asbestos-related conditions.

Asbestos fibers are easily respirable, with inhalation representing the major route of exposure. The range of health effects from asbestos exposure is protean, including both pulmonary and non-pulmonary malignant and non-malignant conditions. This section focuses on two major non-malignant pulmonary sequelae: asbestosis and asbestos-induced pleural disease. Although these two types of outcomes, pleural and parenchymal, have distinct pathologic and physiologic manifestations, both represent dose-dependent outcomes of the same asbestos exposure. Pleural and parenchymal disease may occur either in isolation or together in the same individual.

ASBESTOS EXPOSURE SETTINGS

Worldwide use of asbestos increased steadily from the late 19th century, peaking in the early 1970s, with millions of tons of asbestos used in the United States since 1900.⁴ Asbestos has been used in a wide variety of industrial products, including insulation, textiles, cement, friction products (such as brake linings), and many construction materials. Although consumption of asbestos in the United States and other developed countries has declined significantly over the past three decades, global production and use continue, with active mining in Russia, Canada, China, Kazakstan, and Brazil,⁵ and export to developing countries, including South East Asia, Africa, South America, and Eastern Europe. Both the quantity and conditions of asbestos use in developing countries have led to substantial public health concerns internationally.⁵ Many of the properties that make asbestos such an attractive

industrial product, including durability, tensile strength, flexibility (allowing use in woven textiles), thermal resistance, and low electrical conductivity, are responsible for its hazardous properties and potency, as well as its environmental persistence.

Asbestos is ubiquitous in the environment of industrialized countries, and has become increasingly so in the developing world, where asbestos use has increased annually at a rate of approximately 7%. Historically, workers in industries involved in the production and use of asbestos products were at greatest risk for exposure, including asbestos mining and milling, friction products, asbestos cement, textile, shipyard, and construction industries. Specific trades considered at high risk for asbestos exposure include insulators, sheet-metal workers, plumbers and pipefitters, steamfitters, boiler-makers, plasterboard workers, and numerous shipyard trades such as electricians and shipscaleers.^{6,7}

In addition to manufacturing settings, end-users or handlers of asbestos-containing materials and products are often at risk for exposure, and may be unaware of associated hazards. For instance, studies investigating the incidence of mesothelioma – a malignant outcome specific to asbestos exposure – have identified additional occupations, such as railway and power station workers, wharf laborers, brake mechanics,⁸ transport drivers, welders, and metal workers⁹ as being at risk for significant asbestos exposure. Similarly, needs assessment surveys of Department of Energy sites have identified former workers as an historic cohort having significant risk for asbestos exposure.¹⁰ Mortality studies are also useful in identifying groups of workers at increased risk for asbestos-related diseases. For example, among 12,873 union construction plasterers and cement masons, a proportionate mortality ratio (PMR) of 1677 ($P < 0.01$) was observed for asbestosis.¹¹

Asbestos frequently exists in older buildings, and may be present in machinery, pipes, or appliances. The Occupational Safety and Health Administration estimates that 1.3 million workers in construction and general industry encounter significant occupational exposure, most prominently during manipulation of asbestos during renovation or demolition.¹² In addition to occupational settings, many domestic products continue to contain asbestos, including brake pads and linings, vermiculite (which can be contaminated with tremolite asbestos), roofing products, gaskets, heat and acoustic insulation, fireproofing, and flooring material.¹³

EPIDEMIOLOGY

Following increased use of asbestos in the late 1800s, evidence began accumulating in the early 1900s of adverse respiratory effects related to exposure. Pulmonary fibrosis in asbestos-exposed workers was described at necropsy by 1906, radiographic changes by 1918, and a histopathologic description of pulmonary asbestosis provided by the

1920s.¹⁴ Despite early clinical characterization of asbestos-related diseases, detailed information about populations at risk has been sporadic and largely confined to studies of occupational cohorts. Some variability in disease prevalence among different populations of workers with comparable cumulative asbestos exposure has been observed; factors to explain this are likely to include differences in fiber size, type, and distribution as well as individual host susceptibility factors. Nicholson and colleagues quantified the number of United States workers occupationally exposed to asbestos from 1940 to 1979, identifying about 19 million workers likely to have had significant occupational exposure. These exposures are estimated to result in several hundred thousand deaths, primarily due to lung cancer, as well as asbestosis, mesothelioma, and other cancers.¹⁵

The best evidence regarding the risk for the major non-malignant outcomes of asbestos remains those studies based on specific groups of exposed workers. There is reasonable evidence that, for asbestosis, there is a strong linear dose-response relationship between exposure and the proportion of the population affected. While it is likely that there is some exposure threshold, none has been demonstrated convincingly, such that individuals with low exposures or higher exposures of short duration (e.g., for a period of days to weeks) are not at risk. This pattern is probably different from the relation between exposure and asbestos-related malignancies, in which even low-level or brief exposures may confer at least some increased risk. Among South Carolina asbestos textile workers, Stayner and colleagues identified no evidence of a threshold for development of either asbestosis or lung cancer in relation to cumulative asbestos exposure.¹⁶

While a dose-response relationship is also observed for asbestos-related pleural disease, a clear threshold is even less apparent; pleural as well as parenchymal radiographic changes have been observed with exposure durations ranging from as little as one¹⁷ to 12.7 months.¹⁸ As with asbestosis, the prevalence of pleural disease increases with cumulative asbestos exposure, and is consistently observed in settings of high cumulative asbestos exposures.¹⁹

Asbestos-exposed workers with the highest level of exposures, such as asbestos insulators, accordingly bear the greatest burden of asbestos-related effects. Among workers certified by medical panels as having asbestosis, life expectancy has been found to be significantly shortened due to asbestos-related mortality, with 38% dying from lung cancer, 8% from mesothelioma, and 20% from asbestosis.²⁰

Among populations of asbestos-exposed workers, prevalence rates for asbestosis and asbestos-related pleural thickening vary with intensity and duration of exposure, as well as time since initial exposure (disease latency). In a study of 2907 asbestos insulators, most with latencies of more than 30 years from first exposure, 12% had isolated radiographic fibrotic changes, 24% had isolated radiographic pleural changes, and 49% had both pleural and parenchymal changes.²¹ Prevalence rates for both pleural and parenchymal outcomes are accordingly lower among those

with lower exposures, as measured by both intensity and duration, and shorter latent periods.

