- *Re-assignment of work tasks/Restriction of work activities*: injury requires change in normal work duties. May or may not accompany reduction of income.

Care received

- *Hospitalization*: most severe injuries receiving medical treatment. Duration of hospitalization, procedures, and cost may correlate with severity. Usually only available through worker compensation insurance records.
- *Emergency room*: urgent care needed.
- *Physician office*: professional medical care needed. May or may not be urgent.
- *First aid*: these injuries are not generally reportable unless they result in a restriction or re-assignment of work activities.

Table 31.2 Potential indicators of severity for work-related injuries based on administrative data. Adapted from Haddon W. *Advances in the epidemiology of injuries as a basis for public policy*. Public Health Reports 1980; 95:411–421, by permission of Oxford University Press

permanent or temporary disability and medical care, but the relative severity of most of these injuries is not distinguishable using the existing scoring systems. Moreover, most of the available data for studying occupational injuries reside in administrative or surveillance databases, which may not contain the information necessary to calculate these injury severity scores. Alternative methods of evaluating injury severity for occupational injuries are based on the outcome of the injury and the immediate care received (Table 31.2). The most severe injuries are fatal, followed by those injuries resulting in either total or partial permanent disability. The level of medical treatment required, ranging from first aid to hospitalization, and other administrative variables, including time lost from work and re-assignment of usual tasks, can be used to classify injuries by severity. These methods, however, are not well validated and may be a function of occupation as well as the nature of the injury. An injured foot may not interfere with the work of a typist, but would prevent a construction worker from numerous activities.

SOURCES OF DATA FOR WORK-RELATED INJURIES

Data sources that characterize the injury problem and prioritize prevention measures are a fundamental element of injury prevention programs. Characterizing an injury problem and evaluating prevention efforts require effective means for injury surveillance. Data resources available for general injury surveillance and research include vital records, hospital discharge data, surveillance of emergency rooms, and trauma registries.^{15,16} The extent to which

these traditional sources of injury data can capture work-related injuries is quite variable. Several sources of data on occupational injuries in the United States are available; however, each source uses different methods of collecting information. The usefulness of these data requires an understanding of how the data are collected and their attendant limitations. The sources presented below represent the types of data routinely collected in the United States, but are by no means the only sources of data on occupational injuries.

Fatal work-related injuries

In 2002 an estimated four fatal work-related injuries occurred in the United States for every 100,000 persons employed. Historically, the number of work-related fatalities has been difficult to determine. In the United States, the Bureau of Labor Statistics and the National Institutes of Occupational Safety and Health (NIOSH) previously had systems that used different methods. The BLS primarily used employer reporting, while the NIOSH National Traumatic Occupational Fatality (NTOF) database relied solely on death certificate information collected by the National Center for Health Statistics. Other sources of information on fatal injuries, including OSHA reports, medical examiners, and workers' compensation claims, collected detailed information about fatal injury events, but did not capture most injuries. The available surveillance data were also used by other organizations, specifically the National Safety Council (NSC), to derive estimates of work-related fatalities.

The different approaches to fatality surveillance yielded markedly variable results and the lack of consistency represented a significant limitation. A review by Stout and Bell of the various reporting methods concluded that death certificates had the highest capture rate but only identified, on average, 81% of occupational fatalities, followed by medical examiner records (61%), workers' compensation claim data (57%), and lastly, OSHA records that identified only 32% of occupational fatalities.¹⁷ A problem common to all systems was identifying the work-relatedness of a fatal injury. For example, identifying work-related fatalities from death certificates relies on the recorder to check the designated 'injury at work' box, a fact that is not always apparent to healthcare professionals treating the injury, or coroners and medical examiners. Incidents that happen on an employer's premises while the individual is conducting their job-related tasks are fairly readily identified. However, when the person is self-employed or the location of the incident is not at the work site (e.g., a fatal motor vehicle crash for a person in sales), the ability of most single systems to capture such incidents is limited. Consequently, a segment of the work-related fatalities is under-reported and it is unlikely these are distributed evenly by industry, occupation or cause.

Recognizing the limitations of existing systems, the BLS created the Census of Fatal Occupational Injuries (CFOI) in 1992.² This system uses multiple sources of information to identify cases of fatal work-related injuries, including death certificates, workers' compensation claims, newspapers,

and investigations by OSHA or other state agencies. Each state is contracted to collect available data within the state and provide the BLS with the information. As with any surveillance system, the CFOI will not capture all fatal work-related injuries; however, the use of multiple data sources improves the probability of capture and will likely provide more information on the characteristics of the injured worker and cause of the injury.

Surveillance systems like CFOI are designed to enumerate cases, but are limited in their ability to identify contributing causes to the fatality. These depend on investigations of fatal injury incidents conducted by federal and state regulatory agencies. While these incident investigations are conducted too infrequently to qualify as classic surveillance systems, they provide a wealth of qualitative information on specific injury events and are examples of sentinel surveillance tools that can identify immediate problems. OSHA has developed the Integrated Management Information System (IMIS) based on OSHA inspection records. OSHA is responsible for workplace safety and health inspections in the 29 states and territories that do not have a state occupational health and safety plan. The other 23 states and two territories with state plans submit inspection reports to OSHA for the IMIS.

Other than routine inspections, a large number of OSHA inspections are performed in response to fatalities, which are required to be reported to OSHA within 48 hours of occurrence. OSHA does not investigate all fatalities but focuses on those that appear to be related to workplace safety. Inspections also are conducted in response to worker complaints and as a follow-up of citations from routine inspections. NIOSH has implemented the state-based Fatality Assessment and Control Evaluation Program¹⁸ that conducts detailed investigations of specific types of fatal work-related injury incidents. Collection of these specific data can alert employers and workers to particular problems. NIOSH publishes a series of requests for assistance in preventing work-related injury and illness that is directed at identified problem areas,¹⁹ for example trench cave-ins, falls through skylights, and work-related homicides.

Sources of injury morbidity data

In contrast to fatal injury events that represent the most severe work-related injuries, non-fatal work-related injuries may range from a minor injury that results only in a brief alteration of usual duties to one that results in permanent disability. Though less severe, non-fatal injuries occur over 1000 times more frequently than fatal injuries. The actual number of non-fatal work-related injuries is difficult to determine. In addition to the problems of designating work-relatedness, the mechanisms for surveillance may vary from state to state, with different definitions and rules for reporting. However, several sources of data are available to characterize the extent of the problem. Some of these data sources are amenable to etiologic research, while others are primarily useful as surveillance tools.

In the United States, national data are primarily available from the Bureau of Labor Statistics (BLS). The BLS compiles

data on business and labor activities in the United States, including information on occupational injuries and illnesses occurring in the labor force. The primary source of data is the annual Survey of Occupational Injuries and Illnesses that is based on employer reports from approximately 180,000 private industry establishments. Additional information on mining and transportation activities is provided by the Department of Labor's Mine Safety and Health Administration (MSHA) and the Department of Transportation respectively. Selected establishments submit summarized data from the OSHA 200 forms to the BLS, indicating the number of occupational injuries and illnesses that occurred each year. Employers are required to report all injuries that are fatal and injuries that require medical care beyond first aid, result in loss of consciousness, lost work days or restriction of work, or transfer to another position. The average number of workers and total hours worked that year are collected, enabling rates to be calculated. Each establishment is classified by Standardized Industrial Code (SIC) according to its major enterprise. Annual survey data can be used to estimate the total number and rates of morbidity, mortality, and lost work-days due to occupational injury for each industry. Although this procedure identifies high-risk industries, the data lack information concerning the cause and type of the injury and specific high-risk groups identified by job classification or demographic characteristics.

At the state level, worker compensation claims data provide a reasonable estimate of the burden of non-fatal work-related injuries. The worker compensation insurance laws are state specific, with each state having a mechanism to characterize injury burden, therefore the data are not necessarily comparable between states. Most states require the reporting of fatal injuries and compensable injuries that result in time-loss, generally involving 3 days lost. In some states, such as Washington, the state is the sole-source provider of worker compensation insurance; thus all establishments that do not self-insure or are not covered by a federal program have claims processed by the state. In a majority of states the worker compensation insurance is issued by a third party insurer; thus collecting more than summary statistics is problematic. Nevertheless, worker compensation insurance claims can be a useful tool in monitoring non-fatal work-related injuries and identifying priority problem areas to target.

Other data sources

Several other sources of injury data that are not specific for occupational injuries are available and can be useful in identifying work-related injuries. The National Electronic Injury Surveillance System (NEISS), co-ordinated by the Consumer Product Safety Commission, surveys a sample of hospital emergency rooms throughout the country.²⁰ The NCHS collects fatality data, from which information on occupational fatalities can be extrapolated. The NCHS also collects injury morbidity data through the National Health Interview survey. The NSC does not collect original data on occupational injuries; however, it compiles data

from other sources listed above and provides estimates of the occurrence and cost of occupational injuries.

CHARACTERISTICS OF OCCUPATIONAL INJURIES

Understanding the general distribution of occupational injuries by type of industry, occupation, and characteristics of the worker is necessary for establishing any injury prevention and control activities. These characteristics comprise the first layer of factors influencing the injury event, using the Haddon approach to injury control, and are distinct with increasing severity of injury.

Occupational fatalities

While the completeness of fatality surveillance data can be debated, the CFOI data effectively summarize the major factors related to fatal work-related injuries. In 2002 there were 5524 identified fatalities in the United States. The industry-wide rate was four fatalities for every 100,000 employed persons; however, this varied markedly by industry, occupation, and other characteristics. The highest rates were seen in the agriculture, mining, construction, and transportation industries (Table 31.3). The rates for agriculture and mining were more than five times the industry-wide average. Similar patterns have been identified by occupation type where construction laborers, farm occupations, and truck drivers had the highest rates of fatalities.

The most frequent types of fatal injury incidents were transportation related, falls, and homicides. Fully 43% (2381) of the 2002 fatalities were transportation-related incidents, of which 1372 occurred on highways. Accordingly, truck driving was an occupation with one of the highest fatal injury rates (25/100,000). Fatal fall injuries were predominantly falls from one level to another level, and 77% of the homicides were related to

firearms. Men account for 92% of the occupational fatalities with an annual rate that is 10-fold that of women (6.9 vs 0.69 per 100,000 persons employed); however, homicides account for 31% of fatalities in women, but only 9% in men (Fig. 31.2). The rates of occupational fatalities are similar for younger age groups, but begin to dramatically increase after age 65 (Fig. 31.3). Whether this increase is due to a higher rate of more severe injuries in this age group or a greater case-fatality rate associated with the elderly is not clear. In most traumatic injuries the elderly do have a substantially higher case-fatality rate than younger individuals.

	<i>n</i>	%	Rate*
<i>Industrial division</i>			
Construction	1121	20.3	12.2
Transportation	910	16.5	11.3
Agriculture	789	14.3	22.7
Services	680	12.3	1.7
Manufacturing	563	10.2	3.1
Government	554	10.0	2.7
Retail trade	487	8.8	2.1
Wholesale trade	205	3.7	4
Mining	121	2.2	23.5
Finance	87	1.6	1
<i>Selected occupations</i>			
Truck drivers	808	14.6	25.0
Farm occupations	519	9.4	28.0
Sales occupations	347	6.3	2.1
Construction laborers	302	5.5	27.7
Other laborers	181	3.3	14.2
Groundskeepers	146	2.6	15.0
Police and detectives	140	2.5	11.6
Electricians	116	2.1	13.5
Carpenters	108	2.0	6.9
Pilots and navigators	90	1.6	69.8
<i>Total</i>	5524	100	4.0

*Fatalities per 100,000 persons employed.

Table 31.3. Number and rate of fatal occupational injuries in the United States in 2002 as reported by the Bureau of Labor Statistics Census of Fatal Occupational Injuries

Figure 31.2: Gender distribution of fatal occupational injuries in the United States, 2002. (From the Bureau of Labor Statistics Census of Fatal Occupational Injuries.)

Figure 31.3: Rate of fatal occupational injuries by age group in the United States, 2002. (From the Bureau of Labor Statistics Census of Fatal Occupational Injuries.)

Identifying the industries and occupations with the highest occupational fatality rates provides some direction for injury prevention programs; however, it is necessary to identify the specific mechanism of injury to prevent further fatalities. The mechanism of injury will vary within an industry and occupational group. Among motor vehicle operators, highway fatalities account for 69% of fatal occupational injuries in truck drivers, while homicides account for only 2% of the fatalities. By contrast, 59% of fatalities among taxicab drivers are due to violence, whereas 37% of the deaths are roadway related. A clear difference between taxicab drivers and truck drivers is the degree to which they interact with the public. Similar differences are observed in the construction trades where the rate of fatal injuries among construction laborers is four times higher than for carpenters (27.7 vs 6.9/100,000); however, carpenters are much more likely to die from falls. These differences reflect the types of hazards inherent in the specific job activities.

Non-fatal occupational injuries

Unlike fatalities, non-fatal injuries lack a clear definition; in addition to determining the actual work-relatedness of an injury, it is important to understand which injuries are reportable. The BLS definition of a traumatic injury is an instantaneous event resulting in medical treatment beyond first aid or loss of consciousness, lost workdays, restriction of work or being transferred to another job. According to the BLS Annual Survey, the construction industry has the highest reported rates of injury, followed by agriculture (including forestry and fishing), manufacturing, and mining.² This ranking is essentially the same for the rate of lost workdays, a surrogate measure of severity. Mining, however, which had the fifth highest rate of injury, had the greatest number of lost workdays. Comparing the rankings of fatal and non-fatal injuries along with lost workdays identifies the high-risk industrial groups. Mining, transportation, construction, agriculture, and manufacturing are high-risk industries compared with services, retail and wholesale trade, and finance and real estate, which have relatively low injury rates.

The hazards identified in surveillance of fatal and non-fatal injuries will vary, even when the non-fatal injuries are severe. A comparison of fatal injuries and severe non-fatal injuries in Washington State revealed different patterns. For instance, roofers are at high risk of fatal fall injuries, based on national data, but burns are a significant cause of non-fatal injury. Similarly, in orchard workers fatalities were primarily due to motor-vehicle incidents, but the majority of hospitalized injuries were due to falls.²¹

TRENDS IN INJURY RATES

Rates of occupational injuries have not been stable over time, and trends vary by industry and occupation. The incidence of disabling injuries in manufacturing industries in the United States declined from the 1920s until approximately 1958, after which it appeared to rise. The incidence of injuries in the construction industry decreased from the 1940s until the mid-1950s; from approximately 1975, there has been a marked upward trend. Similar trends have been seen for injuries in wholesale and retail trade.²² Conversely, the rate of fatal injuries in the mining industry dropped drastically over the last century as regulatory measures improved the safety records of mines.²³

A general downward trend has been observed for both fatal and non-fatal injuries in the last two decades; however, the rates vary by industry and mechanism of injury. Fatality data indicate that the rate of motor vehicle-related deaths dropped in the transportation industry, but there was little improvement in the public administration, construction, and agriculture sectors. Within these long-term trends, there is cyclic fluctuation that has been observed to be associated with changes in the strength of the economy. For example, a 10% increase in the rate of new hires is associated with a 10.4% increase in injury rates, providing evidence that new workers have higher injury rates than their more experienced counterparts. Increases in productivity, measured as output per hour, are also associated with increases in injury rates.²⁴ The extent to which this increase is due to laxity in enforcement of safety practices in order to meet increased demand is uncertain.

Changes in occupational injury rates can serve as a measure of the effectiveness of prevention programs as well as pointing to areas in need of more effective interventions. However, the value of such data depends heavily on their quality and validity, as described earlier.

OCCUPATIONAL INJURY TYPES AND SETTINGS

Occupational injuries are characterized largely by the type of occupation or the type of injury. In either case there will be considerable heterogeneity within subsets of the population under study. In this section the characteristics of intentional injuries and agriculture-related injuries will be presented to demonstrate the scope of issues associated with specific injuries and their respective control interventioning.

Assaults and homicides

The classic perceptions of work-related injuries and fatalities evoke images of catastrophic events related to machinery, falls or explosions. The role of intentional injury in the workplace has been somewhat overlooked as a significant cause of morbidity and mortality. Homicide ranks as one of the leading causes of fatal occupational injury in the United States, accounting for the deaths of an estimated 609 workers in 2002 or 11% of all work-related fatalities.¹ While the rate of work-related homicide is two to three times greater for men than women, homicides are the leading cause of work-related death in women, accounting for approximately one-third of occupational deaths. Homicide is the second leading cause of death for workers aged 25–44, behind highway-related deaths, yet the rate of work-related homicide increases in workers over age 55. The majority of the homicides are committed by firearms. Assault-related injuries and fatalities are, to a large degree, specific to occupation. Surveillance data from 2002 indicate that 50–80% of the work-related fatalities in the technical, sales, and administrative support jobs are homicides.

A variety of surveillance systems have identified occupations at higher risk of homicide and assault; a common theme is the close interaction between the worker and the general public, often in isolation, including taxicab drivers, gas station and convenience store clerks, liquor store clerks, police officers, and security guards.^{25,26} The occurrence of these fatal events is often associated with another crime, primarily robbery, and often in establishments with a prior history of such events.^{27,28} In 1982 Baker and colleagues called for uniform standards to protect workers from homicides in the workplace;²⁹ however, none have been enacted to date. Possible prevention strategies include making cash registers visible from the street; the use of a drop safe at night for bills larger than \$5; bullet-proof barriers between driver and passenger in taxis; enclosed cashier booths in gasoline stations; protective vests for law enforcement personnel. Other strategies include the provision of training programs in conflict resolution and non-violent response; these have been implemented in some retail settings.

Non-fatal work-related assault is also a significant morbidity concern. As with homicides, the non-fatal work-related injuries occur disproportionately in occupations that have routine contact with the general public. The risks are higher for healthcare workers, social service workers, public transportation workers, and safety and corrections personnel.^{27,30–33} Sexual assault in the workplace constitutes an important proportion of rape cases, but has received little attention in the occupational health and safety literature. The National Crime Victimization Survey has been used to characterize the victims of work-related physical assaults and robbery,³⁴ while occupational information is not collected by the FBI, nor reported in Uniform Crime Reports.

Violence and assault within the healthcare occupations have been evaluated for potential risk factors. Certain jobs that involve contact with high-risk patients, particularly

patients with mental health conditions, are at highest risk.^{35–37} Low staff-to-patient ratios may increase risk. The administrative recognition of risk as an inherent problem related to the job activities provides an opportunity to target intervention, including assault prevention training or presence of security guards. The success of interventions in workplace violence, however, has not been well documented, with several studies proving inconclusive.^{38,39}

Agricultural injuries

Agriculture is one of the most dangerous industries in the United States. The annual death rate is 22.7 deaths per 100,000 workers compared with 4.0 deaths per 100,000 for the general private sector workforce.¹ Over the course of a typical 40–50-year career, farmers accrue a substantial lifetime risk of occupationally related mortality. Data on agricultural injuries include injuries to individuals involved with agricultural production, agricultural services, forestry, and fishing. Specifically, for agricultural crop production, livestock production and agricultural services, the rates of fatal injuries in 2002 were approximately 37.0, 12.5, and 13.8 per 100,000 workers, respectively.¹ The mortality for farmers 65 years of age and older appears to be two to three times that of younger workers.

Although agricultural machinery including tractors accounts for around 20% of minor farm injuries, they are responsible for more than half of all severe injuries that result in permanent disability, and about 40% or more of the fatalities. In contrast, injuries from animals are very rarely fatal but account for a sizeable proportion of mild injuries. Tractor-related injuries are the most common type of fatal agricultural trauma, accounting for 30–50% of all fatal injuries on the farm. Approximately one-half to three-fourths of these fatal incidents involve tractor rollovers. In the NTOF database, 69% of agricultural machinery deaths involve tractors, of which 52% were rollovers.^{40,41}

One way to prevent these deaths is by using roll bars or crush-proof cabs, commonly referred to as rollover protection structures (ROPS), which were developed as early as 1959. In 1976, OSHA imposed standards requiring ROPS on all tractors used by employees, but this standard does not apply to the many tractor operators who are self-employed or farm family members. Furthermore, special legislation limited OSHA to inspect only farms employing more than 10 non-family members, effectively eliminating 89% of farms in the United States. A population-based study of tractor-related injuries in Minnesota indicated that only 42% of tractors were equipped with a ROPS,⁴² which is representative of use in the US generally.⁴³ In contrast, mandatory standards for ROPS have been markedly effective in nearly eliminating tractor fatalities in Sweden. Since 1959, all new tractors in Sweden have had to be equipped with ROPS and since 1983 all workers, including employers and family members, had to be protected with ROPS on tractors.⁴⁴ A comparison of the number of fatalities, normalized to the number of tractors, suggests a 24-fold greater risk of tractor rollover fatalities in the US compared to Sweden.⁴³

Other important sources of injury related to agricultural machinery include power take-off (PTO) devices and augers.⁴⁵ PTOs are rapidly rotating shafts on the tractor to power other machinery and account for 10–15% of fatal injuries and an even higher percentage of severe, disabling, but non-fatal traumatic injury. The injuries consist of fractures, severe soft tissue trauma, dislocations, nerve injuries and amputations. Although shielding is provided by the manufacturer, the shielding is often removed to make access to the PTO devices easier. Typically, a worker in proximity to an unshielded PTO shaft has an article of clothing pulled into the machine. As with ROPS, OSHA shielding regulations for PTOs apply only to inspected farms, thus most family farms and those with fewer than 11 employees are not covered.

As with ROPS, reliance on voluntary compliance by manufacturers and farmers appears to be ineffective. Grain augers are a source of serious and potentially devastating injuries. Invented by Archimedes to move water up a hill, modern augers and screw conveyors are widely used to transport wood, grain, meat, and other materials on the farm. The screw rotation of augers is 800 to 900 RPM with a pitch of 1:1. An auger with a 6-inch diameter moves material up the tube at 400 feet per minute or 7 feet per second. A finger that is caught in a tube will thus ascend a number of feet before the individual has time to react. The most common injuries are amputations, usually of fingers. Many of the injuries are at multiple levels because the spiral blades strike the limb several times as it is drawn up the tube. One half of those injured suffer significant permanent impairment.

The distribution of both fatal and non-fatal injuries is largely determined by the type of agriculture. In the Midwest, farm animals have been associated with up to 40% of the non-fatal farm-related injuries.⁴⁶ The risk of a farm animal-related injury is obviously related to the amount of contact an individual has with the animals, but is also influenced by the type of work done. For example, injuries among dairy cattle handlers will be affected by the amount of time doing specific tasks such as milking and hoof trimming.⁴⁷ Among California migrant workers, the tasks associated with injury included manual harvest, operating machinery, and cannery work.⁴⁸

CHILDREN

Children make up a significant portion of the agricultural workforce and hence are exposed at an early age and often tragically to its hazards. Children may work for their parents; many more work alongside their migrant families as seasonal laborers. Like adults, children suffer injuries when engaged in agricultural work and the injuries are often severe. Children employed in agriculture production in California had elevated risks for death by machinery (OR = 81), animals (OR = 10), electricity (OR = 5), and non-traffic motor vehicles (OR = 3).⁴⁹ Minors under the age of 15 employed on farms in Washington State were over-represented in the number of claims filed by all minors;⁵⁰ furthermore, 26% of claims filed by minors employed in

agriculture were for serious injuries, compared with 16% for all other occupations. The rates of injury are higher for older adolescents, with males age 15–17 having the highest rates of injury.⁵¹ While children employed in agriculture are clearly at substantial risk of injury, the extent of this problem has not been well characterized.

Estimates vary on the number of fatal injuries that occur among children and adolescents on farms each year, but range from 100 to approximately 300 children, with another 23,000 non-fatal injuries. Farm machinery accounts for one-third of deaths and nearly one-half of deaths of children under the age of 10 years. Firearms account for one in 10 deaths of children on farms, whereas farm animals are responsible for less than 2% of farm deaths among children, despite the relatively frequent exposure to this hazard.

There are very different attitudes and legislation for child farm labor compared with other employment of children in the workplace. Under the Fair Labor Standards Act, children as young as 12 and 13 years of age may be employed on any farm with the consent of their parents. These federal regulations are in marked contrast to those applying to non-agricultural occupations. For most other occupations, the basic minimum age is 16 years. Adolescents are especially prohibited from employment in manufacturing industries, which have a lower rate of fatalities than agriculture.

SUMMARY

In summary, occupational injuries are a complex problem requiring an array of preventive strategies. The first steps necessary for attacking the problem are (1) a change in orientation to one that views these injuries as events that are intrinsically preventable and (2) the use of a scientific approach to development of interventions. An important requirement for the success of this approach will be the development of adequate data systems in order to better understand the magnitude of the problem among specific populations, industries, and jobs at risk.

LUNG CANCER

Epidemiology

Lung cancer, a virtually unknown disease 100 years ago, now kills more American men and women than any other tumor. Although cigarette smoking represents the most important risk factor for lung cancer, occupational and environmental exposures, both singly and in conjunction with tobacco, are responsible for a substantial burden of preventable disease. This chapter addresses current estimates of the proportion of lung cancer attributable to occupation, provides a framework for the occupational medicine practitioner to make etiologic judgments, and discusses specific exposures associated with lung cancer.

Estimates during the 1960s and 1970s regarding the percentage of lung cancer attributable to occupation varied from 1% to greater than 60%. More recent studies suggest a narrower range of risk. Doll and Peto in the early 1980s proposed that 15% of male lung cancer cases and 5% of female lung cancer cases in the US resulted from occupational exposures.¹ The combined data from five American case-control studies spanning a wide range of industrial activities suggested that between 3% and 17% of lung cancers were due to well-recognized occupational carcinogens.² Another multicenter case-control study suggested that 9% of lung cancers were due to work in occupations with excess lung cancer risk.³ A recent review has suggested that occupational exposures are responsible for 9% of lung cancer among men and 2% among women.⁴ Much of the burden of lung cancer morbidity among working populations has been attributed to heavy exposures in the past.

There may be numerous complex interactions between the risk factors for lung cancer. Studies illustrating the combined effect of cigarette smoking with asbestos, arsenic, and radon exposure provide illustrative examples. When interactions exist between occupational or environmental exposure and any other risk factor, such as cigarette smoking, the percentage of lung cancer associated with the exposure reveals only what percentage of lung cancer could be eliminated through elimination of the exposure. The percentage itself does not reveal whether another exposure or several other exposures must be present to induce disease, only what percentage of disease would be eliminated if the exposure did not exist.

Assigning the proportion of lung cancer attributable to specific occupational or environmental exposures has been challenging due to the difficulty of both estimating accurate exposure levels in the workplace and extending the results

of studies in highly exposed groups to the population at large. Estimates of risk may vary considerably due to wide ranges of exposure among different occupational groups to agents of importance, such as asbestos. Further, reconstructing an accurate exposure history for cohorts of workers over several decades is difficult. Once data exist for a highly exposed population, extension to the general population requires accurate exposure estimates for all occupations, as well as domestic and environmental exposure settings. An alternative method extends job category-based risk estimates for specific occupations to the total number of workers employed in such occupations based on census data. While such studies provide a simpler extrapolation method, they do not consider exposures outside the workplace, and job category-based risk estimates themselves may be subject to a number of biases. Better data regarding interacting risk factors, occupational carcinogen doses, and exposures of the population at large may lead in the future to more precise estimates of the percentage of lung cancer due to occupational or environmental exposures.

Clinical evaluation

In individuals exposed to one or more carcinogens, a determination of etiology may be difficult. Although a few occupational lung carcinogens predispose more persons to one histologic type or location than others, lung cancers caused by occupational exposures do not differ from cancer induced by other causes in a way that allows pathologic, anatomic, or clinical distinction. From a public health standpoint, recognition of the cause of an individual worker's lung cancer may serve to identify excess risk at the group level, an indication for action to reduce exposure. Although individual etiologic diagnosis does not have an impact on selection of therapy, the occupational and environmental medicine physician may be called on to decide whether or not an individual's cancer is work related, often for purposes of workers' compensation.

A legal solution to this issue, as seen in the case of specific exposures in certain countries and specific occupations in the US, has been to establish a legal presumption that the cancer was caused by workplace exposures if an agreed-upon degree of exposure in the specified settings can be proved. However, such approaches currently are limited, and include asbestos-associated cancers, and some radiation-associated lung cancers in certain settings. Most individual cases arise in industries or exposure groups not formally recognized to have presumptive exposure under the workers' compensation laws.

An alternative approach bases individualized etiologic diagnosis of occupational lung cancer on the *probability* that a given cancer is occupational. This does not imply medical certainty but only that the exposure most likely caused or contributed to the development of the cancer. In the case of lung cancer due to uranium mining, various formulas have been developed to rate factors influencing the assessment of probability, including dose (average amount of exposure multiplied by years of exposure), amount of cigarette smoking, age, latency (years since first exposure), and histologic type of lung cancer. Similar formulas have been attempted for asbestos-related cancer.

Typically, however, the clinician must use quantitative or semiquantitative reasoning without a simple or legally sanctioned formula. The first step is to determine whether or not the patient was exposed to a factor causally related to lung cancer or that he or she worked in an industry with known increased risk. A complete occupational and environmental history, including a thorough review of all potential workplace carcinogens, is a prerequisite. Although workers may have histories of lifelong employment in well-established risky industries such as shipbuilding, insulating, or smelting, more often than not, a complicated history of numerous potential work exposures must be pieced together carefully.

Assessment of dose is the next step. Most epidemiologic studies of occupational lung cancer have used surrogates for dose, such as job description, or attempted rough reconstructions based on worker interviews. Quantitative information is rarely available, and dosages are often listed as only low, medium, or high. In assessing an individual's exposure, one may access certain information by interview and review of industrial hygiene data, but historical estimates of exposure for the industry or occupation in question must often suffice. Often, dose cannot be determined because the suspect exposure is not fully characterized. Work in the vicinity of coke ovens provides an example in which the specific carcinogen is unknown but the association between occupation and lung cancer is strong. Dose in such cases must be estimated by the individual's proximity to the coke oven and length of employment.

Latency must also be taken into consideration because many cancers do not appear until 30 to 40 years after exposure has occurred. Latency is dependent on whether a substance acts early in the carcinogenic process or at a later stage. A simplified initiator and promoter model of carcinogenesis may apply to cigarette smoking and asbestos exposure, but not to some other etiologies, including radiation. Asbestos probably acts as a tumor promoter, albeit with a long latency. Arsenic may be an example of a lung carcinogen that acts late in the transformation process.

Finally, a thorough smoking history – including passive smoke exposure – must be gathered from any patient with lung cancer. The individual's smoking history deserves special attention in cases in which the relative risk associated with the occupational or environmental exposure of interest is small. Domestic radon exposure should also be considered, though most individuals with radon-induced lung cancer will have been exposed to relatively average dose levels.