Because latency plays such a major role in the radiographic appearance of non-malignant asbestos-related disease, which often occurs two decades or more following initial exposure, the mean age of populations studied is of major significance when considering whether populations have comparable outcomes. General population surveys may thus underestimate disease prevalence in high risk groups. In a review of chest radiographs from the first US National Health and Nutrition Examination Survey (NHANES) in the mid-1970s, 2.3% of men and 0.2% of women had occupationally related pleural thickening, extrapolated to a US population estimate of 1.3 million individuals, with a total of 8 million exposed to asbestos.²²

Non-occupational environmental asbestos exposures occur, and are most concerning for malignant sequelae. Anderson and colleagues observed that both pleural and parenchymal changes were significantly more prevalent in exposed household contacts of asbestos workers than controls ($P < 0.001$), with 35% demonstrating pleural changes and 17% parenchymal changes, respectively.²³ Population surveys have identified higher rates of pleural abnormalities in locations where asbestos occurs naturally, ranging from 2% to 17% of individuals. An unfortunate sequela of such environmental contamination has occurred in Libby, Montana, where years of extensive environmental asbestos contamination resulted from vermiculite mining, processing, and commercial use. A cross-sectional investigation of 6668 adults from this community observed radiographic pleural thickening in 17.8% of individuals, with parenchymal changes in less than 1%.²⁴ In individuals with significant vermiculite exposure pathways identified, up to 34.6% had pleural abnormalities.

While air-borne asbestos is detectable at low concentrations in the ambient air of urban settings (e.g., 2×10^{-6} f/ml by phase contrast microscopy [PCM]), and to a lesser extent in rural areas (2×10^{-7} f/ml PCM),²⁵ this is unlikely to result in substantial risk for non-malignant asbestos disease in the absence of additional indirect exposures. These levels are orders of magnitude less than the current occupational exposure standard of 0.1 f/ml (PCM) for air-borne asbestos, that is predicted to result in an excess lifetime risk of 2/1000 for asbestosis and 5/1000 for lung cancer.

PATHOGENESIS AND PATHOLOGY

Asbestos fibers are inhaled deep into the respiratory tract, exerting their main influence at the level of the respiratory bronchioles and alveoli. Fibers migrate to the pulmonary interstitium via uptake by alveolar epithelial cells, with accumulation of macrophages leading to an inflammatory response, namely alveolitis and peribronchiolitis.²⁶ Despite activation of macrophages, many asbestos fibers are

Figure 19.8.1: (a,b) Example of grade 1 asbestosis. This region of lung tissue shows peribronchiolar fibrosis in association with ferruginous bodies consistent with asbestos bodies (arrow). ((a) $\times 125$; (b) $\times 500$.) (Courtesy of Sam Hammar, MD.)

retained in the pulmonary interstitium, or migrate to the pleura via lymphatic channels, causing a chronic inflammatory response.

Asbestos fibers cause direct cytotoxicity from generation of reactive oxygen intermediates,²⁷ with injury to intracellular macromolecules and associated lipid peroxidation. In addition, activated macrophages produce cytokines, interleukins, tumor necrosis factor, fibronectin, and other mediators, enhancing tissue inflammation and injury.²⁸ These inflammatory mediators stimulate granulocytic and fibroblastic responses, leading to tissue fibrosis.²⁹ This chronic inflammatory and fibrotic tissue response to asbestos represents the primary pathophysiologic mechanism for progressive lung injury.

Pathologic descriptions and diagnostic criteria for parenchymal and pleural asbestos-related diseases have been provided by the College of American Pathologists and NIOSH.³⁰ The macroscopic appearance of asbestosis (used here to refer only to parenchymal asbestos-induced fibrosis) is that of small, firm and brownish lungs, occasionally laced with gray fibrous streaks. Pulmonary fibrosis is linear and involves predominantly the lower (basilar) lung fields; honeycombing may be present. Histologically, the parenchymal interstitial fibrosis is similar to that observed in other diffuse interstitial lung diseases, except that asbestos bodies and elevated asbestos fiber content are typically present. The histologic diagnosis of asbestosis

is based on the minimal findings of fibrosis of the walls of the respiratory bronchioles, which may be the sole manifestation of early disease, in association with asbestos bodies (Fig. 19.8.1). The distribution of parenchymal fibrosis in early or mild disease is in subpleural regions, progressing centrally with more advanced disease.

Pleural plaques are discretely elevated gray-white areas of fibrous tissue, involving the parietal pleura in the region of the mid-thoracic chest wall and domes of the diaphragm. Plaques may be smooth or nodular, and round or irregularly shaped. Parietal plaques tend to calcify with time; histologically, there is no difference between non-calcified and calcified plaques, other than the presence of calcium. These sequelae have been collectively referred to as hyaline plaques. Diffuse pleural thickening results from thickening and fibrosis of the visceral pleura, often with fusion to the parietal pleura. Diffuse pleural thickening is also a common sequela of benign asbestos-induced pleural effusions. Diffuse pleural thickening and extensive pulmonary fibrosis are the classic features of advanced asbestosis.

In addition to the pathologic findings associated with pleural and parenchymal fibrosis, evidence of exposure itself can be found in sputum, lung tissue, and by bronchoalveolar lavage (BAL). The asbestos body or 'ferruginous body' represents an asbestos fiber coated with ferroprotein by macrophages (see figure 19.8.1B). Microscopically,

asbestos bodies are brownish club-shaped and symmetrically nodular structures, that stain for iron due to high ferritin content. Because asbestos bodies are larger than fibers, they can be identified with light microscopy of lung and BAL specimens. Analysis of BAL in individuals with asbestosis may also identify a macrophage-predominant alveolitis, with some neutrophilia. While apparent asbestos bodies can arise in response to an array of foreign fibers, the large majority have asbestos cores, correlating with fiber lengths of greater than 10 microns. Asbestos bodies are a better reflection of amphibole than chrysotile asbestos lung burden, and represent only a small proportion of the total asbestos fiber load.

In contrast to asbestos bodies, quantification of asbestos fibers is generally performed by electron microscopy, and is not as widely available. Those with parenchymal asbestosis typically have the highest concentration of asbestos fibers in lung (number of fibers per weight of lung tissue); those with pleural plaques have higher numbers of fibers than those without, and those with occupational exposure have higher concentrations than those without, regardless of radiographic or functional manifestations of exposure. There is substantial variability among labs for quantitation of both asbestos bodies and tissue fiber concentration; interpretation generally requires specific knowledge of laboratory reference ranges.

CLINICAL EVALUATION OF THE PATIENT

Exposure history

Fundamental to the consideration of any of the asbestos-related outcomes and their probability is the occupational and environmental history of asbestos exposure. Three aspects of the history are essential: onset, duration, and intensity of exposure.

Exposure onset and latency

Exposure onset is of importance because of the characteristic latent period between first exposure and disease manifestation (termed 'latency'). For both interstitial fibrosis and pleural plaques, latencies are typically greater than 20 years.³¹ Shorter latency periods do occur, and correlate with more intense and higher cumulative exposures. Shorter latent periods should heighten suspicion of other diagnostic entities. Diffuse pleural thickening, if it follows a benign asbestos effusion, is the one non-malignant outcome that may occur relatively early following exposure (e.g., several years), although mean latencies are still close to 20 years.

Exposure duration

The duration of exposure is also an important factor in determining whether or not abnormalities are attributable to asbestos exposure. Cumulative asbestos exposure durations are frequently greater than 6 months in individuals with asbestosis. If exposure has been intense, this duration may be shorter but evaluation should include

consideration for other causes of interstitial fibrosis. Similar exposure durations are observed in individuals with asbestos-related pleural thickening, although shorter exposure periods may be observed.