Substance	Major exposure settings
Asbestos	Insulation workers, shipyard workers
Arsenic	Smelting of copper, zinc, lead; arsenical pesticide processing
Chloromethyl ethers	Chemical production workers
Chromium	Chromate production, pigment manufacture, electroplating
Crystalline silica	Mining, sandblasting, stonework, foundry work
Mustard gas	Mustard gas production workers
Nickel	Nickel mining, refining, plating
Polyaromatic hydrocarbons	Coke oven workers, rubber workers, aluminum reduction workers, roofers
Radon	Uranium mining, hard rock mining, widespread domestic exposure
Environmental tobacco smoke	Environments with active smokers

Table 30.1.1 Known lung carcinogens

Substance	Exposure settings
Beryllium	Beryllium production/processing
Cadmium	Smelting, battery production
Man-made vitreous fibers (MMVF)	Insulating, rock slag, wool production
Ambient air pollution	Indoor and outdoor environments

Table 30.1.2 Probable lung carcinogens

In the end, rational judgment as to the work-relatedness of a case of lung cancer demands careful consideration of a patient's exposure history and a working knowledge of the epidemiology of occupational or environmental carcinogens. The following section addresses known and probable agents, summarized in Tables 30.1.1 and 30.1.2, respectively.

KNOWN LUNG CARCINOGENS

Asbestos (see Chapter 46)

The earliest recognition of asbestos as a possible lung carcinogen occurred in a case report by Kenneth Lynch and Atmar Smith in 1935.⁵ Subsequent work by Merewether in 1949⁶ and Gloyne in 1951⁷ revealed an increased frequency of lung cancer at necropsy in patients with asbestosis when compared with patients with silicosis. A proven or highly probable causal relationship between asbestos and lung cancer was agreed upon in 1953 at the International Symposium on the Epidemiology of Lung Cancer (Council of the International Organizations of Medical Sciences). In 1955, a careful study by Sir Richard Doll based on necropsy data from 105 asbestos textile workers revealed a 10-fold increased rate of lung cancer in workers employed over 20 years in the trade, firmly establishing asbestos as a major lung carcinogen.⁸ Further support was lent by Selikoff's study of 632 insulation workers in 1964, which revealed a sevenfold increase in the rate of lung and pleural tumors over that of the general population.⁹ Numerous studies have since confirmed the carcinogenic potential of asbestos.^{10–14}

As epidemiologic and basic scientific research of asbestos exposure has progressed, a number of secondary

issues have arisen.¹⁵ The interaction between cigarette smoking and asbestos exposure in producing lung cancer remains to be precisely quantified. The question of whether lung cancer arises from asbestos exposure itself or merely from lung fibrosis induced by asbestos is also a topic of some debate. Markedly different dose-response relationships in different trades and industries are still unexplained, and controversy exists regarding the carcinogenic potential of various asbestos fiber types. Finally, the concept of a threshold effect and its implications for the risk of very low-level asbestos exposure remain unresolved.

Although various models have been proposed for the interaction of cigarette smoking and asbestos exposure, the bulk of epidemiologic evidence implicates asbestos as a carcinogen by itself, whose effect is augmented by cigarette smoking. A synergistic relationship between the two carcinogens is commonly accepted, and a recent review of 23 studies addressing smoking and asbestos exposure lends support to a multiplicative interaction.¹⁶ Asbestos exposure appears to multiply lung cancer risk by a similar factor in smokers and non-smokers. Because smoking impedes clearance of inhaled fibers, smokers may suffer increased penetration of fibers into airway walls.^{17,18} Carcinogenic polycyclic aromatic hydrocarbons (PAHs) in cigarette smoke may also adsorb onto asbestos fibers, enhancing their transport into cells.¹⁹

The question of whether asbestos itself or asbestosis is the true risk factor for lung cancer has implications for present surveillance practices as well as compensation issues. If the development of asbestosis is not a necessary intervening step in carcinogenesis, the current practice of close radiologic monitoring of asbestotics also may be appropriate for significantly exposed persons without asbestosis. Clearly, most lung cancers arising in persons with significant asbestos exposure occur in the setting of radiologically documentable asbestosis, and cohort studies of asbestotics have revealed some of the highest rates of lung cancer mortality.²⁰⁻²² Correlations between asbestosis and lung cancer also have been shown to be stronger than those between cumulative asbestos exposure and lung cancer.²³ The finding in some studies that asbestos-related cancers frequent the lower lobes where fibrosis is maximal, as well as the occurrence in some series of a disproportionate number of adenocarcinomas, a cancer that may arise in areas of scar formation, is cited as evidence that fibrosis is a prerequisite for asbestos-related lung cancer. On the other hand, lung cancers do appear in heavily exposed individuals without clinical, radiologic, or pathologic evidence of asbestosis;²⁴⁻²⁶ many studies reveal no predominance of adenocarcinoma among asbestos-related lung cancer cases; some studies reveal no lower lobe predominance of asbestos-related tumors;^{27,28} and in-vitro experimental models have demonstrated a tumor-promoting effect of asbestos.¹⁵ Because a clear understanding of the pathophysiologic mechanisms underlying both asbestosis and cancer remains elusive at present, resolution of these issues likely will come only with continued study of host-related and exogenous mechanisms of disease, as well as epidemiologic investigation of heavily exposed subgroups without evidence of asbestosis.

Cohort mortality studies conducted to date have revealed that the dose response for asbestos and lung cancer may be 50-fold higher in occupations involving insulation products and chrysotile textiles than it is in the lower-risk occupations of chrysotile mining and friction products work. Although in some cases the discrepancy has been attributed to inadequate historical dose estimates, many claim that examining the fiber types and sizes most commonly used in these industries may yield a more complete explanation of the phenomenon. Asbestos minerals are divided into two classes: (1) the amphiboles, including amosite, crocidolite, anthophyllite, actinolite, and tremolite; and (2) the serpentine class, of which the only member is chrysotile. Ninety percent of all asbestos used in the US is chrysotile. Although some of the lowest rates of lung cancer have been reported in miners, cement manufacturers, and friction products workers, whose sole exposures are to chrysotile, some of the highest rates have been found in the asbestos textile industry, where chrysotile is used exclusively. And although autopsy studies have revealed low levels of chrysotile asbestos in heavily exposed persons, suggesting greater clearance of chrysotile from the lung relative to other fibers and possibly reduced overall toxicity, animal studies of asbestos-related lung cancer reveal chrysotile to be a potent carcinogen.²⁹

One explanation for the paradoxically high rates of lung cancer in chrysotile asbestos textile workers is that low-level contamination of the textile with other forms of asbestos such as tremolite is responsible. Although tremolite fibers are seen at autopsy in the lungs of chrysotile workers, this explanation would imply an inordinately high toxicity of tremolite given the relatively low exposure doses. Studies of populations exposed solely to chrysotile also reveal elevated lung cancer risk.³⁰ Another proposed resolution to the controversy derives from fiber length measurements. It may be that carcinogenicity is more directly a function of exposure to very long asbestos fibers (exceeding 10 to 20 μm) than merely to all fibers greater than 5 μm .³¹ Because chrysotile textile contains higher proportions of very long fibers than does the chrysotile to which miners and other lower-risk groups are exposed, lung cancer rates may be elevated on that basis alone. As more detailed environmental exposure data, including mineralogic analysis and fiber length distributions, are combined with careful reconstructions of historical exposure settings, much of the present paradox may clarify itself.¹⁵

A final issue that has arisen out of asbestos research is the degree to which very low-level exposures pose risk to the general population. The manner in which this issue is resolved carries important implications for the allocation of public health and economic resources for asbestos abatement in public buildings. In favor of a threshold level, below which cancer risk is not elevated above that of the general population, stand the majority of cohort mortality studies, animal studies of low-dose laboratory exposures, negative autopsy-derived asbestos fiber counts in lung cancers drawn from the general population, and the lack of elevated cancer rates among a well-studied population of non-miner residents of Quebec asbestos mining regions with higher than normal background asbestos exposure.^{32,33}

Arguments against the existence of a safe level of asbestos exposure include the linearity of dose response to asbestos at higher levels in both cohort mortality studies and animal inhalation studies, as well as the results of two cohort mortality studies in which exposure to low levels for brief periods has been associated with increased lung cancer risk.¹⁵ Some have suggested that the assumption of linear dose response with no threshold is conservative and appropriate for public and individual health practice. Nonetheless, given the quality of present data, decisions to allocate resources to asbestos abatement in public buildings with negligible potential for exposure should be made with serious consideration of the relative reduction in risk compared with that obtainable through alleviation of other, possibly more pressing, public health hazards. Removal of asbestos already in place also raises the possibility of increased rather than decreased total exposure under conditions of substandard abatement practices.

Arsenic (see Chapter 39.2)

The first cases of arsenic-induced lung cancer were reported by Saupe in 1930.³⁴ Subsequent studies have revealed lung cancer risk elevations associated with arsenic exposure in the settings of copper smelting,^{35–38} tin mining,³⁹ and the manufacture of arsenical pesticides.⁴⁰ A recent study reported elevation of lung cancer risk among lead smelter workers also exposed to arsenic.⁴¹

Arsenic is considered a late-stage promoter of cancer and may act by interfering with DNA repair and by modulating cell growth signaling pathways.⁴² Arsenic-induced lung cancer was found to have a predilection for the upper lobes in one study. Another study of copper smelter workers suggested a higher percentage of adenocarcinomas when compared with controls. A clear dose–response relationship has emerged from studies of arsenic-exposed workers, and the risk of lung cancer may be increased by as much as ninefold in heavily exposed workers. There appears to be synergism between arsenic exposure and smoking in the induction of lung cancer.⁴³

Chloromethyl ethers

Bis-chloromethyl ether (BCME) and chloromethyl methyl ether (CMME) were first suspected as lung carcinogens in 1962, when cases of small-cell carcinoma of the lung were noted in a chemical manufacturing plant in Philadelphia. Subsequent institution of a screening program documented additional cases, and in 1973, a report associating lung cancer with CMME was published by Figueroa and colleagues.⁴⁴

The chloromethyl ethers are associated primarily with the ion exchange resin industry. They also may form when chloride reacts with formaldehyde under appropriate conditions in textile manufacturing plants. BCME is the more potent of the two carcinogens, and both are highly reactive as alkylating agents *in vivo*. They are associated primarily with the induction of small-cell lung carcinoma.

Numerous studies have documented the association of chloromethyl ethers with lung cancer, including an industry-

wide cohort study sponsored by the National Institute for Occupational Safety and Health (NIOSH).⁴⁵ The relative risk of lung cancer may be quite elevated, and long-term exposure does not appear to be an absolute prerequisite for disease. Standardized mortality ratios (SMR) from 2.8 to 5.0 have been reported in exposed populations, with relative risks as high as 7.0 to 18.0 within the highest exposure categories.⁴⁶ Risk appears to peak at less than 20 years following exposure, and several authors have documented a decline in risk following cessation of exposure.

Chromium (see Chapter 39.5)

In 1935, two cases of lung cancer that had occurred more than 20 years previously were reported in a German chromium manufacturing facility. A subsequent report by Machle in 1948 detailed respiratory cancers occurring in the chromate-producing industry in the US.⁴⁷ Chromium has since proved to be a human carcinogen, with increased incidences of lung cancer in the chrome plating, chrome alloy, chromate pigment, chromate production, and ferrochromium industries. Highest risks of lung cancer are in the chromate production industry, and may persist at 20 years following cessation of exposure.⁴⁸ Risks in the pigment industry are lower and generally associated only with zinc chromate exposure. Although chromium exposure in electroplating facilities is a risk factor for lung cancer,^{49,50} exposures to other lung carcinogens such as nickel may confound this relationship. Risk is not as well established in the ferrochromium industry, in which study results are conflicting, and concomitant exposures to PAHs and asbestos may play a more important role. Similarly, elevated rates of lung cancer among chromium-exposed welders in some studies may be confounded by nickel and asbestos exposures.^{51–54} Conflicting results exist regarding the role of chromium as a carcinogen in the leather tanning industry. Several studies suggest that industries with improved controls over chromium exposures are not associated with elevated lung cancer risks, though statistical power to detect marginal risk elevations has been limited by cohort sizes.^{55–59}

Chromium exposure appears to be a risk factor for all lung cancer cell types, and hexavalent chromium is listed by the International Agency for Research on Cancer (IARC) as a known human carcinogen.⁶⁰ The evidence implicating trivalent chromium as a human carcinogen is less compelling. While some studies suggest elevated risk among trivalent chromium-exposed workers,⁶¹ concomitant exposures to hexavalent chromium have made dose reconstructions challenging. A recent study combined historical air sampling data with analysis of settled dust samples to estimate trivalent and hexavalent exposures. Cumulative hexavalent exposure was associated with an increased lung cancer risk, while cumulative trivalent exposure was not.⁶²

Crystalline silica (see Chapter 46)

Crystalline silica exposures occur in mining, sandblasting, construction, and foundry work. In 1996, the IARC upgraded its classification of crystalline silica from a prob-

able human carcinogen (Group 2A) to a definite human carcinogen (Group 1).⁶³ The strongest evidence implicating crystalline silica as a human lung carcinogen derives from studies of individuals with silicosis. Steenland and Stayner have reported a lung cancer summary relative risk from 19 cohort and case-control studies of silicotics as 2.3 (95% confidence interval [CI], 2.2–2.6).⁶⁴ Both smoking and non-smoking silicotics have been shown to have elevated lung cancer risks. The same authors reported a lung cancer summary relative risk based on 16 large studies of silica-exposed workers as 1.3 (95% CI, 1.2–1.4).⁶⁴

More recent studies have largely corroborated the combined relative risks reported by Steenland and Stayner. A recent mortality study of silicotic patients in Sardinia revealed a SMR for lung cancer of 1.37 (95% CI, 0.98–1.91), though the correlation with severity of silicosis based on the chest radiograph was weak.⁶⁵ A study of 4626 industrial sand workers found a lung cancer SMR of 1.60 (95% CI, 1.31–1.93) and revealed a significant dose response based on average exposure.⁶⁶ An important recent study pooled 10 cohorts comprising 65,980 workers and 1072 lung cancer deaths and produced quantitative exposure estimates comparable across the cohorts. The study revealed that the log of cumulative silica exposure, with a 15-year lag, was a strong predictor of lung cancer ($P = 0.0001$).⁶⁷

Mustard gas

The first association between mustard gas (bis [β-chloroethyl] sulfide) exposure during World War I and lung cancer was made by Case and Lea in 1955.⁶⁸ Subsequent studies of Japanese workers involved in the production of mustard gas during World War II revealed substantial lung cancer risk elevations.⁶⁹ British production workers during World War II exhibited much less pronounced elevations of risk.⁷⁰ Latency has been estimated at 20 years, and there appears to be a higher rate of squamous cell carcinomas among those exposed.

Nickel (see Chapter 39.6)

The first mention in the literature of respiratory cancers associated with nickel was a report of nasal cancer cases in a nickel refinery in 1933 by Bridge.⁷¹ Subsequent studies of workers in nickel mining, nickel refining, and nickel subsulfide roasting facilities have revealed high rates of lung cancer and nasal cancers. Nickel carbonyl, nickel subsulfide, nickel oxides, nickel acetate, nickel hydroxide, nickel fluoride, soluble nickel dusts, and nickel itself are animal carcinogens, but the specific forms of nickel carcinogenic to man remain the subject of ongoing investigation. Results of a collaborative investigation of nine cohorts of nickel workers and one case-control study attribute most respiratory cancers to oxidic and sulfidic nickel.⁷² Soluble forms of nickel appear to induce cancers at lower doses than do less soluble forms. Nickel-associated lung cancers have been noted more frequently in the large airways.

Exposure to metallic nickel has not been associated with increased lung cancer risk in humans.⁷³ Studies of workers exposed to nickel alloys and pure nickel dust have not revealed an elevated rate of lung cancer, and elevated rates of lung cancer among nickel-exposed welders may be attributable to chromium or asbestos exposures.^{52–54} Similarly, confounding by chromium may be responsible for elevations of lung cancer risk among nickel/chromium plating workers.⁴⁹

Polycyclic aromatic hydrocarbons (see Chapter 44)

The link between human cancer and the PAHs was first forged by Sir Percivall Pott when he reported the development of scrotal cancer among English chimney sweeps in 1775.⁷⁴ In the early part of the 20th century, many investigators suggested that increasing rates of lung cancer in the general population might be due to the use of tar and tar products. The first formal study of PAHs and lung cancer was carried out at a coal carbonization facility in Japan in 1936. Of the malignant neoplasms occurring in men at this facility, 80% (12 of 15 cases) were lung cancer – this at a time when lung cancer accounted for only 3% of all cancers in Japan.

PAHs occur as large mixes of substances formed through the incomplete combustion of coal tar, pitch, coke, and oil. Each compound is made up of at least three aromatic rings and contains only carbon and hydrogen. Occupational exposure to the PAHs of coal tar occurs in coal gasification facilities, gas and coke works, iron and steel foundries, aluminum reduction plants, tar distillation facilities, shale oil extraction operations, wood impregnation facilities, and in the roofing and transportation industries. Other sources of PAHs include carbon black (a pyrolysis product of petroleum or natural gas), petroleum distillates, soot, and diesel exhaust.

Increased risk of lung cancer has been found in coke oven workers,^{75,76} tar distillation workers,⁷⁷ roofers,⁷⁸ chimney sweeps,⁷⁹ truckers,^{80,81} and persons employed in coal gasification facilities⁸² and aluminum reduction plants.^{83–85} Coke oven workers have been well studied, and a dose response based on proximity to the coke oven is firmly established. Risk among tar distillation workers is less well documented, and not all studies have revealed correlations between exposure and disease. Elevations of lung cancer risk among roofers and asphalt workers are likely due to coal tar and bitumen fume exposure. A long-term cohort study among Swedish chimney sweeps reported a doubling of lung cancer risk, and several smaller studies have revealed similar findings. Excess lung cancer risk has been reported among truckers and attributed to diesel exhaust, which contains variable amounts of PAHs. Estimation of dose in many such studies has been challenging, and dose responses have not been consistent.^{86,87} Coal gasification has been long associated with increased risk of lung cancer. Among aluminum reduction workers, those exposed to Soederberg electrolysis typically experience both higher PAH exposure and greater risk of lung cancer than those

employed in plants using the prebake process. Although many studies of aluminum reduction workers have revealed no excesses of lung cancer nor clear dose–response relationships,^{88,89} a nested case–control study of workers from two Soederberg plants showed a dose–response relationship based on years of exposure as well as measured benzene soluble fraction and benzo[a]pyrene.⁸⁵ Exposure to PAHs appears to elevate the risk for all cell types of lung cancer.

Exposure to PAHs is also widespread in the environment, deriving from tobacco smoke, fire fumes, ambient air pollution, and cooked food. Several studies have demonstrated increased lung cancer mortality associated with urban air pollution, but it is uncertain to what degree such excesses can be attributed to PAH contamination. There is evidence implicating environmental PAH as a lung cancer risk factor from studies in China of women heavily exposed to cooking and/or heating fumes.^{90–92}

Radon (see Chapter 33.1)

In 1597, Georgius Agricola wrote of a characteristic wasting disease observed in central European miners.⁹³ Nearly 300 years later, Harting and Hesse identified ‘mountain illness’ as lung cancer and associated it with underground mining.⁹⁴ Ongoing studies in the early 20th century supported the link between radon and lung cancer at the mines of Schneeberg in Germany and Joachimsthal in Czechoslovakia. By the late 1950s, a study of uranium miners on the Colorado plateau demonstrated elevated rates of lung cancer in heavily exposed workers, and numerous subsequent studies have confirmed that risk in other mining populations. With the discovery of high radon levels in homes built on the Reading Prong geologic formation in Pennsylvania in the 1980s, considerable attention turned to the hazard of low-level radon exposure in the general population.

Radon 222 is an inert gas released in the radioactive decay of uranium 238. It has a half-life of 3.8 days and decays with alpha-particle emission through the short-lived radon daughters of polonium 218, lead 214, bismuth 214, and polonium 214 to lead 210. Polonium 218 and polonium 214 are themselves alpha-particle emitters. The radioactive particles may attach to aerosols or inhaled particles, gain access to cells lining the airways, and irradiate those cells at close range, causing chromosomal damage. Radon is an established carcinogen only in the respiratory tract.

Units of radiation most commonly used for occupational and domestic exposures are the working level (WL), the working level month (WLM), and the concentrations of picocuries per liter (pCi/L) or becquerels per cubic meter (Bq/m³). One WL is any combination of radon progeny in 1 liter of air that ultimately releases 130,000 MeV of alpha energy during decay. Exposure to 1 WL for 170 hours equals 1 WLM. A radon concentration in the domestic setting of 1 pCi/L (2.2 radioactive decays per minute per liter of air) is approximately equal to 0.005 WL. One pCi/L is approximately equal to 37.5 Bq/m³. A typical domestic indoor radon exposure of 0.8 pCi/L is roughly equivalent

to 0.2 WLM/year, which translates into an approximately 15 WLM exposure over a lifetime. The present occupational standard for exposure in mines is 4 WLM per year.

A high lung cancer mortality rate has been recognized among underground miners. Most studies have focused on uranium and iron miners, but elevated rates of lung cancer in miners of tin, zinc and lead, magnetite, fluorspar, metal ores, and niobium have been revealed as well. A pooled analysis of data from 11 mining cohorts determined that 40% of lung cancer among miners was due to radon.⁹⁵ The study, which comprised over 65,000 men and more than 2700 lung cancer deaths, found that the association between estimated radon exposure and risk of lung cancer remained linear throughout the dose range examined. Overall excess relative risk was 0.0049 per WLM. Risk tended to decline with increasing age and time since last exposure. Consistent with other studies,⁹⁶ it increased with duration of exposure, suggesting that for a given cumulative dose, longer duration exposures to lower radon levels are more harmful than short-term exposures to higher levels.

The interaction of smoking with radon exposure has been addressed in a number of studies. Analyses of non-smoking miners as well as a case–control study in Navajo men in whom smoking rates were very low have confirmed radon’s status as an independent carcinogen.^{97,98} The interaction of smoking and radon exposure contributes to the difficulty of assigning radon-related relative risks for the various tumor histologies. Early reports suggested relatively high rates of small-cell carcinoma, but more recent studies reveal a distribution of cell types that does not differ from that of the general population. In the combined analysis of 11 mining cohorts, it was estimated that radon accounted for 70% of lung cancer among non-smoking miners and 39% among miners who smoked. An extrapolation based on these data suggested that 30% of lung cancer deaths among non-smokers in the general population may be due to radon, while radon may account for as much as 11% of lung cancer deaths among smokers.⁹⁵

With the investigation of indoor air quality in the 1970s, it became apparent that radon was invariably present in homes and other indoor spaces. Little attention was directed at the problem, however, until the mid 1980s, when a home located on the Reading Prong in Pennsylvania was found to have extremely high radon levels. Subsequent investigation of other dwellings located on the same geologic formation revealed radon concentrations in excess of 110 pCi/L. The lifetime dose for an individual living in such a dwelling would exceed 1500 WLM and would lie well within the dose range of heavily exposed miners. Subsequent surveys have revealed other areas with unusually high radon levels, including a region in the Tyrolean Alps, where indoor radon levels exceeding 6000 pCi/L have been measured.⁹⁹

Surveys suggest that average domestic exposures in the US range from 0.8 to 1.5 pCi/L. Primary sources of domestic radon are rock, soil, building material, and drinking water. Domestic radon levels are determined by the ease with which air can pass from soil or rock into the dwelling and the adequacy of ventilation; older dwellings are some-

what more prone to elevated levels. Most domestic radon measurements are made under conditions intended to maximize instrument readings – namely, basement sampling with windows closed. Such levels may differ by as much as fivefold from the average radon exposure in lived-in areas over the course of a year. Estimates that one in three homes have unacceptably high radon levels (greater than 4 pCi/L) are based largely on basement sampling and may not accurately reflect actual domestic exposures.

Three principal study types have been used to evaluate the lung cancer risk of domestic radon exposure: ecologic surveys, case-control studies utilizing geologic and construction characteristics to estimate dose, and case-control studies utilizing measured radon levels. Ecologic surveys carried out in the US, Canada, Europe, and China have related estimates of prevailing radon exposure to lung cancer trends within specific geographic areas. Some such studies have shown higher rates of lung cancer in regions with greater average radon exposures, while others have not. Case-control studies, in which domestic radon levels have been estimated based on the geologic and construction characteristics of houses and neighborhoods, have been carried out in Sweden, the US, and Canada. Study results are mixed and suffer from small numbers of cases and controls. Surrogate exposure indices also do not consistently parallel measured levels of radon exposure. One study revealed that only 5% of the variance among domestic radon levels could be accounted for by geologic variables, and that geologic and housing-related variables combined accounted for only 15%–18% of the variance.¹⁰⁰

The most reliable data regarding an association between domestic radon exposure and lung cancer come from a series of case-control studies in which actual radon measurements have been made in dwellings inhabited by subjects. More than 20 such studies have been undertaken. A meta-analysis of eight studies, each of which examined at least 200 lung cancer cases, has revealed a statistically significant summary odds ratio of 1.14 (95% CI, 1.0–1.3) associated with exposures of 4 pCi/L.¹⁰¹ The meta-analysis, which included more than 4200 lung cancer cases and over 6600 controls, concluded that actual risk in the general population from radon exposure is not likely to be higher than mining study-derived estimates. Several studies published subsequent to the meta-analysis have produced corroborating results.^{102–104} Domestic radon studies of non-smokers have revealed similar risk elevations.^{105,106}

Based on the accumulated evidence, it is reasonable to estimate that 15,000 lung cancer deaths per year in the US population are attributable to radon exposure. Because most individuals are exposed to low levels of radon, it has been estimated that mitigation of all dwellings to below 4 pCi/L would result only in a 2%–4% drop in lung cancer mortality.⁹⁵ Due to the mobility of the US population, only a small percentage of radon-related lung cancers will occur in individuals currently living in dwellings with radon levels above 4 pCi/L. Still, radon levels in certain dwellings yield cumulative lifetime exposures comparable to those of miners. Although the use of radon mitigation systems in

such dwellings is clearly desirable, disagreement exists both as to how such high-risk dwellings should be identified, and whether or not radon mitigation should be instituted in dwellings with levels only marginally above the Environmental Protection Agency (EPA) action level of 4 pCi/L. Unfortunately, there is little that can be done to reduce background low-level lung cancer risk within the large segment of the population with low or average lifetime radon exposure.

Environmental tobacco smoke

Environmental tobacco smoke (ETS) contains over 5000 chemicals, of which 43 are listed as known human or animal carcinogens by the IARC.^{107,108} ETS consists of sidestream smoke from the burning tip of a cigarette, as well as mainstream smoke inhaled and exhaled by the smoker. Most vapor phase contaminants and more than half of the air-borne particulates derive from the sidestream component.¹⁰⁹

A meta-analysis carried out by the US EPA examined more than 30 studies, generating country-specific summary relative risks. Most studies enrolled female non-smokers, with exposure tagged to the spouse's smoking habits. The summary relative risk for the US based on eight studies was 1.22 (90% CI, 1.04–1.42). To date there have been more than 75 epidemiologic studies which have examined ETS and lung cancer, and 20 meta-analyses.¹¹⁰ One meta-analysis of 37 published studies involving more than 4600 cases of lung cancer reported a 26% (95% CI, 7%–47%) adjusted excess lung cancer risk among non-smokers who lived with a smoker.¹¹¹ Dose response based on both number of cigarettes smoked by the spouse and duration of exposure was statistically significant. A more recent meta-analysis examining 35 case-control studies and five cohort studies generated a pooled relative risk associated with exposure to husbands' smoking of 1.19 (95% CI, 1.10–1.29) for case-control studies and 1.29 (95% CI, 1.04–1.62) for cohort studies.

Because workplace exposure to ETS continues to be prevalent in many industries, ETS is also an important occupational risk factor for lung cancer. Based on the pooled results of five ETS studies, it has been estimated that non-smoking women exposed to smoking in the workplace have a 25% increased risk (95% CI, 8%–41%) over their baseline lung cancer risk.¹¹² Studies which have directly assessed workplace exposures to ETS generate risk estimates similar to those from studies of domestic exposures to spousal smoking.¹¹³ Compared with mean nicotine concentrations from 1 to 3 $\mu\text{g}/\text{m}^3$ in the homes of smokers, mean concentrations in workplaces which permit smoking range from 2 to 6 $\mu\text{g}/\text{m}^3$ in offices, from 3 to 8 $\mu\text{g}/\text{m}^3$ in restaurants, from 1 to 6 $\mu\text{g}/\text{m}^3$ in the workplaces of blue-collar workers, and from 10 to 40 $\mu\text{g}/\text{m}^3$ in bars.¹¹⁴ According to the NHANES III study, nearly 40% of US workers report being exposed to ETS in the workplace.¹¹⁵

Accumulated epidemiologic evidence strongly implicates ETS as a significant lung cancer risk factor. The US

EPA has estimated that ETS accounts for approximately 3000 lung cancer deaths per year in non-smokers.¹⁰⁹

PROBABLE LUNG CARCINOGENS

Exposures considered as probable lung carcinogens are summarized in Table 30.1.2.