Exposure intensity

The intensity of asbestos exposure is best determined by information about the job or trade, the industry in which it was performed, and the circumstances of asbestos use or exposure and protection from it. While epidemiologic studies may characterize cumulative exposures quantitatively (e.g., fiber-year/ml of asbestos exposure), such measurements are rarely available for individual workers. Three general settings of exposure should be considered, namely direct, bystander, and indirect exposure. Direct exposure occurs with application, removal, or manipulation of asbestos or asbestos-containing materials. Bystander exposure occurs when a worker is exposed through proximity to coworkers generating asbestos dust through their direct activities. Indirect exposure occurs when asbestos is carried away from the worksite (e.g., dusty work clothing and shoes), exposing family members and other household contacts.

Asbestos insulation procedures, involving mixing and application of asbestos, provide a useful example of the range of exposure intensities encountered in industrial settings. Until the mid-1970s in the United States, it was common for asbestos insulators to work without respiratory protection, often in dusty, poorly ventilated environments, with resulting high intensity direct exposures. In a prospective study of 17,800 US and Canadian asbestos insulation workers, extremely high mortality rates for asbestosis were observed (e.g., 413–1187 deaths/10⁵/year for those with more than 30 years from employment onset);³² with 11% of deaths attributable to asbestosis in a sub-group of these workers.³³ Sheet-metal workers, who frequently worked in proximity to these insulators, also experienced high bystander exposures. In a US national survey of 9605 sheet-metal workers, 31% were identified as having asbestos-related radiographic changes.³⁴ Similarly, other trades, including electricians, carpenters, plumbers, and pipefitters, worked side by side with insulators, and although lower on average than the insulators, exposures were often of moderate to high intensity, through a combination of direct and bystander routes. The significant effect of indirect exposure related to asbestos insulation work is reviewed above, with highly prevalent radiographic changes among family members of these insulators.

An occupational history occasionally reveals unexpectedly high intensity asbestos exposures in unusual jobs, such as mixing asbestos powder into paints or glazing material. In taking the history, it is important to inquire about how asbestos was encountered, including work setting (indoor vs outdoors, enclosed vs open space), presence of engineering controls or personal protective equipment (e.g., exhaust hoses and use of fit-tested HEPA respirators), and observed levels of dust. While respirable asbestos fibers are not visible, the observed level of dust in the environment may serve as a qualitative index of

exposure. For instance, diminished visibility (e.g., 'snow-storm' effects) in enclosed areas during application or removal of asbestos is indicative of very high intensity exposure (e.g., ship construction settings). Intact asbestos impregnated in material is not generally of concern, unless friable or otherwise disrupted to generate air-borne fibers. A partial list of occupations with common asbestos exposure is provided in Chapter 46.

Clinical history

The insidious onset of dyspnea, typically progressing over a number of years in association with diminished exertional tolerance, is the most common respiratory symptom in individuals with asbestosis. A non-productive cough may be present, and can progress to a productive cough later in the course of the disease, even in non-smokers. Wheezing and dyspnea are associated with significantly diminished ventilatory capacity in asbestos-exposed workers, with an 11–17% reduction observed in a cross-sectional study of 816 asbestos-exposed workers ($P < 0.001$),³⁵ and a lesser 2–8% reduction observed for cough, phlegm and chronic bronchitis ($P < 0.001$). Development and progression of respiratory symptoms are associated with accelerated loss of lung function. In a longitudinal study of 446 asbestos-exposed workers, an excess decline in FEV₁ of 28 ml/year for development of dyspnea, and 67 ml/year for development of wheezing ($P < 0.01$), was observed relative to asymptomatic individuals.³⁶ Dyspnea was associated with an almost two-fold increased mortality from asbestosis in a 10-year follow-up of 2609 insulators from the North American insulator cohort (RR 1.9; 95% CI 1.10–3.28). Respiratory symptoms should be assessed in the context of pulmonary function testing and other objective parameters discussed below.

The individual with isolated pleural plaques usually is asymptomatic unless other sequelae, non-radiographically apparent, are present, or plaques are extensive. Patients with plaques may report episodic pleuritic or non-pleuritic chest pain, that has no other explainable cause. In cohort studies, presence of pleural thickening has been associated with increased dyspnea, for any given grade of radiographic fibrosis. Although individuals with diffuse pleural thickening often do not have symptoms, they more frequently report the presence of dyspnea, chest discomfort, or difficulty with full inspiration. These symptoms may be prominent in settings of bilateral diffuse thickening and fibrothorax. Among 64 individuals with bilateral diffuse pleural thickening, 56% reported chest pain, with 63% reporting moderate and 11% severe breathlessness.³⁷ Development of prominent or severe chest pain may indicate a pleuritis (e.g., asbestos-related pleural effusion), but should be evaluated further to rule out other causes, including malignancy (e.g., mesothelioma or lung cancer).

Asbestos exposure, independent of other pathologic endpoints, may also cause upper respiratory tract irritation,³⁸ and has been implicated as a cause of industrial bronchitis (e.g. asbestos insulators; see Chapter 19.4).

Physical examination

The major physical finding in asbestosis is basilar rales,³⁹ that may be pan-inspiratory or apparent only on end-inspiration. Rales are dose dependent, and can occur in the absence of radiographic changes. Finger clubbing or cyanosis may be present in advanced cases. When seen in patients with evidence of only mild interstitial fibrosis, clubbing should raise suspicion for possible malignancy. Physical findings are useful clinically; rales, clubbing, or cyanosis were associated with an almost two-fold increased mortality from asbestosis in the North American insulator cohort. The clinician should recognize that while useful when present, physical findings are not a sensitive indicator of asbestosis, particularly in early or mild disease, and may be minimal or absent even in patients with significant radiographic and functional abnormalities.

Radiographic features

While high-resolution CT (HRCT) scan of the chest has represented a major advance over the past 15 years, and is particularly valuable in equivocal cases, the plain chest roentgenograph remains the standard for radiographic evaluation of non-malignant asbestos-related disease.

Plain chest radiograph

On posteroanterior (PA) chest x-ray, pleural plaques have a variable appearance depending on their location in the chest, commonly having the density of pulmonary nodules at the lateral chest walls, and less density more medial to the chest wall. Non-calcified pleural plaques are difficult to detect in the medial two-thirds of the lungs, because they are then perpendicular to the x-ray beam and too thin for definition; calcified plaques, however, are sufficiently radiopaque to be detectable in all portions of the chest (Fig. 19.8.2). Plaques occur most commonly on the middle part of the diaphragm, on the posterolateral chest wall between the 7th and 10th ribs, and on the lateral chest wall between the 6th and 9th ribs. Plaques are often bilateral and symmetric in distribution, but asymmetric or unilateral pleural plaques are sufficiently common that they are indicative of past asbestos exposure, in the absence of other apparent causes, such as rib fractures.