Beryllium (see Chapter 39.3)

The primary occupational groups exposed to beryllium are miners, beryllium production workers, workers in the production and fabrication of beryllium alloys, and workers in the electronics industries. Data supporting the association between beryllium exposure and lung cancer are derived from cohorts of workers at beryllium production facilities in Ohio and Pennsylvania and from the US Beryllium Case Registry, a database which has tracked clinical outcomes among individuals with acute and chronic beryllium disease. Follow-up of men and women enrolled in the Beryllium Case Registry has revealed a doubling of lung cancer risk based on 28 observed lung cancer deaths,¹¹⁶ while a cohort study of over 9000 workers employed in seven beryllium processing facilities reported an SMR of 1.26 (95% CI, 1.12–1.42).¹¹⁷ Significantly elevated SMRs were found at two of the seven plants, and the highest rates of lung cancer were seen among employees with a history of acute beryllium disease at a Lorain, Ohio, facility. A recent nested case-control study from one of seven production facilities found that lung cancer cases had shorter work tenures and lower lifetime cumulative beryllium exposures than controls, but higher average and maximum exposures.¹¹⁸

Some controversy surrounds the association between beryllium exposure and human lung cancer.^{119–121} Cancer excesses were primarily associated with work during early production years, when exposures were greatest, and questions persist regarding why certain processing facilities had greater excesses than others. Concern has been raised regarding a possible contribution to lung cancer mortality from acid mists at certain facilities and from residual confounding due to cigarette smoking. The IARC has concluded that there is sufficient evidence that beryllium is carcinogenic to humans.¹²²

Cadmium (see Chapter 39.4)

Primary occupational exposures to cadmium occur in the smelting and refining of copper, zinc, and lead, as well as in electroplating, welding, and the manufacture of batteries, plastics, and paints. Human epidemiologic study results have been mixed regarding the potential of cadmium exposure to cause lung cancer in humans. Elevated risk has been observed among US cadmium-exposed production workers,^{123,124} and a study of cadmium recovery workers found elevated lung cancer risk among those exposed to both cadmium and arsenic.¹²⁵ However, the same study did not show elevated lung cancer risk among workers exposed solely to cadmium, and a study of copper

cadmium alloy workers did not reveal a positive correlation between cadmium exposure and lung cancer risk.¹²⁶ Swedish nickel-cadmium battery workers were shown to have an elevated lung cancer risk, with an SMR of 176 (95% CI, 101–287), but there was no apparent dose response between cadmium or nickel and lung cancer risk.¹²⁷ The IARC concluded in 1993 that there was sufficient evidence that cadmium is carcinogenic to humans.¹²²

Man-made vitreous fibers (MMVF) (see Chapter 46)

MMVF include rock wool, slag wool, glass fibers, and ceramic fibers. These materials are used primarily for insulation and have received particular scrutiny because the occupational groups exposed to them are those that have borne the legacy of past widespread asbestos use. There are two large study populations of MMVF-exposed workers: an American cohort of over 16,000 male workers at 17 US production plants¹²⁸ and a European cohort of over 22,000 workers in 14 plants.¹²⁹ Only one cohort study has examined workers exposed to refractory ceramic fibers (RCF).^{64,130}

In the large American cohort, the overall lung cancer SMR was 1.13 (95% CI, 1.03–1.23). Glass wool workers had an SMR of 1.12 (95% CI, 1.00–1.24), while rock/slag wool workers had an SMR of 1.36 (95% CI, 1.06–1.71).¹²⁸ In the large European cohort, overall SMR for workers with 1 year or more of employment was 1.05 (95% CI, 1.02–1.09). Glass wool workers had an SMR of 1.27 (95% CI, 1.07–1.50), while rock/slag wool workers had an SMR of 1.34 (95% CI, 1.08–1.63).¹²⁹ A recent study of over 32,000 workers employed for 1 year or more at any of 10 US fiberglass manufacturing facilities found a 6% excess mortality from respiratory cancer ($P = 0.05$). There was a statistically non-significant 3% excess mortality among longer-term (>5 years) workers. Duration of exposure and cumulative exposure did not appear to be associated with increased risk of respiratory cancer.¹³¹ Several nested case-control studies examining glass wool and rock/slag wool exposures have allowed more detailed exposure and dose-response assessments, and have shown mixed results.^{132–134}

RCF, potent carcinogens in animal models, have not been shown to be carcinogenic in human studies.¹³⁰ However, the limited size of the exposed cohort and its relatively young age do not allow one to conclude that such fibers are without risk. A recent risk analysis has concluded that deaths in the RCF cohort are significantly below that which would be expected if RCF had the potency of either crocidolite or amosite. Mortality was also reported to be lower than would be expected if RCF had the potency of chrysotile, but the difference was not statistically significant.¹³⁵

The current human epidemiologic evidence regarding lung cancer risk is strongest for rock wool and slag wool. Results regarding glass wool are mixed. Though recent follow-up data on exposed workers suggest a small risk, dose-response relationships have not been consistent. It is not possible to draw positive or negative conclusions from the limited epidemiologic study of RCF. The IARC considers MMVF to be possible human carcinogens (Group 2B).¹³⁶

Figure 30.1.1: Gross anatomy of malignant mesothelioma. A: Right lung encased with malignant pleural tumor. B: Peritoneal tumor.

Ambient air pollution (see Chapter 51)

Considerable evidence has accumulated to suggest that exposure to ambient air pollution may increase lung cancer risk. Studies addressing the issue are extremely challenging due to a number of issues: pollution levels are difficult to characterize over the long periods of time which must be considered when evaluating lung cancer incidence; factors which affect exposure levels to the individual are challenging to measure, as are confounding exposures over large population groups; the air pollutants measured may themselves not impart cancer risk, and may or may not correlate well with potentially carcinogenic agents; and most measurement data represent average levels over large areas.

Still, compelling results have accumulated from case-control and cohort studies, which suggest relative risks for lung cancer in the range of 1.5.¹³⁷ In general, more recent studies have better controlled for differences in smoking among subjects, and some have tagged increased lung cancer risk to elevations of specific pollutants, such as fine or sulfate particulates.^{138,139} Pope et al have recently reported on the lung cancer mortality in a prospective cohort of approximately 1.2 million adults enrolled in 1982.¹⁴⁰ Fine particulate and sulfur oxide-related pollution were associated with all-cause, lung cancer, and cardiopulmonary mortality. Each 10 $\mu\text{g}/\text{m}^3$ elevation in fine particulate air pollution was associated with an approximately 8% increased risk of lung cancer mortality. The authors reported no associations with coarse particle fraction or total suspended particles.

OTHER RESPIRATORY TRACT CANCERS

Mesothelioma

The link between malignant mesothelioma and asbestos exposure was first suggested in case reports from the 1940s. Further evidence was gathered by Wagner and associates in 1960 in a study of diffuse pleural mesotheliomas associated with asbestos mining in South Africa.¹⁴¹ In 1964, Selikoff and colleagues reported a surprisingly high incidence of death from mesothelioma in a cohort of 632 insulation workers.⁹ In a larger cohort of 17,800 asbestos insulation workers followed from 1967 to 1976, nearly 8% of deaths were due to the tumor.¹⁴² Subsequent studies

have found consistently elevated rates of mesothelioma in asbestos workers.

Diffuse malignant mesothelioma is a rare tumor of the serosal membranes of the lung and abdomen (Fig. 30.1.1). Incidence rates in American men range from four to 11 cases per million per year, and in American women, from one to four cases per million per year. Between 50% and 100% of all malignant mesotheliomas in North America and South Africa are attributable to asbestos exposure. In Turkey, the fibrous mineral zeolite has also been associated with a large epidemic of cases. Pleural mesotheliomas are more common than peritoneal mesotheliomas and account for nearly 90% of cases. Studies demonstrate an average latency period from first exposure to onset of disease of 30 to 35 years. Although higher cumulative exposures to asbestos generally correlate with a greater risk of malignant mesothelioma, studies have revealed that the tumor may occur with short-term (1 to 2 years) exposures and lower exposure levels. Household contacts of asbestos workers who may have washed asbestos-contaminated clothing, for example, are a recognized risk group.¹⁴³ Smoking does not appear to increase the risk of mesothelioma. There is no evidence that asbestos increases the risk of solitary benign mesothelioma.

Asbestos fiber type may influence the incidence of malignant mesothelioma. Lower rates have been reported in those exposed only to chrysotile, and some studies of chrysotile miners have not revealed elevated risk of mesothelioma.^{144,145} Malignant mesothelioma may be more common with exposure to the longer crocidolite fibers than with exposure to amosite and anthophyllite. A recent autopsy study employing analysis of retained asbestos fibers in young people who died of mesothelioma has estimated that 80% of the disease is due to amosite and crocidolite.¹⁴⁶ Others have suggested that chrysotile asbestos is the main cause of pleural mesothelioma, citing the necessity to consider longer follow-up periods for exposed cohorts, limited data regarding mesotheliomas among exposed household members, and more widespread exposure to chrysotile.¹⁴⁷ A reasonable synthesis of the current data is that chrysotile imparts a lower risk of mesothelioma than do the amphiboles, but that chrysotile-exposed workers are at risk for mesothelioma.¹⁴⁸ Peritoneal mesothelioma has not been associated with chrysotile exposure alone.

There is concern that other fibrous substances may induce mesothelioma. Erionite exposure appears to profoundly increase risk of mesothelioma, while MMVF do not. A recent study examined a cohort of 162 immigrants to Sweden from Karain, a Turkish village in which there is

low-level environmental exposure to erionite, a fibrous zeolite. Of 18 deaths which occurred in the cohort, 14 (78%) were due to malignant pleural mesothelioma. In addition, there were five patients with mesothelioma who were still alive. Risks of mesothelioma were elevated 135-fold and 1336-fold, respectively, in men and women, compared with an age-matched Swedish population.¹⁴⁹ In contrast, no excesses of mesothelioma have been detected in the American cohort of MMVF production workers.¹⁵⁰ A recent German case-control study could neither detect nor exclude an association between MMVF and mesothelioma.¹⁵¹

Clinical features

Typical symptoms of malignant mesothelioma include chest pain, dyspnea, weight loss, and cough. Fever also may be present. Chest pain of a dull gnawing quality is the most common symptom and tends to localize over the involved side, although radiation to the arm or shoulder may occur. Cough is usually not a prominent symptom until the tumor has invaded the mediastinum.

Pleural effusion is the most common physical finding, and chest radiographs usually reveal unilateral fluid with persistent pleural thickening and nodularity following fluid removal. Early on, thoracic structures often are drawn towards the tumor by its dense desmoplastic growth (Fig. 30.1.2). In advanced disease, there may be enlargement of the affected hemithorax, bulging of intercostal spaces, and displacement of the trachea and mediastinum to the unaffected side. Local tumor growth also may depress the diaphragm, giving the impression of splenomegaly or hepatomegaly. Supraclavicular and axillary lymph node enlargement, subcutaneous nodules in the chest wall, and rib tenderness also may be seen in advanced disease.

Figure 30.1.2: Plain chest X-ray study showing right-sided pleural malignant mesothelioma, with shift of thoracic contents.

Diagnosis

Diagnosis often is delayed due to the indistinct clinical features of early disease. Despite the fact that the overwhelming majority of cases of malignant mesothelioma are caused by asbestos exposure, asbestosis or other non-malignant effects are present in only about 20% of individuals diagnosed with the tumor. Pleural or peritoneal fluid is always exudative but of variable cellularity. Cytologic distinction of malignant cells from reactive mesothelial cells is often difficult. The presence of hyaluronic acid in fluid may be useful.

Ultimately, the diagnosis depends on defining the anatomy of the tumor and obtaining definitive tissue. In cases in which plain X-ray studies of chest and abdomen may be non-diagnostic, computed tomography (CT) scans are often very revealing (Fig. 30.1.3). Biopsy is definitive but may be difficult to interpret, even by experienced readers. The spindle cell types (Fig. 30.1.4) are generally differentiable from benign lesions and other tumors, but some mesotheliomas have striking adenomatous features, making them difficult to differentiate from metastatic adenocarcinoma. Immunohistochemical stains to exclude GI or GU cell origin and confirm mesenchymal surface markers are now widely employed to differentiate the two.

Treatment

No effective therapy exists for malignant mesothelioma. Also, there is no demonstrated benefit of early diagnosis beyond the timely acquisition of compensation benefits for the occupationally exposed. Average survival is 12 to 15 months from onset of symptoms, and most patients die within 1 year of diagnosis; there are a few long-term survivors, however, for unclear reasons. Death usually occurs from extension of the tumor into adjacent struc-

Figure 30.1.3: Malignant peritoneal mesothelioma encasing abdominal organs on CT scan.

Figure 30.1.4: Histology of spindle cell malignant mesothelioma (H & E stain, high power).

tures in the chest or the abdomen; metastases occur uncommonly. Hypoglycemia and hemolytic anemia have been reported as paraneoplastic complications. In general, palliative care should be emphasized, although surgery, chemotherapy, and radiotherapy have potential value in individual cases.

Upper respiratory cancer

Known and probable carcinogenic agents are summarized in Table 30.1.3.

Sinonasal and nasopharyngeal cancers

The first recognized cases of occupational sinonasal cancer were reported in a Welsh nickel refinery in 1932. Since that time a number of industrial processes and specific exposures have been associated with the tumor. Sinonasal cancers are rare, occurring at a rate of less than 10 cases per million per year in the US. Squamous cell cancers, which make up about half of all sinonasal tumors, and adenocarcinomas have been linked with occupational exposures. Adenomas, lymphomas, melanomas, and adenoid cystic carcinomas make up the remainder of sinonasal cancers.

The primary exposures linked to sinonasal cancer are nickel, wood dust, formaldehyde, cutting oils, and chro-

mium. Cancers in nickel workers have occurred most frequently in the nose and ethmoid sinuses, and usually are of squamous histology.¹⁵² Most epidemiologic studies were carried out in nickel refineries where exposures occurred to nickel oxides, nickel sulfide dust, soluble nickel compounds, and nickel carbonyl. Wood dust has been recognized as a sinonasal carcinogen since 1965, when a strikingly high incidence of the tumor occurred in an English furniture factory, and several case-control studies have documented increased risk among wood dust-exposed occupations since then.^{153,154} The most frequently occurring tumor histology following wood dust exposure is adenocarcinoma. Wood dusts contain a number of biologically active substances as well as preservatives, pesticides, and fungal proteins. The active carcinogen in wood dust is unknown, although PAHs may play a role because wood often is charred in the furniture-manufacturing process.

A number of case-control studies have evaluated risk of sinonasal cancer among formaldehyde-exposed workers.¹⁵⁵⁻¹⁵⁷ Pooled analyses suggest that risk of both adenocarcinoma and squamous cell carcinoma is increased. Risk of nasopharyngeal cancer has also been shown to be significantly elevated. Formaldehyde may potentiate the carcinogenic potential of wood dust exposure. An association between cutting oils and sinonasal cancer has been demonstrated in a small number of case-control studies, though a recent investigation found a significant association with nasopharyngeal cancer only.¹⁵⁸

Occupations in which an increased risk of sinonasal tumors have been reported include shoe manufacturing and repair, textile and clothing manufacture, agricultural work, and food preparation. Leather dusts, natural fibers, pesticides, and PAHs have been suggested as possible etiologic agents. Exposure to wood smoke under poorly ventilated conditions in the home has been proposed as an environmental etiology, which may explain higher rates of nasopharyngeal carcinoma among Chinese, other Asians, and natives of Alaska. Cigarette smoking has not been implicated as a major cause of sinonasal cancer.

Although it is a rare tumor, sinonasal cancer should be suspected in a patient with significant exposures who complains of chronic nasal discharge, obstruction, fullness, intermittent bleeding, sinus pain, or pain in the upper teeth. The persistence of such symptoms despite usual clinical interventions for more typical sinus problems is cause for referral to an otorhinolaryngologist for further evaluation. The diagnostic evaluation, natural history, and treatments of occupational sinonasal cancer do not differ from non-occupationally related disease.

Laryngeal cancer

Laryngeal cancer is considerably more common than sinonasal cancer, making up about 2% of the annual cancer incidence in the US. The primary risk factor is cigarette smoking, with some additional risk imparted by alcohol consumption. Occupational risk factors may include exposure to asbestos, cutting oils, acid mists, and nickel. Nearly all tumors are of squamous histology.

Agents	Exposure settings
Sinonasal cancer	
<i>Known carcinogens:</i>	
Nickel	Nickel refining
Wood dust	Furniture making
<i>Probable carcinogens:</i>	
Chromium	Chromium pigment production
Cutting oils	Machinists
Formaldehyde	Production of formaldehyde resins, particle board, apparel
Laryngeal cancer	
<i>Probable carcinogens:</i>	
Asbestos	Insulating, shipyard work
Cutting oils	Machinists

Table 30.1.3 Upper respiratory tract carcinogens

Increased rates of laryngeal cancer linked to asbestos exposure have been observed in miners, insulators, shipyard workers, and manufacturers of asbestos products. A recent meta-analysis of 69 asbestos-exposed occupational cohorts yielded SMRs for asbestos of 157 and 133 with and without latency, respectively.¹⁵⁹ Greater risks have generally been found in older studies with less rigorous control for tobacco exposure.¹⁶⁰ Results have been mixed with regard to a dose response between asbestos exposure and elevation of laryngeal cancer risk.^{161,162} Machinists have been shown to have an elevated risk of laryngeal cancer in several studies.^{163–165} Risk appears to be attributable to straight mineral oil exposure and may be enhanced during processes likely to produce PAHs. Acid mists also have been associated with laryngeal cancer in some, but not all, studies.^{166–168} Long-duration, high-level exposures appear to impart greater risk than do short-term exposures to lower levels. Rates of laryngeal cancer among nickel workers have been elevated in some studies based on small numbers, but others have reported no significant increases.^{169–171} As with other respiratory tract cancers, occupationally related laryngeal cancer does not differ from non-occupational disease in its clinical presentation, natural history, or recommended therapy.

PREVENTION OF RESPIRATORY CANCER

Given the lack of effective treatment for most respiratory cancers, the most effective method to reduce their considerable mortality rate is primary prevention. Identification of etiologic agents in the workplace is an ongoing task that requires physicians, industrial hygienists, epidemiologists, and policy makers to be sensitive to patterns of exposure and disease and to act prudently even when information is incomplete. Adherence to workplace standards is likely to yield decreasing rates of occupational respiratory cancer over the next several decades because many cancers today reflect exposures prior to the implementation of current standards. Still, standards must be continually reassessed as better epidemiologic studies yield new information. Smoking cessation efforts in the workplace also are vitally important.

Secondary prevention in the form of mandated medical monitoring is an adjunctive approach to occupational disease prevention. The efficacy of lung cancer screening in high-risk populations and choice of diagnostic tools to use remains an area of controversy. Presently, the Occupational Safety and Health Administration (OSHA) mandates medical monitoring for workers exposed to the following carcinogens: asbestos, acrylonitrile, arsenic, bis-chloromethyl ether, cadmium, coke oven emissions, silica, and vinyl chloride. Medical monitoring in each case involves physical examination, chest radiograph, and ILO rating. Sputum cytology examination is required for some workers, including those exposed to arsenic or coke oven emissions. The asbestos standard requires chest radiographs every 5 years for the first 10 years after the initial exposure, and, after 10 years of latency, every 2 years

between the ages of 35 and 45 years and annually after age 45.

NIOSH recommends medical monitoring in addition for workers exposed to beryllium, carbon black, chromium VI, coal tar products, inorganic nickel, chrysene, and coal gasification processes. Recommended monitoring includes history, chest examination, chest radiograph, and, in some cases, sputum cytology.

Several studies have been performed to evaluate current tools for medical monitoring of lung cancer in the workplace. The value of the screening chest radiograph, even in workers with considerably elevated lung cancer risk, has yet to be firmly established, though re-analyzed results of clinical trials suggest that screening may improve clinical outcomes in detected cases.^{172,173} One study has shown that lung cancer cases detected through chest X-ray screening have a 5-year survival rate of 19% versus 10% among cases detected through conventional healthcare.¹⁷⁴ Sputum cytology monitoring has been proposed as an alternative or supplemental monitoring tool. Lung cancers detected by sputum cytology tend to be squamous cell carcinomas of the major or segmental bronchus, whereas peripheral adenocarcinomas and large- and small-cell carcinomas more often are detected by X-rays. The addition of sputum cytology examination to radiographic screening has not brought about a decreased mortality from primary lung carcinoma. Sputum cytology results, however, may reveal mucosal changes that can identify individuals at increased risk.

Low-dose spiral CT has been proposed as a more effective means of screening high-risk populations for lung cancer.¹⁷⁵ In one study, 62 lung cancers were detected among 6341 participants. For single CT examinations, the mean detection rate (0.36%) was nearly 10 times greater than that achieved through chest X-ray screening.^{176,177} Of the lung cancer cases detected, 83% were pathologic state IA, and 66% were less than 15 mm in diameter. Conventional radiography did not detect 63% of the cancers detected by spiral CT. The reported sensitivity and specificity were 57% and 95%, respectively. Another study evaluated spiral CT screening of 1000 smokers 60 years of age and over, of whom 14% reported asbestos exposure. Screening initially identified 233 individuals with non-calcified nodules, among whom 27 lung cancers were ultimately resected. Malignant disease was detected four times more frequently with spiral CT than with chest radiography (2.7% versus 0.7%), and stage I tumors were detected six times more frequently (2.3% versus 0.4%).^{175,178,179} A screening program for 602 asbestos-exposed Finnish construction workers found abnormalities in 65 workers, among whom five lung cancers and one mesothelioma were detected. Sensitivity and specificity were estimated at 100% and 90%, respectively, with a positive predictive value of 8% in the studied population.¹⁸⁰

The search for chemopreventive agents which might be administered to populations at high risk for lung cancer, such as heavy smokers or asbestotics, has not proven fruitful to date. Primary prevention trials with alpha-tocopherol with or without beta-carotene in the

Alpha-Tocopherol, Beta-Carotene (ATBC) Trial in 29,133 smokers in Finland, and with beta-carotene and retinyl palmitate in the Beta-Carotene and Retinol Efficacy Trial (CARET) in 18,254 smokers, former smokers, and asbestos-exposed workers in the US, have shown increases in lung cancer incidence, suggesting that beta-carotene itself or retinol might have carcinogenic properties.¹⁸¹⁻¹⁸³ A randomized trial in a population of 22,071 male physicians, of whom 11% were current smokers and 39% former smokers, showed no significant difference in the number of lung cancer cases between those receiving placebo and those receiving supplemental beta-carotene.¹⁸⁴ Despite the failures of such trials, epidemiologic evidence suggests that diets rich in fruits and vegetables confer some protection against respiratory and other cancers.¹⁸⁵ Beta-carotene may also affect different epithelial tissues differently, as evidenced by its apparent protective effect against precancerous oral lesions and a statistically non-significant reduction in secondary head and neck cancers.^{186,187} Clearly, successes with chemoprevention, if they are to come, await a better understanding of the mechanisms underlying lower cancer rates among populations with apparently protective dietary habits.

30.2 Lymphohematopoietic Malignancies

Howard M Kipen, Daniel Wartenberg

Lymphohematopoietic (LH) malignancies are a heterogeneous group of neoplasms that arise from the clonal malignant transformation of various cell lines of the blood and lymphoid tissues. The transformed cell lines proliferate initially in the lymphoid tissues or bone marrow, where they may disturb normal immune function and hematopoiesis. Eventually, malignant cells spill over into the peripheral blood and other tissues, where traditional clinical syndromes become apparent. All LH neoplasms combined account for about 8% of the 1,300,000 new malignancies expected annually in the US. A 15% to 25% male predominance is evident for all subgroups (see Table 30.2.1).

Leukemic clones are characterized by an arrest in maturation of the multipotent stem cell, which is now believed to be the effect of a prior genetic or chromosomal alteration. Although the malignant clone is not truly hyperplastic, its growth is unregulated and becomes independent of homeostatic feedback controls. The particular LH neoplasm that affects a given individual depends on the level of stem cell development at which the maturation block has occurred. For example, developmental blockade at the pluripotent stem cell level causes aplastic anemia (see Chapter 21). If the block occurs a stage later, acute myelogenous leukemia (AML) results. Later stages of maturation arrest result in progressively more differentiated cells up through acute megakaryocytic leukemia. In chronic myelogenous leukemia (CML), relatively mature, although dysfunctional, cells are produced by an incomplete maturation block; however, the cells from this line typically become unstable due to subsequent development of an earlier block, with eventual proliferation of promyelocytes and blasts, leading to crisis.

Acute and chronic lymphocytic leukemias (ALL, CLL) are disorders of committed lymphopoietic stem cells, originating in lymphoid precursors of bone marrow, thymus, and lymph nodes. The solid tumors of the LH system, sometimes known as B-cell immunoproliferative disorders, include multiple myeloma (MM), Hodgkin's disease (HD), and non-Hodgkin's lymphoma (NHL).

LH neoplasms are often regarded as sentinel health events, but as with all occupational and environmental disease, the exposure and risk factor history are of paramount importance because none of these conditions, nor their associated markers such as cytogenetic aberrations, is regarded as pathognomonic for a particular cause. Genetic abnormalities, both inherited and acquired, and environmental factors have been shown to be etiologically important.^{1,2} Families with increased incidence have been described, although in some cases, shared environmental influences have been present and certainly should always be sought. Identical twins have a high concordance for leukemia in the first year of life, but this concordance is not known to persist in later life, suggesting predominance of environmental factors. Individuals with some congenital disorders, such as Down's, Bloom's, Wiscott-Aldrich,

Fanconi's, and Klinefelter's syndromes, have an increased incidence of leukemia. Acquired genetic factors are discussed later. Variations by sex and race of the major LH neoplasms are shown in Table 30.2.1. Aplastic anemia from any cause is associated with a markedly increased risk for the development of acute leukemia. Previous treatment with alkylating agents, radiotherapy, or both, also predisposes an individual to various LH disorders, and therapeutic immunosuppression such as that accompanying transplantation produces an exceedingly high relative risk of NHL, over 40-fold within 2 years, with a latency as short as a few months.³

CLASSIFICATION

The study of the distribution and causes of the LH neoplasms, as with all diseases, is limited by accurate nosology. As a unit, the LH disorders are a fairly well-delineated group of cancers comprising the following conditions.

THE ACUTE LEUKEMIAS

Acute myelogenous leukemia
Acute lymphocytic leukemia

THE LYMPHOMAS

Hodgkin's disease
Non-Hodgkin's lymphoma
T-cell lymphoma (mycoses fungoides)

OTHER

Multiple myeloma
Myeloproliferative disorders (including chronic myelogenous leukemia, myelofibrosis with myeloid metaplasia, and polycythemia vera)
Chronic lymphocytic leukemia

A number of caveats are important. Nomenclatures within the LH neoplasms have changed frequently over the last three decades. The International Classification of Diseases (ICD) and clinical coding practices are not well synchronized with one another nor with trends in clinical diagnostic practice.^{1,4-6} Thus, deaths due to myelodysplastic syndrome (see Chapter 21) are sometimes classified as a type of AML and sometimes separately, and within the NHLs there have been numerous shifts in nomenclature, whereas the ICD has retained older terminology.^{2,7} Because in any population LH neoplasms are relatively rare, such inconsistency influences the relative incidence of specific LH cancers, and thus impedes epidemiologic recognition and investigation of etiologic associations. Consequently, the total number of LH neoplasms or leukemias based on death certificates usually is reliable, because LH tumors rarely are classified outside the overall leukemia and lymphoma rubric, but specific cell types still cannot be reliably ascertained from death certificates.

	Males		Females	
	White	Black	White	Black
Leukemia	13.8	10.3	8.4	6.2
Lymphocytic	6.3	4.4	3.7	2.3
Acute	1.9	1.2	1.4	0.8
Chronic	4.3	3.1	2.2	1.4
Myelogenous	5.5	4.6	3.7	3.2
Acute	3.4	2.6	2.4	2.0
Chronic	1.8	1.9	1.1	1.0
Lymphomas	23.5	19.6	16.2	10.9
Hodgkin's	3.2	2.5	2.7	1.9
Non-Hodgkin's	20.3	17.1	13.5	8.9

Table 30.2.1 Rates (per 100,000) of the major lymphohematopoietic malignancies, 1994–1998, based on nine registries, adjusted to 1970 US standard populations. (Data from Ries et al.⁸⁶)

For practical reasons, in many epidemiologic analyses, the leukemias are considered as one. But the various LHs are a diverse group of conditions, both hematologically and etiologically. The emergence of various unifying understandings of pathogenesis such as oncogene activation adds some coherence to lumping together conditions whose distinguishing characteristics may be limited to subtle aspects of morphologic and functional cellular phenotype. Whereas virtually all LH tumors share the mechanistic similarity of one or more genes of lymphoid cellular origin having been abnormally activated and expressed, the mechanism may be a mutation, a translocation, a chromosome aberration, or acquisition of new viral DNA. Some have even hypothesized that a non-specific stimulus such as clonal hyperstimulation of B cells could eventuate in malignancy such as lymphoma or MM. The use of the broader term B-cell immunoproliferative disorders has been proposed for a combination of CLL, NHL, HD, and MM. The paradox is that, to the extent that the tumors are distinct entities with distinct sets of causes, imprecision in classification makes etiologic associations more difficult to observe with consistency, whereas to the extent that one cause may result in multiple distinct histologic abnormalities, splitting arbitrarily reduces epidemiologic power and the opportunity to observe statistically significant associations.

LABORATORY EVALUATION IN THE DIAGNOSIS OF LYMPHOHEMATOPOIETIC MALIGNANCIES OF OCCUPATIONAL OR ENVIRONMENTAL ORIGIN

Leukemias usually are recognized when a white blood cell count is elevated in the presence of circulating blast cells in a symptomatic individual, although presentations with normal white blood cell counts or with cytopenias are not uncommon. Diagnosis is based on a finding of leukemic cells in either peripheral blood, bone marrow, or

extramedullary tissue. Examination of marrow classically shows an infiltrate of uniformly appearing blast cells, causing an overall hypercellular appearance with a reduction in normal formed elements. The therapeutically important distinction between AML and ALL is made by a combination of morphology (e.g., Auer's rods in AML), reactions with cytochemical stains (e.g., TdT positive in ALL; lysosomal enzyme positive in AML), and cell surface immunophenotypic markers. CLL usually is associated with elevated numbers of apparently mature B lymphocytes in peripheral blood, although 5% have T-cell surface markers. Cytogenetic (karyotypic) characteristics are used to define subsets of therapeutic and prognostic significance within the major leukemic groups, and they also can be used to make etiologic inferences.

Lymphomas are diagnosed and classified by histopathologic examination of resected tissue, because reliance on aspirates is associated with an unacceptably high error rate. Disagreements in classification between experienced pathologists using biopsy material is reported to be higher than for most types of solid tumors, although immunologic markers are increasingly applied. Immunophenotyping through use of monoclonal antibodies has shown that 60% of NHL is B-cell derived and 30% to 40% is of T-cell origin. Cytogenetic evaluation commonly reveals abnormalities, including translocations in proximity to known oncogenes such as *c-myc*, and such data are becoming more incorporated into diagnosis and classification.

A number of studies have reported a statistically significant relationship between certain chromosome changes in AML and NHL and exposure to broad categories of occupational agents such as pesticides, solvents, petrochemicals, combustion products, and asbestos. This finding is consistent with the abnormal cytologic characteristics of secondary leukemia after cytotoxic and radiation therapy (see later), although such associations have been variably noted, with positive findings in Scandinavia and relatively more negative findings in the US and Canada. The most frequently implicated abnormalities are -5 and -7, which have been associated previously with leukemia occurring after prior administration of chemotherapy.^{8–12} This work is enabled and complicated by rapid advances in chromosome banding techniques, which now demonstrate some sort of visible chromosome rearrangement in nearly all cases of AML, in contrast to much lower rates in earlier years. The stage of the leukemia at the time of analysis also complicates the picture because the karyotype is known to evolve during the natural history of AML and other leukemias.

Although these types of epidemiologic investigations are relatively new, they offer a tantalizing approach to the exploration and clarification of the relationship between endogenous carcinogenic factors such as oncogenes and activation by environmental factors. This approach assumes one can distinguish the chromosome changes due to the environment factor from those due to progression and transformation of the disease, and has not yet been widely applied to resolution of environmental etiology problems. A slightly different use of laboratory abnormalities relies on

the possibility that chromosome changes such as sister chromatid exchange (SCE) may be predictive of neoplasms. Ethylene oxide, an animal carcinogen and probable human leukemogen, has been shown to cause increases in SCE in exposed workers,¹³ although not all studies have been positive.^{14–16} Benzene, a known human leukemogen, causes chromosomal abnormalities in exposed individuals.^{7,17} Of course, all of these chromosomal markers may be thought of as exposure indices, but much work remains to be performed to improve their specificity, and they must be interpreted with care in clinical settings.

ACUTE MYELOGENOUS LEUKEMIA OR ACUTE NON-LYMPHOCYTIC LEUKEMIA

Epidemiology

The 31,500 annual incident leukemias in the US comprise about 3% of all malignant neoplasms. Of these, myeloid types represent about 45%, with lymphoid types about 37%, and the remainder other and unspecified.