The criterion of costophrenic angle blunting is required in the current 2003 ILO classification for reporting of diffuse pleural thickening.⁴⁰ In addition to costophrenic angle blunting, diffuse pleural thickening is characterized radiographically by a thickness of the pleura greater than 1 mm medial to the chest wall, often involving more than one-third the extent of the thoracic wall. Distinguishing discrete from diffuse pleural thickening is not always easy. Table 19.8.1 describes some characteristics helpful in making this determination.⁴¹ Apical pleural thickening up to 10 mm (to the level of the 4th rib) can be a variant of normal; more pronounced apical thickening in asbestos-exposed individuals, with a mean of 21 mm, has been reported as an unusual complication in individuals with diffuse parenchymal fibrotic changes involving the upper

	Pleural thickening		Extrapleural shadows
	Discrete (plaques)	Diffuse	
Composition	Parietal pleura	Parietal and visceral pleura (affects only visceral pleura if interlobar fissures)	Muscles (serratus anterior, external oblique), intercostal extrapleural fat, companion shadows
Location*	Lateral and posterior chest wall at level of lower ribs (5–10) sparing costophrenic sulcus; can involve mediastinum, pericardium, middle third of diaphragm	Usually bilateral, along lateral chest wall; may involve costophrenic sulcus	Companion shadows; most prominent in association with upper ribs Muscle shadows: apparent pleural shadows are in continuity with well-developed muscle shadows along lateral chest wall
Appearance on posteroanterior chest x-ray study	May be calcified Uneven, sometimes with bizarre shape, well-defined medial border when seen in profile (tangential to x-ray beam), faint when seen en face (perpendicular to x-ray beam). May show abrupt change in density from dense, lateral to faint, medial shadow	Rarely calcified Ill-defined and irregular medial margin parallel to lateral chest wall; may show graded increase in density from medial to lateral border and widens inferiorly	Not calcified Pleural line along lateral chest wall often widens superiorly and tapers inferiorly. Muscles have rhythmic, symmetrical appearance of triangular, V, or quadrilateral shape, with one sharply defined border, often fading into adjacent soft tissue
Appearance on right and left anterior oblique chest x-ray	Shadow remains adjacent to lung field with similar appearance to posteroanterior film except for rotation in orientation (and hence density) to x-ray beam	Shadow remains adjacent to lung field within thoracic cage; identify if greater than 10 mm width	Shadows demonstrated to continue with those of adjacent soft tissue and may rotate outside of lung fields. Fat: rhythmic wavy appearance most prominent adjacent to rib rather than in intercostal space
<p>* Apical pleural thickening alone (to level of 4th rib) is a variant of normal and should not be ascribed to asbestos unless associated with thickening below this level.</p> <p>Adapted from Rosenstock L, Hudson LD. The pleural manifestations of asbestos exposure. <i>Occup Med</i> 1987; 2(2):383–407.</p>			

Table 19.8.1 Distinguishing pleural thickening from extrapleural shadows

lobes, and significant restrictive impairment⁴² (Fig. 19.8.3). Interlobar tissue thickening may be the sole manifestation of asbestos exposure, but may also occur in association with other pleural abnormalities or interstitial fibrosis.

Parenchymal changes on posteroanterior chest radiographs are typically lower lobe (basilar) in location, and are described as a profusion of small irregular opacities. These opacities are present peripherally, beyond the normal bronchovascular markings of the lower lung fields. With more advanced disease, the middle and even upper lung fields may become involved. The small irregular opacities typical of asbestos-induced interstitial fibrosis are designated radiographically as 's' and 't' by the ILO classification (see also Introduction to Chapter 19). In advanced disease, opacities may have a honeycomb appearance (Fig. 19.8.4). When opacities are sufficiently dense and appropriately located, they may obscure the definition of adjacent structures, causing the appearance of an irregular diaphragm or heart border, the latter known as the shaggy heart sign. There has been no convincing evidence that asbestos itself can cause progressive massive fibrosis or large opacities. Although a few such cases have been reported in asbestos-exposed workers, it is likely that these manifestations are best explained by concomitant exposure to silica.

Even among heavily exposed cohorts with a high prevalence of interstitial changes, the large majority, often up to 90%, of abnormal chest radiographs fall in the mild grades of profusion by ILO criteria (1/0 and 1/1). Standard chest radiographs may have limited sensitivity in early or mild

parenchymal disease. For example, 25 of 138 (18%) asbestos insulation workers with histologic fibrosis on tissue specimens (obtained in the course of lung cancer resection) had no parenchymal changes apparent on chest radiograph.⁴³ Similarly, among 169 asbestos-exposed workers with normal chest radiographs, 57 (33%) had abnormal findings on HRCT consistent with asbestosis.⁴⁴

Of interest to the clinician, most series have identified a non-concordance in individuals between the development of parenchymal versus pleural manifestations of asbestos exposure. Among those occupationally exposed who have radiographic evidence of interstitial fibrosis, about half will have concomitant pleural thickening; conversely, those with pleural thickening usually have a smaller proportion (less than 30%) of concomitant interstitial findings.

High-resolution computed tomography

High-resolution CT (HRCT) of the chest has become increasingly used in the radiographic assessment of asbestos-related pleural and parenchymal disease. While conventional CT has been shown to be a more sensitive indicator than standard chest radiographs in detecting asbestosis, rounded atelectasis, and pleural plaques, high-resolution techniques offer improved sensitivity for detection of asbestosis.^{45–47} High-resolution CT studies should use algorithms with 2 cm or finer intervals. Because asbestosis is most prominent in basilar, posterior, and subpleural regions, it is important that prone views be

Figure 19.8.2: (a) PA chest radiograph of 70-year-old retired insulator with calcified diaphragmatic pleural plaques and normal parenchyma (ILO 0/1). (b) Lateral radiograph that better demonstrates calcified diaphragmatic plaques.

obtained to differentiate these fibrotic changes from dependent atelectasis in posterior fields. Characteristic features of asbestosis on HRCT include fibrotic intralobular interstitial thickening and interlobular septal thickening, subpleural lines and opacities, parenchymal bands, ground-glass opacities, and, in more severe disease, variable honeycombing.^{48,49} A classification system for CT and HRCT findings in asbestos-related disease and other pneumoconioses, analogous to the ILO system, has been proposed.⁵⁰ Parenchymal fibrotic changes on HRCT have

Figure 19.8.3: PA chest radiograph of 44-year-old asbestos insulator with diffuse bilateral pleural thickening and interstitial fibrosis (ILO 1/2).

Figure 19.8.4: PA chest radiograph of 64-year-old painter with minimal diffuse bilateral pleural thickening and extensive fibrosis with honeycombing (ILO 3/3).

correlated with other clinical parameters of asbestosis, including diminished vital capacity and diffusing capacity. Similarly, the extent of pleural thickening determined quantitatively by HRCT correlates strongly with diminished total lung capacity ($P = 0.002$).⁵¹

Pulmonary function

Pulmonary function tests are the most important tool for the functional assessment of non-malignant asbestos-related effects.

The pattern of pulmonary function abnormalities in individuals with asbestos-induced parenchymal disease (asbestosis) is classically described as a restrictive one. Typical findings include decreased ventilatory capacity on spirometry (diminished FVC and FEV₁, with well maintained FEV₁/FVC ratio); abnormal static lung volumes, with decreased total lung capacity (TLC) and residual volume, and abnormalities in gas exchange, characterized by reduced diffusing capacity (DLCO). A widened alveolar-arterial oxygen gradient, with or without hypoxemia, may be observed. The earliest and most sensitive finding in asbestosis is frequently a diminished diffusing capacity, which may occur in isolation or in combination with other findings.

While isolated restrictive impairment is the most common functional manifestation of asbestosis, a mixed restrictive and obstructive impairment is also common (with greater relative reductions in FEV₁ than FVC, resulting in a diminished FEV₁/FVC ratio). In addition to parenchymal effects, asbestos can cause airflow obstruction,^{52–56} with pathophysiologic changes in the small airways. A consistent correlation between pathologic changes of fibrosis in respiratory bronchiolar walls and diminished FEV₁ and FEF_{25–75} has been observed.⁵⁷ The finding of diminished mid-expiratory flow rates (e.g., FEF_{25–75}) appears to be the most sensitive parameter for assessing early obstructive changes among asbestos-exposed workers,^{58–60} reflecting small airways effects. Among 225 non-smoking female asbestos workers, with and without concomitant asbestosis, an increased RV/TLC ratio, suggestive of air trapping, and reduced airflow at mid to low lung volumes were observed, consistent with small airways obstruction. Asbestos-related airflow obstruction interacts with the effects of smoking, resulting in more pronounced obstructive changes.

Total lung capacity is generally an insensitive measure of functional impairment.⁶¹ This is likely a result of the competing forces on TLC in mixed restrictive and obstructive impairment, with a reduction in TLC related to restrictive disease, and an increase in TLC related to concurrent obstructive air trapping. It is unlikely that isolated severe obstructive disease is attributable solely to asbestos exposure.

Pleural plaques have traditionally been viewed as markers of asbestos exposure; the isolated effects of asbestos-induced pleural disease on lung function have been more difficult to assess, due to the confounding effect of non-radiographically apparent interstitial disease. Evidence of an independent effect of pleural thickening on lung function was observed by Miller and associates among six asbestos-exposed workers with diffuse pleural thickening and minimal parenchymal disease on radiographic and pathologic examination.⁶² A pattern characteristic of pleural-induced restriction was observed, with diminished vital capacity and DLCO, but increased DLCO/TLC ratio consistent with normal lung parenchyma that has become encased.

Several large cohort studies have subsequently provided additional evidence that pleural thickening is independently associated with functional respiratory impairment,

most consistently affecting FVC.^{63–65} In rare cases, isolated pleural disease may be sufficient to cause respiratory failure, with CO₂ retention and cor pulmonale. In those studies assessing the relative contribution to functional impairment of plaques versus diffuse pleural thickening, diffuse – particularly bilateral – pleural thickening was found to confer a greater adverse effect.⁶⁶

Other laboratory tests

A number of other laboratory tests have been employed in assessing the pulmonary effects of asbestos exposure. Bronchoalveolar lavage (BAL) may demonstrate asbestos (ferruginous) bodies.^{67,68} Neutrophilia, indicative of alveolitis, has correlated with objective findings of rales and diminished oxygenation, as well as accelerated loss of FEV₁ and DLCO.⁶⁹ While bronchoalveolar lavage findings in asbestos-exposed workers have demonstrated an altered immune response,⁷⁰ correlation between these findings and cumulative asbestos exposure has been variable, and BAL is appropriately reserved for excluding other etiologies.

The presence of pleural plaques indicates significant exposure to asbestos, and is associated with a more than 10-fold increased risk for development of mesothelioma compared to the general population.⁷¹ In cases of prominent unilateral, progressive, or asymmetric pleural thickening, single positron emission computed tomography (e.g., SPECT with thallium-201 scintigraphy) may be useful in assessing metabolically active tumor such as mesothelioma.⁷² Inflammatory changes associated with diffuse pleural thickening (e.g., pachypleuritis or 'crow's feet') may be characterized by gallium scanning. These scans do not have a role, however, in the routine evaluation of asbestos-exposed individuals.

Exercise testing has not proven useful as part of the routine evaluation of individuals with suspected or known asbestos-related non-malignant conditions, and is not required for diagnosis. Little correlation has been observed between the degree of respiratory impairment measured by static pulmonary function tests compared with maximal oxygen uptake (VO_{2max}) and other parameters of exercise testing.⁷³ Exercise testing is appropriately reserved for individuals who have dyspnea out of proportion to radiographic and static lung function findings.

CLASSIFICATION OF NON-MALIGNANT ASBESTOS-RELATED DISEASE

Pleura

- Pleural thickening
- Plaques (discrete pleural thickening)
- Diffuse pleural thickening
- Benign exudative pleuritis
- Rounded atelectasis

Parenchyma

- Asbestosis

Pleura

Pleural thickening

Pleural inflammation results from the migration of inhaled asbestos fibers to the pleura. Pleural thickening may be discrete (pleural plaques) or diffuse; both reflect significant prior exposure to asbestos and duration since initial exposure, with latency from exposure (often more than 20 years) being the most important determinant. These two abnormalities share many features in common, but are worth considering separately because they represent distinct pathophysiologic responses, with differential effects on pulmonary function and related symptoms. These distinct effects are coded separately in the current ILO classification of pneumoconiosis, and have been coded separately since 1980. Pleural thickening, when observed radiographically without other obvious cause, should always prompt a thorough occupational and environmental history to identify past asbestos exposure.

Plaques

Plaques represent areas of discrete or circumscribed thickening of the parietal pleura, and are the most common biologic effect of asbestos exposure. In contrast to the general population, plaques are highly prevalent in historically heavily exposed populations; for instance, plaques were identified in 82% of asbestos insulators with a latency of more than 40 years from exposure onset. Histologically, plaques are characterized by uniform hyaline connective tissue, classically described in a 'basket-weave' pattern, covered by normal mesothelial cells, without adhesions. Associated inflammatory cells may be present peripherally. Plaques are most frequently bilateral in location, a finding pathognomonic for asbestos exposure, but they may be unilateral. Calcification occurs over time, and is a function of duration from first exposure (latency).

Plaques are effectively identified on chest radiograph as discrete raised surfaces, with well-defined margins against the chest wall, frequently in the mid-thoracic or diaphragm region. Plaques may also appear 'en face' with serpiginous borders. It is useful to the clinician that the differential diagnosis of discrete pleural thickening is limited (Table 19.8.2). Subpleural fat pads are also located against the mid-thoracic wall, but typically have less distinct edges.⁷⁴ Plaques can be confirmed by conventional CT or HRCT when chest radiographic features are unclear. Features used to distinguish calcified asbestos plaques from those of other causes include the findings that non-asbestos plaques are more often unilateral, and more extensive than those due to asbestos; such plaques often involve the visceral pleura, so that a thickness of pleura is apparent between the calcification and the ribs.