Ionizing radiation, benzene, and cytotoxic drugs are well-established acute leukemogens. Each is discussed in detail later in the chapter. In all three cases, investigations have progressed from whether they are leukemogens to questions of dose–response, mechanism of action, and risks posed by lower-dose environmental exposure. Ethylene oxide is now classified as a human carcinogen, and suspected to cause AML in addition to other LH neoplasms (see Chapter 40); styrene, 1,3-butadiene, vinyl chloride, paints, and nitrites have been reported causes. Industries that have used any of these agents (e.g., printing, rubber manufacturing, and painting) may be implicated, although benzene exposure is often implicated as the most potent among the mixtures. A recent case–control study confirmed well-known risks and raised new questions.¹⁸

It is an accepted generalization that the leukemias have much shorter latencies than the 10- to 30-year periods accepted for solid tumors. Acute leukemia risk in atomic bomb radiation survivors peaked at 2 to 5 years after detonation and declined after 10 years. After chemotherapy, the peak incidence is at 5 to 8 years and there appears to be a decline in risk by 10 to 15 years (as opposed to the persistent and progressively higher increased risk for solid tumors). Based on these high-dose, high-intensity exposure situations, some investigators have inferred that risks from environmental exposures to benzene, ionizing radiation, and perhaps other leukemogens diminish after a certain latency has been achieved. There are no clear epidemiologic data to support this.

Dose–response relations for acute leukemogens remain controversial as well. It is possible that the pattern and rate of exposure, as well as simple cumulative dose according to Haber's law, influence the risk of leukemia from ionizing radiation, the risk increasing as exposure is concentrated in time. This finding has not been clearly demonstrated for chemical leukemogens, and appropriate models of

carcinogenesis remain an area of scientific ferment. The very high risk of AML after high-dose benzene-induced aplastic anemia may be an example of the influence of the exposure rate, but there is no clear indication that the leukemogenic properties of benzene require clinical marrow injury. Study of US and Chinese cohorts has led to some convergence of the dose–response relationships between benzene exposure and AML, extending evidence for causal relationships to exposures reported to be below 40 parts per million-years (ppm-years) of cumulative exposure.⁷

Clinical features

Of potentially great mechanistic significance for epidemiologic studies of occupational and environmental agents is the marked increase in clonal cytogenetic abnormalities, with 7q- or 5q- detectable in 70% of AMLs secondary to chemotherapy versus 10% of de-novo AMLs.⁹ These leukemias secondary to alkylating agents or radiotherapy are usually characterized by a latency period of 5–10 years which may be preceded by a myelodysplastic phase. These particular chromosomal markers are also associated with particularly poor prognoses. The converse finding that the aberrations most common in de-novo AML are rare in the secondary cases lends credence to the potential causal mechanistic specificity of cytogenetic evaluation. Interestingly, some feel that de-novo AML in older adults bears cytogenetic similarities to secondary AMLs, leading to the hypothesis that AML and myelodysplastic syndrome developing in the elderly may reflect cumulative mutagenic environmental exposures in genetically susceptible individuals.¹⁹ As stated earlier, field epidemiologic studies so far have yielded inconsistent results with respect to environmental and occupational agents and their specific associations with characteristic cytogenetic markers.^{10–12,20}

Diagnosis, prognosis, and treatment

Cytotoxic chemotherapy with transfusion support has led to increasing numbers of initial remissions, currently 60% to 80%. Maintenance therapy is needed for some months. Between 10% and 30% of patients are free of disease at 5 years and apparently are cured. Secondary leukemias are becoming an increasingly prominent issue as survival rates increase.⁹

Screening

There is no practical approach to screening or early diagnosis for either prevention or reduction of morbidity. Screening based on cytogenetic abnormalities in peripheral blood lymphocytes or DNA adducts has been suggested but is not validated and should be considered only in experimental settings.²¹ Routine complete blood counts (CBCs) to detect benzene-induced marrow depression, and urinary phenols to detect excessive benzene exposure are not likely to be sensitive enough to be useful at current levels of exposure in the developed world,

except for indicating serious breaches of industrial hygiene, leading to overexposures greater than 10-fold the permissible exposure limit (PEL).

ACUTE LYMPHOCYTIC LEUKEMIA

Epidemiology

ALL is primarily a disease limited to the first two decades of life, with peak incidence at ages 2 to 9 years, although there is a smaller late peak in incidence after age 60. It is the type of leukemia most closely associated with several congenital disorders characterized by chromosomal abnormalities. However, because ALL does not affect the majority of patients with Down's, Fanconi's, Bloom's, and Klinefelter's syndromes, an environmental contribution to cause is still strongly implied. Studies of the effect of paternal and maternal occupations on childhood leukemia risk usually have not been cell-type specific (30% of childhood leukemias are ANLL) and, in fact, usually combine leukemias and lymphomas. Paternal occupations linked to the combined tumor types include nuclear industry workers, motor vehicle mechanics, hydrocarbon-exposed occupations, and medical and social service workers. In mothers, leukemia is linked to employment as a pharmacist, textile worker, chemical-exposed worker, hydrocarbon-exposed worker, and work in a domestic, hotel, or catering job (for a review, see Colt & Blair²²). Solvent exposures at home have also been implicated.²³ The data for the nuclear industry have the most biologic plausibility and consistency with worker outcomes. Although some studies have suggested that paternal exposure through employment at nuclear facilities increases childhood leukemia risk, alternative hypotheses have also been offered for the observed cluster of childhood leukemias around the Seascale nuclear facility in England (see below).

Clinical features

ALL typically is exhibited by constitutional symptoms, easy bruising, and lymphadenopathy due to infiltration and replacement of bone marrow and lymphatic tissue by an abnormal lymphoid precursor. This usually is a null cell but occasionally has T-cell or, very rarely, B-cell markers.

Diagnosis, prognosis, and therapy

Diagnosis is arrived at by examination of peripheral blood and bone marrow for excessive lymphoblasts. Combination chemotherapy currently results in a 4- to 5-year disease-free survival with a significant long-term cure rate.

Screening

No screening is indicated.

HODGKIN'S DISEASE

Epidemiology

HD (lymphoma) is a tumor of histiocytic or reticulum cells, which is pathologically distinguished by the presence of Reed-Sternberg cells, as well as the somewhat atypical clinical features of an infection. There are about 7400 new cases annually in the US, with an average age at diagnosis of 32 years. It has the unusual epidemiologic feature of a pronounced bimodal age distribution with peaks around age 20 and age 70 in developed countries. In contrast to NHL and MM, the incidence is not linearly increased with age. Although disease presentation patterns in young adults still suggest an infectious pattern, this is not suggested in older patients, and some occupational associations have been discovered, although not with consistency. The roles of ionizing radiation, benzene, and other environmental agents are considered later; however, a recent review emphasized the paucity of confirmed association with environmental agents.²⁴

Clinical presentation

HD usually is characterized by lymph node enlargement, either asymptomatic or associated with constitutional symptoms. Staging is performed based on the extent of nodal and extranodal involvement, and whether or not disease is present on both sides of the diaphragm. A functional T-lymphocyte defect usually is present, and normochromic-normocytic anemia is often present.

Diagnosis and treatment

Accurate diagnosis usually requires a surgical biopsy because aspiration rarely is adequate. Thorough exploration using physical examination, radiologic, and nuclear medicine modalities to detect all possible areas of involvement is required for accurate staging. Although radiotherapy is difficult and demanding owing to shielding requirements to reduce acute complications as well as risk of secondary malignancies and hypogonadism, over 70% of patients are now considered curable by radiotherapy, with or without combination chemotherapy.

Screening

There is no applicable screening for HD.

NON-HODGKIN'S LYMPHOMA

Classification

NHL is characterized by monoclonal neoplasms associated with proliferation of lymphocytes, macrophages, and their precursor and derivative cells. They are dominantly of B-cell phenotypic lineage, although some may have mixed B and T markers, and T-cell types may be particularly malignant.

Classification has rapidly and competitively evolved in this field from the histologically based Rappaport

Classification of 1966 to the immunologically based Lukes–Collins Classification of 1973 to 1974 and, in 1982, to the more clinically and prognostically based Working Formulation of NHLs for Clinical Usage. Further classifications have been proposed in an attempt to delineate individual diseases likely to have distinct etiologies.^{5,25} The implications for studies of etiology are difficult to specify but will surely complicate assessment of causal factors for a tumor observed today in light of epidemiologic information collected based on earlier nomenclatures, including the pre-Rappaport data, on which much of current epidemiologic understanding is based.

Epidemiology

NHL accounts for approximately 3% of new cancer cases annually in the US and has an annual incidence rate of about 16/100,000 based on 1994 to 1998 Surveillance, Epidemiology, and End Results (SEER) tumor registry estimates. The incidence of NHL is 50% higher in males than in females, and it is much higher in persons beyond the fifth decade. These characteristics plus a steep secular rise have been used to argue for etiologic attribution to occupational and chemical exposures, although detailed analysis does not yield a completely satisfactory explanation.²⁶ Except for Burkitt's lymphoma, which is highly prevalent in equatorial Africa, rates are higher in whites than in blacks, and they also increase with socioeconomic status in most studies. Clusters of T-cell lymphoma in southwestern Japan and the Caribbean, where 10% to 15% of the population is seropositive, are strongly associated with endemic human T-cell lymphocytic virus (HTLV-1) infection.^{27,28} Burkitt's is strongly associated with EB virus.

Known risks apart from socioeconomic status include hydantoin therapy and immune suppression. The latter may be either a primary (genetic) defect, secondary to drug therapy (e.g., prophylaxis for transplant rejection), or acquired from infection (HIV, HTLVs), autoimmune disorders, or therapeutic irradiation. Although impaired immune surveillance has been proposed to explain the increased incidence associated with the above-mentioned factors (up to 40- to 100-fold in the case of immunosuppressive therapy), there are other hypotheses of the origin of B-cell neoplasms that may be more germane to the role played by occupational and environmental chemical exposures. This line of reasoning maintains that lymphomas may develop as a result of imbalanced immunoregulation rather than deficient immune surveillance. Whereas the immune impairment is clinically apparent in the congenital or therapeutic immunodeficiencies, the impairments associated with NHL developing in the general population are hypothesized to be much more subtle. It is hypothesized that individual and, perhaps, idiosyncratic reactions to common physical, chemical, and viral agents may lead to lymphoma, without frank immune deficiency. Oncogene activation or immune gene dysregulation due to mutagens and clastogens also may play a role. Occupations for which the risk of NHL has been reported to be elevated include rubber workers, veterinarians, uranium miners,

asbestos-exposed workers, lumberjacks, metal workers, female textile workers, chemists, benzene-exposed workers, and farmers (see discussion later).^{29,30}

Clinical presentation

The clinical presentation of occupation-related NHL is not known to be different from de-novo cases.

Diagnosis, prognosis, and therapy

Examination of lymph node material usually is preferable to examination of involved extranodal tissue. Selection of therapy is more dependent on histologic type (Burkett's, follicular, diffuse) than on staging, in contrast to the dominant importance of staging for HD. The dominant favorable prognostic indicator is the presence of a follicular pattern in the nodal architecture, because patients with this characteristic finding follow a more indolent course than do those with a diffuse pattern of equivalent cytologic characteristics.

Screening

No screening techniques are clinically applicable to this disease.

MYCOSIS FUNGOIDES (see Chapter 30.9)

This rare cutaneous T-cell lymphoma has been linked to metals, solvents, arsenic, and bismuth in case reports. Industries such as petrochemical, rubber, metals, machinery production, printing, and textiles also have been suggested to have an association. The construction industry, too, was implicated in one study, which showed a particularly high risk among machinists. Viral etiologies have also been considered.³¹

Clinical presentation, diagnosis, prognosis, and treatment

The clinical presentation, diagnosis, prognosis, and treatment of occupation-related mycosis fungoides are not known to be any different from those of de-novo cases.

Screening

Although, in general, skin cancer screening may be indicated, especially for outdoor workers, mycosis fungoides is too rare to warrant special attention.

MULTIPLE MYELOMA Epidemiology

MM, with 15,000 new cases annually in the US, accounts for 1% of all malignant diseases and 15% of the LH

malignancies that are relevant to this chapter. Its annual incidence is about twice that for HD. Less than 2% of MM occurs in patients younger than 40 years old, and the peak incidence occurs in patients 70 to 80 years old. Rates in non-whites are twice those of whites. Prior to 1949, it was classified as a bone tumor. In the US and other industrialized countries, there has been a striking increase in the age-standardized incidence over the past three to four decades.³² Although some investigators maintain that this increase is attributable to diagnostic bias, it also is compatible with and suggestive of environmental and occupational factors as etiologic agents for MM. Ionizing radiation and occupational benzene exposure are well linked to increased myeloma risk and are discussed later. Excess risks, mostly less than twofold, also have been reported for petroleum refinery and petrochemical workers, farmers, woodworkers, food workers, printers, and those exposed to arsenic, lead, cutting oils, pesticides, and paint-related compounds.³¹

Clinical presentation

The clinical presentation of patients with occupation-related MM is no different than in de-novo cases.

Diagnosis, prognosis, and treatment

The classic diagnostic triad is marrow plasmacytosis (>10%), lytic bone lesions, and a monoclonal immunoglobulin spike in serum or urine.

Although 10% of patients have an indolent and very slowly progressive course, the vast majority require both chemotherapy for the myeloma and supportive care for complications such as hypercalcemia, renal failure, infections, and anemia.

Fifteen percent of patients die within 3 months of diagnosis, with a subsequent death rate of about 15% per year. Typically, there is a 2- to 5-year chronic course before refractory cytopenias and associated complications develop. Five percent of patients die with acute leukemia; whether this finding might represent an interaction with some of the common (leukemogenic) etiologic agents is unknown.

Screening

There is no screening relevant to the occupational setting.

MYELOPROLIFERATIVE DISORDERS

Myeloproliferative disorders are neoplastic disorders of the multipotent hematopoietic stem cell. Included are CML, polycythemia vera, essential thrombocythosis, agnogenic myeloid metaplasia with myelofibrosis, paroxysmal nocturnal hemoglobinuria (PNH), and, for purposes of this discussion, myelodysplastic syndrome, frequently called preleukemia or smoldering leukemia. Other than CML and myelodysplastic syndrome, the diseases run a prolonged

course over many years. We discuss CML, myelofibrosis, and polycythemia vera in detail because of relatively stronger links to environmental agents, although environmental and occupational causes of these disorders are not well studied. Myelodysplastic syndrome may be considered to have the same etiologic risk factors as AML (see also Chapter 21).

Chronic myelogenous leukemia

Epidemiology

Ionizing radiation exposure is clearly linked to the development of CML³³ and benzene is linked to CML but slightly less clearly than it is to AML.³⁴ Rubber workers and electrical workers have been found to be at increased risk for this particular malignant phenotype,³⁵⁻³⁷ electrical workers perhaps due to non-ionizing radiation exposure. The incidence of CML is roughly comparable to that for AML during the first five decades (about 50/100,000) and then doubles after age 60, as opposed to AML, which increases over sixfold.³⁸

Clinical features

CML is clinically characterized by an accumulation of both immature and mature granulocytic cells, leading to suppression of normal myelopoiesis and erythropoiesis. Twenty percent of cases are diagnosed by an elevated white blood cell (WBC) count in the absence of symptoms. Lymphadenopathy is rare. CML is characterized in 90% of cases by the well-known cytogenetic marker, the Philadelphia chromosome, resulting from a reciprocal translocation between the long arms of chromosomes 22 and 9. The breakpoints are near the proto-oncogenes, *c-sis* on 22 and *c-abl* on 9. Although this abnormality persists in all phases of the illness, the blastic phase usually is characterized by additional chromosome abnormalities, including aneuploidy, reflecting the more malignant character of this phase.³⁹

Diagnosis, prognosis, and treatment

The high WBC count, marrow aspirate with a Philadelphia chromosome, and depressed leukocyte alkaline phosphatase activity are all considered diagnostic hallmarks of CML. Therapy for the chronic phase usually includes moderate doses of alkylating agents, most commonly busulfan, whose most serious complication is prolonged myelosuppression. Transplant approaches have been added over the past decade.⁴⁰

Screening

No screening measures are applicable.