The natural history of pleural plaques is one of slow progression. Since plaques do not form adhesions with the visceral pleura, they tend to have a minor impact on respiratory function. Studies of asbestos-exposed populations have variably observed small reductions in ventilatory capacity associated with plaques. Among 1211 sheet-metal

Discrete	Diffuse
Asbestos-related*	Asbestos-related
Mesothelioma	Loculated effusions
Lymphoma	Infectious processes* (e.g., tuberculosis, paragonimiasis, bilateral empyema)
Myeloma	Collagen vascular disease (e.g., scleroderma, SLE, rheumatoid arthritis)
Metastatic cancer	Sarcoidosis
Post-traumatic*	Uremia
Post-infectious, e.g., tuberculosis*	Drug reactions
Mica and talc*	Chronic beryllium disease
Scleroderma*	Silicosis
Chronic mineral oil aspiration*	Mica and talc

* May calcify.

Table 19.8.2 Differential diagnosis of pleural thickening

workers, circumscribed plaques were associated with a 140 ml reduction in FVC. A 6.5% average reduction in FVC associated with circumscribed plaques was similarly observed among 2611 asbestos insulators. However, in a clinic-based study of 1150 shipyard and construction workers, no reduction in FVC was observed in association with circumscribed plaques.⁷⁵ Interestingly, evidence of excessive and altered dead space ventilation was reported in 23 asbestos-exposed workers with dyspnea, pleural thickening and normal pulmonary function tests, suggestive of diminished chest wall or lung compliance.⁷⁶

Plaques raise clinical concern as a marker of significant asbestos exposure, and have been associated with parenchymal changes of peribronchiolar fibrosis ($P < 0.001$) and alveolar fibrosis ($P < 0.05$) in autopsy series.⁷⁷ In addition to asbestosis, plaques are also associated with increased risk for the malignant outcomes of asbestos exposure, including mesothelioma and lung cancer. In a review of epidemiologic studies assessing relative risk of lung cancer in asbestos-exposed cohorts, Hillerdal and colleagues reported a 1.3–3.7-fold increase in risk for lung cancer in workers with radiographic evidence of plaques without fibrosis.⁷⁸

Diffuse pleural thickening

In contrast to plaques, diffuse pleural thickening involves the visceral pleura, and may have more portentous clinical implications. In diffuse pleural thickening, adhesions frequently form with the parietal pleura, with radiographically indistinct borders, blunting of the costophrenic angle (Figure 19.8.5). Fibrous extensions into lung parenchyma, termed pachypleuritis (or 'crow's feet') may also occur. As noted above, diffuse pleural thickening is defined radiographically by involvement of the costophrenic angle. Rarely, isolated apical pleural thickening may occur, associated with fibrosis of the upper lobe, which must at times be distinguished from tuberculosis, mesothelioma, or other etiologies. Diffuse pleural thickening may occur in isolation, or in combination with pleural plaques. As with pleural plaques, diffuse thickening is associated with cumulative asbestos exposure and latency, but may also be seen following episodes of benign asbestos pleuritis.⁷⁹

In contrast to the mild effect of plaques on lung function, diffuse pleural thickening may result in more significant restrictive respiratory impairment, with a 270 ml reduction in FVC observed among sheet-metal workers, an almost 20% predicted reduction in FVC among asbestos insulators, and a 13% decrement in FVC, on average, among shipyard and construction workers. Overall, restrictive ventilatory impairment is much more common than in circumscribed pleural disease, and may not correlate with extent of radiographic findings. In extreme cases, marked pleuritis and fibrothorax may occur, resulting in severe restrictive impairment and need for surgical decortication.

As discussed above, diffuse pleural disease may be associated with chest discomfort and associated respiratory symptoms. While this is typically mild or moderate, and frequently responds to non-steroidal anti-inflammatory therapy, in some patients chronic, severe, and disabling pleuritic pain can occur, prompting surgical pleurectomy in rare instances.⁸⁰ Once present, diffuse pleural thickening is likely to become more extensive with time.

The differential diagnosis of diffuse pleural thickening is broader than for plaques but it is often possible on the basis of radiographic findings and clinical history to exclude other likely causes (Table 19.8.2). Both mica and talc have been reported to be able to induce diffuse as well as discrete pleural lesions similar to those caused by asbestos, which may be explained by contamination of these products with asbestiform minerals.

For the clinician, identifying pleural thickening should serve as an added basis for increased vigilance in an asbestos-exposed individual at risk for other sequelae. In addition, the identification of otherwise clinically unimportant thickening may play a role in prompting greater attention by the physician and patient to the importance of prevention and specifically to smoking cessation. In addition to lung cancer risk, cigarette smoking diminishes mucociliary clearance of particulates such as asbestos, increasing the biologically available dose of fibers for a given level of exposure. An association between heavy cigarette smoking and mildly increased radiographic parenchymal changes in asbestos-exposed individuals has been observed,^{81,82} interestingly, there is no evidence that cigarette smoke enhances risk for asbestos-related pleural thickening.⁸³

Benign exudative pleuritis

The inflammatory effect of asbestos on the pleura may be manifest by an acute or sub-acute pleural effusion.^{84,85} Effusions often last several months, with a mean duration of 4.3 months in one series of 22 patients, but may be persistent or recurrent in some cases.⁸⁶ The most common symptoms are pain, experienced by approximately one-third of individuals, and dyspnea reported by 6%; almost half are without any symptoms. Effusions are usually small, but may on occasion be up to several liters in volume. This asbestos-related outcome may be the sole manifestation of exposure.

Benign exudative pleuritis, also known as benign exudative pleurisy (BEP) or asbestos effusion, is defined as follows:

(1) history of asbestos exposure, (2) confirmation of effusion by radiographic studies or thoracentesis, (3) absence of other diseases to better account for the effusion, and (4) no occurrence of associated malignancy within 3 years of diagnosis. Doseresponse relationships for asbestos pleural effusion have not been well characterized, and specific prevalence and incidence rates are unknown. The diagnosis is complicated by the fact that these effusions are usually transient, although they often leave the residua of diffuse pleural thickening, with obliteration of the costophrenic sulcus.

The clinical approach should include differential diagnostic considerations for exudative pleural effusion, including malignant, infectious (e.g., tuberculosis), and other inflammatory conditions (e.g., connective tissue disorders). Given the increased risk of pulmonary malignancy and mesothelioma in asbestos-exposed workers, excluding a malignant pleural effusion is essential. This frequently requires CT imaging of the chest, and direct examination of the pleura (e.g., thoracoscopy with biopsy of suspicious areas). While development of mesothelioma has been reported in individuals with chronic or recurrent asbestos-related pleural effusions, there is no evidence that this represents a direct progression of disease. Nevertheless, mesothelioma should be a concern in such individuals, because it can present with minimal evidence of a solid lesion and an exudative effusion that is indistinguishable from a benign one. Fluid characteristics are variable; commonly, the fluid is a sterile exudate that may be serosanguinous. In addition to neutrophils, lymphocytes and mesothelial cells, one of the more specific findings is an increased number of eosinophils (identified in pleural fluid and peripheral blood counts), that may be useful in establishing the diagnosis when present. The sensitivity for this finding is limited, however, with eosinophilic effusion reported in only 26% of cases in one series.

The reported mean latency for benign exudative pleuritis varies among series, ranging from 14 to 45 years. Importantly, BEP can be seen within the first 10 years of exposure and, given the longer minimum latencies for other non-malignant processes, it is not surprising that in one series, it was the most common asbestos-related abnormality within the first 20 years of asbestos exposure.⁸⁷ Pulmonary function may be abnormal, either as a consequence of mechanical restriction from the effusion or related to underlying pleural or parenchymal disease.

Rounded atelectasis

Rounded atelectasis, or pseudotumor, is thought to arise when pleural thickening of the visceral or parietal pleura, or both, compresses underlying parenchyma to form a radiographically appearing nodule or mass. In a series of 74 patients with rounded atelectasis, 64 (86%) had been exposed to asbestos.⁸⁸ Multiple or bilateral areas of involvement have been described.⁸⁹ This undoubtedly is the least common of the manifestations of exposure, although the exact prevalence is unknown. The radiographic appearance of these nodules is characteristically irregular, with a visible

Figure 19.8.5: Posteroanterior chest x-ray of a 48-year-old insulator with a restrictive pulmonary impairment and exertional dyspnea, showing diffuse pleural thickening and bibasilar fibrosis (ILO 1/2).

Figure 19.8.6: Chest CT of patient in Figure 19.8.5, showing right-sided posterior mass found at resection to be rounded atelectasis.

band connecting the mass-like density to a region of pleural thickening. A more specific finding is the 'comet tail' or 'broom' sign, caused by pleura, bronchi, and blood vessels swirling from the hilum toward the rounded mass. CT scan (or occasionally bronchography) can provide adequate anatomic definition of the pleural base of the lesion and its distinctive features. Nonetheless, in the asbestos-exposed individual with pleural thickening and suspect rounded atelectasis, the risk for carcinoma remains high (Figs 19.8.6–19.8.8).

Figure 19.8.7: Posteroanterior chest x-ray of a 68-year-old brick mason with a restrictive pulmonary impairment and exertional dyspnea, and previous open thoracotomy, demonstrating the right pleural-based mass as pleural fibrosis; bilateral diffuse pleural thickening and bibasilar fibrosis are present.

Figure 19.8.8: Chest CT of patient in Figure 19.8.7, showing left-sided posterior mass found at resection to be a well-differentiated adenocarcinoma.

Parenchyma

Asbestosis

Inhaled asbestos fibers cause an inflammatory response in the lung, characterized initially by alveolitis as well as peribronchiolitis, leading ultimately to persistent fibrotic parenchymal changes. Although some investigators have used the term asbestosis to encompass non-malignant asbestos-related pleural abnormalities, it is employed here to refer solely to the interstitial fibrosis and accompanying peribronchiolar fibrosis found in the parenchyma of affected individuals. Fibrosis may or may not be accompanied by pleural thickening and other pleural abnormalities. Among 4060 asbestos-exposed men enrolled in a randomized prospective chemoprevention trial (CARET Asbestos-Exposed Cohort), 18% had parenchymal opacities alone (ILO profusion score > 1/0), while 21% had both parenchymal opacities and pleural thickening.

As noted above, all asbestos fiber types, including a wide spectrum of fiber lengths, cause asbestosis; there is thus no classification system based on fiber type or length. Further, it is often difficult to distinguish fiber types retrospectively, either historically, since many asbestos-containing materials represented a mixture of fiber types, or pathologically, due to variable biopersistence of specific fiber types in lung tissue. For example, chrysotile fiber bundles tend to fragment into narrower fibers in tissue, with leaching of magnesium, leading to greater degradation over time relative to amphibolic fibers but cumulative fibrogenic potential dose for dose is comparable.

The radiographic features of asbestosis, described in an earlier section, are similar to a number of other diffuse interstitial lung diseases, such as idiopathic pulmonary fibrosis. Concomitant pleural change, if present, increases the likelihood that the radiographic fibrosis is asbestosis; however, the absence of pleural change is not uncommon, and by no means excludes the diagnosis. It is useful for the clinician to consider the differential diagnosis of lower lobe (basilar) radiographic parenchymal fibrotic patterns, with associated volume loss or concomitant pleural thickening, listed in Table 19.8.3.

Asbestosis is classically described as a restrictive lung process, with impaired gas exchange manifest by diminished diffusing capacity. As discussed above (see Pulmonary Function), obstructive airway impairment also occurs, correlating with prominent and diffuse small airways changes.⁹⁰ Mixed obstructive and restrictive impairment is common, with bronchiolar effects of diminished mid-expiratory flow rates (e.g., FEF₂₅₋₇₅). Obstructive changes have been well documented in cohort studies after controlling for smoking, as well as in studies of non-smoking asbestos-exposed workers demonstrating airway dysfunction. The contribution of cigarette smoking, whether additive or synergistic, and the relative importance of parenchymal fibrosis versus dust load and concurrent occupational irritant exposures (e.g., welding fumes) are important factors contributing to risk for airflow obstruction.

The natural history of asbestosis is variable, and not always explained by exposure parameters, such as intensity, duration, and effect of exposure cessation. There is good

evidence that a significant proportion of those with asbestosis will worsen clinically with time, even after exposure ceases; most, however, do not! Asbestosis is characterized by an accelerated loss of pulmonary function, that is likely mediated by an alveolitis, with asbestos-activated macrophages inducing inflammatory and subsequent fibrotic responses. Respiratory symptoms, particularly development or progression of dyspnea, correlate strongly with this accelerated ventilatory loss.

Asbestosis is associated with increased risk for lung cancer, mesothelioma, and other cancers. In a large prospective cohort study utilizing the Finnish Registry of Occupational Diseases, men with asbestosis ($n = 1376$) experienced a greater than sixfold increased risk for lung cancer (SIR 6.7; 95% CI 5.6–7.9), a 32-fold increased risk for mesothelioma (SIR 32; 95% CI 14–60), and a fourfold increased risk for laryngeal cancer (SIR 4.2; 95% CI 1.4–9.8).⁹¹ Notably, among a subgroup of this cohort with identified progression of asbestosis radiographically, substantially increased lung cancer risk was observed (SIR 37; 95% CI 18–66).⁹²

DIAGNOSIS AND TREATMENT

Many non-malignant asbestos-related pulmonary changes do not occur in isolation. The following discussion provides a general overview and summary of the approach to individual patients with asbestos exposure, at risk for a number of adverse outcomes. Criteria for the diagnosis of non-malignant asbestos-related diseases have been published,⁹³ and are currently being updated by the American Thoracic Society.

Diagnosis

The diagnosis of asbestosis, as with pleural thickening, rests on a history of sufficient exposure of appropriate latency and clinical, radiographic, and pulmonary function findings. The exposure history is a necessary but insufficient criterion. Suspicion for asbestos-related lung disease should be raised when moderate or greater exposure of more than six months duration, with latency of greater than 20 years from onset of exposure, has occurred. Rarely, high level exposures may be associated with shorter exposure durations and latencies.

Clinical, radiographic, and pulmonary function features are variably present. The patient with the classic presentation has basilar rales on physical examination, ILO profusion abnormalities of 1/0 or greater on chest radiograph (the minimal grade diagnostic of interstitial fibrosis), and restrictive or mixed restrictive-obstructive impairment on pulmonary function testing. A patient with asbestosis, however, may have the examination and pulmonary function findings just described, with an x-ray study not demonstrating significant parenchymal markings (e.g., ILO score 0/1). This is not surprising, given the non-concordance between histologically documented fibrosis and radiographic findings of parenchymal changes; such patients should be further evaluated with HRCT.

Asbestosis*‡
Idiopathic pulmonary fibrosis‡
Collagen vascular diseases‡
 Progressive systemic sclerosis
 Polymyositis
 Rheumatoid arthritis*
 Systemic lupus erythematosus*‡
Acute hypersensitivity pneumonitis**
Eosinophilic pneumonia
Lymphangitic carcinomatosis*

* Concomitant pleural involvement possible

† Variable mid-zone involvement with pneumonitis

‡ Diminished lung volumes often present

** Low lung volumes possible if persistent (chronic hypersensitivity reaction)

Table 19.8.3 Differential diagnosis of lower lobe (basilar) radiographic parenchymal fibrotic pattern

Although HRCT examination is more sensitive and specific than chest radiographs in detecting asbestos-related parenchymal disease, it is not required for diagnosis in most cases. Appropriate indications for HRCT in the diagnosis of non-malignant asbestos-related disease include equivocal chest radiographic findings, presence of significant respiratory symptoms and/or pulmonary function changes with an unremarkable chest radiograph, and the presence of extensive pleural abnormalities obscuring parenchymal markings.

The importance of diagnosing benign exudative pleuritis and rounded atelectasis rests largely on the need to exclude other diagnoses, particularly asbestos-related malignancies. The finding of isolated pleural thickening in an asbestos-exposed individual usually can be attributed to asbestos exposure when other causes are excluded, which is almost always possible by assessing clinical and radiographic findings.

Finally, invasive tissue sampling is virtually never required for the diagnosis of asbestosis or asbestos-related pleural disease. Pathologic assessment for parenchymal fibrosis, asbestos bodies, and fiber content may be useful, however, should tissue specimens become available from other therapeutic procedures (e.g., lung tissue obtained during thorascopic or open procedures for diagnosis and/or treatment of malignancy).

Treatment and management

As with a number of chronic interstitial lung diseases, asbestosis has an unfavorable clinical response to corticosteroids and other immunosuppressive agents (e.g., cyclophosphamide and azathioprine). While it is possible that a subset of individuals with progressive alveolitis might benefit, no randomized clinical trials have established the efficacy of such therapy. The use of steroids is not routinely recommended, but may be considered on a case-by-case basis, with close monitoring of objective parameters (e.g., DLCO) to guide continuation of therapy.

Therapy for patients with asbestosis is supportive. Those with active respiratory symptoms and evidence of airflow obstruction may benefit from bronchodilators alone, or in combination with ipratropium or inhaled steroid therapy. In severe cases, oxygen saturation should be monitored periodically to assess need for supplemental oxygen. Bacterial infections should be promptly treated. Unlike silicosis, there is no evidence that asbestosis is associated with increased rates of tuberculosis or other atypical infections. Influenza and pneumococcal vaccines should be provided routinely.

Clinical management should focus on prevention, with smoking cessation being the primary emphasis, given the profound synergism between asbestos and smoking and lung cancer risk. Interestingly, evidence exists for a protective role of β -carotene on loss of ventilatory function in asbestos-exposed workers, with a 90 ml improvement in ventilatory capacity (FEV_1) associated with a 155 ng/ml increase in serum β -carotene concentration.⁹⁴ While this can be achieved with 15 mg/day β -carotene vitamin supplementation, routine supplementation cannot be

recommended, due to the fact that participants in the trial taking 20–30 mg/day β -carotene experienced increased lung cancer and cardiovascular mortality. Given these findings, an adequate dietary intake of fruits and vegetables rich in β -carotene is prudent.

There is no evidence that removal of an affected individual from further exposure will alter the natural history of asbestos-related pleural or parenchymal fibrosis. Nonetheless, given the dearth of effective secondary interventions, it is prudent to eliminate or otherwise minimize all future asbestos exposures. Because of the economic ramifications, these decisions should be assessed on a case-by-case basis. Factors to be considered in whether or not even minimal exposure should continue include the extent of disease, and the intensity of exposure likely in the job. In developed countries, few jobs with exposures of fibrogenic potential still exist.

Although there is no clear evidence of the benefit of ongoing medical surveillance once a diagnosis of pleural or parenchymal abnormalities is made, the increased risk of lung cancer in this population, coupled with the benefits of early detection (e.g., surgical therapy for early stage cancer), has provided a cogent rationale for periodic examinations. Much recent interest has focused on the use of CT scan (e.g., spiral CT) to detect early asbestos-related cancers.⁹⁵ While the sensitivity of CT is excellent, high false-positive rates have limited the utility of CT lung cancer screening in asbestos-exposed workers. For example, a Finnish surveillance program reported 106 of 111 (95%) false positives among the nodular densities detected.⁹⁶ The benefits of early detection must therefore be weighed against the risks and costs of evaluating false positives (including invasive procedures). Routine CT screening is not recommended until prospective studies assessing impact on mortality are available.

Recommendations for periodic surveillance examinations for exposed workers without evidence of asbestos-related disease have ranged from every 2 to 5 years, and should be based on a consideration of latency from initial exposure. A Canadian task force on occupational respiratory diseases has made the following recommendations, which continue to provide useful guidelines, and which are required for some workers under regulatory standards (e.g., OSHA Regulations 29 CFR) (see Chapter 59): (1) occupationally exposed asbestos workers with normal chest radiographs and spirometry should receive an x-ray examination and spirometry every other year and (2) those with ILO category 1 profusion changes or greater, or suspicious symptoms or physical findings (e.g., increasing dyspnea or rales), should receive annual chest radiographs and spirometry, with full pulmonary function tests on alternate years. Medical monitoring for those with isolated pleural thickening should probably be no less than that recommended for those with normal radiographs, namely, biannual spirometry and x-ray studies, with more frequent testing in the presence of increasing symptoms or extensive pleural involvement.

Finally, the identification of these asbestos outcomes has the potential for affording affected individuals the

benefit of compensation. Specific compensation systems vary within the United States and internationally,⁹⁷ depending on state or federal jurisdictions (see Chapter 57 Legal and Regulatory Issues in the Workplace). In general, workers' compensation covers the costs of medical care, including medical monitoring and treatment of complications, vocational rehabilitation, if needed, and the costs associated with attendant impairment and disability.