Myelofibrosis with myeloid metaplasia

Epidemiology

Myelofibrosis with myeloid metaplasia (agnogenic myeloid metaplasia) is another clonal stem cell disorder

der resulting in marrow fibrosis in association with proliferation of granulocytes, erythrocyte precursors, and megakaryocytes in extramedullary sites. The incidence appears to increase in individuals with prior ionizing radiation exposure (including radioactive phosphorus [^{32}P]-treated polycythemia vera) and has been reported to occur with benzene exposure⁴¹

Clinical features

Myelofibrosis usually is associated with constitutional symptoms and anemia (over 50% of patients are anemic at diagnosis), with virtually all patients developing anemia at some time during the course of the disease, due to decreased erythropoiesis, splenic pooling, and shortened red blood cell survival. High WBC counts are common, leading to a difficulty in differentiating this condition from CML, in which 10% to 15% of patients also may have marrow fibrosis.

Diagnosis, treatment, and prognosis

Bone marrow biopsy is required. Polycythemia vera and CML are the major considerations in the differential diagnosis. No therapy has been demonstrated to prolong life, but androgens have been used for anemia, myelosuppressive therapy for marked splenomegaly or thrombocytosis, and allopurinol to control hyperuricemia from tissue breakdown. The natural history is prolonged, with a median survival rate of 5 years from diagnosis. One-quarter of patients live 15 years after diagnosis.⁴²

Polycythemia vera

Epidemiology

Polycythemia vera is characterized by elevated hemoglobin levels in a setting of increased production of all marrow cell lines. Splenomegaly is common. It is a disease of adults, with a slight male predominance and no known familial aggregation. Information on occupational or environmental etiology is lacking. However, because this is a clonal myeloproliferative disorder, often associated with chromosomal abnormalities, myelotoxic factors may well be operative.

Clinical features

No differences have been found in cases suspected to be caused by environmental factors versus those arising de novo.

Diagnosis, prognosis, and treatment

The diagnosis, prognosis, and treatment are independent of etiologic consideration. In cases treated with myelosuppressive agents or ^{32}P , cytogenetic abnormalities may increase from the approximately 10% rate reported for untreated patients.

Screening

No screening measures are applicable.

CHRONIC LYMPHOCYTIC LEUKEMIA

This disease of later life, characterized by high circulating levels of mature-looking lymphocytes, is actually a variant of well-differentiated NHL. Generally, it has a favorable prognosis and often requires no specific therapy. Although some environmental associations have been noted, this disorder has not been convincingly linked to any myelotoxic agent. Notably, sufficient data exist to rule out an association with ionizing radiation, at least in Japanese and perhaps other Asian populations, based on data from the atomic bomb.

OCCUPATIONAL AND ENVIRONMENTAL RISK FACTORS FOR LYMPHOHEMATOPOIETIC MALIGNANCIES

There are four well-accepted risk factors for LH malignancies:

- ionizing radiation;
- benzene inhalation;
- agricultural work; and
- cytotoxic and immunosuppressive drugs.

Less clear-cut evidence is suggestive of an association between LH malignancies and certain non-agricultural occupations, exposure to electromagnetic fields (one type of non-ionizing radiation), and exposure to solvents, notably trichloroethylene (TCE) in drinking water. We consider each in turn.

Known causes

Ionizing radiation (Table 30.2.2)

The importance of ionizing radiation as an etiologic agent for LH malignancies has been known since the early part of this century from studies of radiologists. The most compelling evidence for this association has come from studies of survivors of the atomic bomb blasts in Hiroshima and Nagasaki and patients treated for ankylosing spondylitis. For both of these types of exposures, leukemias (other than CLL) were noted as early as 3 years after exposure, with peak incidence occurring 5 to 10 years after exposure, and additional excess cases were still being diagnosed for three decades after.

There also is limited evidence for leukemia risk for occupational exposure to ionizing radiation. Studies of military personnel on maneuvers at a nuclear bomb test showed statistically elevated leukemia incidence and mortality, as do the most recent studies of workers at nuclear facilities. A review and pooled analysis of nuclear worker studies conducted by the International Agency for Research on Cancer⁴³ found statistically significant excesses for leukemia and MM in more than one study of individual facilities. Their pooled analysis found statistically significant excess relative risks for leukemia excluding CLL and

Risk factor	Specific exposure	Comments	Reference
Ionizing radiation	Radiologists	Radiologist RR ~ 10 for leukemias, relative to other physicians	March, 1944 ⁸³
	Atomic bomb blasts	Noted a positive response for leukemias	Beebe et al., 1978 ⁸⁷
	Treatment for ankylosing spondylitis	Peak leukemia incidence 5 years after first course of treatment	Court Brown & Doll, 1965 ⁶⁸
	Nuclear bomb test workers	RR ~ 2.5 for leukemias	Caldwell et al., 1983 ⁸⁸
	Nuclear facility workers	SMR ~ 1.6 for leukemias	Cardis et al., 1995 ⁴³
	Naval shipyard workers	RR ~ 2–6 for leukemias	Stern et al., 1986 ⁸⁹
	Bomb test fallout	RR < 2; children's OR elevated for ALL	Stevens et al., 1990 ⁹⁰ ; Archer, 1987 ⁹¹
Non-ionizing radiation	Ingestion of radium-containing water	Local ecologic study; SIR ~ 1.5 for leukemias	Lyman et al., 1985 ⁴⁸ ; O'Brien et al., 1987 ⁹²
	Ingestion of radium-containing water	Broad ecologic study; no association found	Cohen, 1991 ⁹³
	Paternal occupation in nuclear facility	RR ~ 2–6	Gardner et al., 1990 ⁵²
	Residential magnetic fields	RR ~ 2–3	Wartenberg, 2001 ⁷⁶ ; Ahlbom et al., 2000 ⁷⁷ ; Greenland et al., 2000 ⁷⁸
	Occupational magnetic fields	Risk varies by occupation	Savitz & Loomis, 1995 ⁷¹ ; Floderus et al., 1993 ⁷² ; Theriault et al., 1994 ¹⁵

RR, relative risk; SIR, standardized incidence ratio; SMR, standardized mortality ratio.

Table 30.2.2 Selected studies demonstrating the association between radiation exposure and lymphohematopoietic malignancies

for MM. The leukemia effect was consistent with, but smaller than, values estimated from the studies of atomic bomb survivors reported in the BEIR V report from the National Research Council.⁴⁴ All LH neoplasms studied in this Japanese population reveal a high incidence following radiation exposure, with the notable exception of CLL. The absence of positive data on this neoplasm from the atomic bomb data makes it one of the rare proven negative findings that can be asserted in environmental epidemiologic causation, or perhaps an indication that Japanese individuals are not susceptible for presumably genetic reasons.

No safe threshold has been demonstrated, but direct evidence for radiation carcinogenesis has been derived almost entirely from studies of single high doses in excess of 50 rads. The case-control study with the best dosimetry for diagnostic X-ray exposure showed no increased risk for leukemia at highly fractionated doses up to 300 rads,⁴⁵ although two earlier questionnaire studies did show an increased risk.^{46,47}

Another suggested environmental cause of leukemia is ingestion of radium-containing ground water. One study that generated this hypothesis noted the geographic overlap of counties in Florida with both relatively high radium concentrations in the ground water and relatively high leukemia incidence rates.⁴⁸ This observation is ecologic and particularly subject to confounding, which could explain the findings. Suggestive but not clear-cut results have followed in subsequent studies.^{49,50}

Several studies have investigated the possible association between inhaled radon exposure and leukemia. The suggested mechanism is that radon inhalation may result in a small amount of irradiation to the bone marrow that could lead to leukemia. A recent weight-of-evidence review of 19 ecologic studies, six miner cohort studies, and eight

case-control studies concluded that while an ecologic association exists, it is not supported by the other studies and is unlikely to be etiologic.⁵¹

One unanticipated occupational risk for leukemia has been suggested by studies of a local cancer excess (cluster) near a nuclear plant in England. After adjusting for antenatal X-ray exposure, Gardner and associates found an association between childhood leukemia risk and paternal occupation in the nuclear plant, the risk increasing with larger cumulative paternal exposure.⁵² Although no such preconception risk was noted for survivors of the Hiroshima and Nagasaki atomic bomb blasts, the authors note that exposure to radiation from these atomic bombs was instantaneous, whereas that for workers is accumulated over many years. Laboratory studies of mice show similar paternal heritability of increased tumor risk, including tumors of the lung and lymphocytic leukemia.

An alternative explanation involving an infectious etiology has been proposed for this and related clusters. Kinlen and colleagues have suggested that the children in this community might have been at higher than normal risk because they were resident in an isolated, rural town without frequent exposure to infectious agents that are common among children in less isolated locales, impeding the establishment of herd immunity.^{53–55} Mixing with populations from more urban areas, with wider exposure to viral agents, resulted in increased contacts between susceptible and infected individuals, promoting epidemics of underlying infections. Then, if the populations were large enough, these infectious epidemics could have resulted in extra cases of leukemia, an extremely rare response to a common and widespread infection. Regions with high population densities would be more likely to have established herd immunity, thereby preventing the infectious epidemics and subsequent leukemias. Many

subsequent ecologic studies in other communities are consistent with this hypothesis.

Greaves developed a related hypothesis proposing an infectious etiology for childhood ALL, suggesting that children were at greater risk if they lived in more affluent areas because with greater affluence came more effective hygiene and thus reduced exposure to infectious agents in earliest childhood.^{56–58} Like Kinlen, he argued that for susceptible children, in this case affluent, early childhood exposure to infectious agents underlay a substantial number of childhood leukemia cases. The Greaves hypothesis suggests that the increased risk is due to decreased immune responsiveness and thus exposure to any or many infectious agents would confer similar risk.^{56–58} More detailed studies and identification of specific infectious agents are needed for confirmation of any of these competing hypotheses.

Benzene (Table 30.2.3)

Benzene is the best-recognized chemical leukemogen in the workplace and environment. Benzene's profound abilities to depress marrow function were recognized around the turn of the last century and actually led to its unsuccessful use as an antileukemic agent, persisting into the 1930s.

Based on series of cases observed from the 1940s through the 1960s, Italian and Turkish hematologists suggested that there may be a relationship between acute leukemia and occupational exposure to benzene-based inks and glues in the rotogravure printing and shoemaking industries, respectively.^{59–61} Exposures were not well quantified, but both industries are known to have resulted in substantial numbers of cases of marrow depression as well, implying substantial exposure.

In the late 1970s and 1980s, cohort studies began to emerge, focusing on industrial rubber workers, refinery workers, and chemical workers. The most convincing and widely cited study involves a cohort of about 1200 rubber workers,⁶² who at the most recent follow-up had nine cases of myelogenous leukemia, compared with 2.7 expected.⁷ Clearly, the issue concerning the use of benzene now is not

whether it is a cause of leukemia but rather what level of risk accompanies a given level of exposure.

Under a US Supreme Court requirement to show the magnitude of the effect of a reduction in the Occupational Safety and Health Administration (OSHA) benzene PEL from 10 ppm to 1 ppm, the National Institute for Occupational Safety and Health (NIOSH) performed a quantitative risk assessment on the previously described group of rubber workers.⁶³ A dose-response was noted, including the projection that even 1 ppm of exposure for 40 years would lead to a 70% increase in leukemia risk (95% confidence interval [CI], 1.1–2.5). More recent observations of a large benzene-exposed cohort of Chinese workers from multiple industries seems to confirm this projection and suggests increased risk even below the 40 ppm-year cumulative level.⁷ Epidemiologic evidence from relatively low-dose occupations, such as service station attendants and auto mechanics, has suggested a relationship of benzene with leukemia, but the evidence is not regarded as conclusive.⁶⁴ Beyond aplastic anemia and AML, there are varying levels of evidence supporting a role for benzene in the causation of numerous other LH malignancies, which are summarized in Table 30.2.3.

Agricultural exposures

A large amount of epidemiologic literature addresses the incidence of LH neoplasms in farmers and in children exposed to pesticides.^{65,66} These studies partially overlap those of other agricultural workers, such as lumberjacks, forestry workers, wood mill workers, meat packers, and ranchers of poultry and cattle. Although various studies report excesses of leukemias, myelomas, HD, and NHL, there are discrepancies between well-studied geographic areas.⁶⁷ Technically rigorous studies have reported high rates of NHL in agricultural workers exposed to phenoxy-acetic acid herbicides, chlorophenols (e.g., 2,4,5-T and 2,4-D), or both in the US, Canada, and Sweden since 1977. However, other reliable studies from New Zealand have repeatedly failed to find these associations. A possible interpretation of the discrepancy is the role of various confounding factors such as co-carcinogens and oncogenes in the various populations, although no specific explanation has been documented. A reasonable conclusion at this time is that NHL is probably causally associated with exposure to the herbicides listed above; HD, MM, and leukemias cannot be linked specifically to herbicides, although the higher occupational incidence among agricultural workers as a whole is clear. Hopefully unresolved questions will emerge from ongoing NCI/NIOSH studies of agricultural health.

Medical exposures

Although not strictly occupational or environmental, LH malignancies due to medical therapy provide a critical context for consideration of broader causes, both epidemiologically and mechanistically. CLL is the only LH malignancy (and one of only a handful of cancers) whose risk is not increased by therapeutic levels of ionizing radiation, at least not in the Japanese population.

Known

Pancytopenia: aplastic anemia⁹⁴
Acute myelogenous leukemia and variants^{7,63,95}

Suspected

Chronic myelogenous leukemia^{7,61}
Chronic lymphocytic leukemia^{7,36,37,60,80}
Paroxysmal nocturnal hemoglobinuria⁶⁰
Multiple myeloma^{7,96}

Reported

Acute lymphoblastic leukemia⁵⁹
Myelofibrosis and myeloid metaplasia⁹⁷
Non-Hodgkin's disease⁹⁸
Thrombocythemia⁹⁷

Table 30.2.3 Causal relation between benzene exposure and various hematologic disorders

The classic cohort⁶⁸ of 14,558 young men who were therapeutically irradiated for ankylosing spondylitis in the 1930s showed 52 leukemias versus 5.5 expected, with the risk cresting at 4 to 5 years and diminishing 8 to 9 years after exposure.

Cytotoxic drugs Alkylating agents and, to a lesser extent, antimetabolite therapy significantly increase the risk for AML, often with the identifiable 5q- or 7q- markers, and myelodysplastic syndrome. More specific immunosuppressive therapies preferentially promote NHL, with the relative risk (RR) estimated at 40- to 100-fold.²⁹ There is substantial cross-over of LH malignancy phenotype between the different classes of agents in spite of the useful distinction. Although there has been interest in the effects of cytotoxic agents on nurses, pharmacists, and others who are occupationally exposed, evidence of biologic effects has not been proved.⁶⁹ Nonetheless, rigid precautions to limit exposures are well justified by the risk in medically exposed individuals.⁷⁰

Suspect causes

Non-ionizing radiation

Concern also has been raised over the leukemia incidence among workers exposed to electric and magnetic fields (EMF).^{15,71,72} The risk was first documented in a case-control study of children living in homes with high magnetic fields, but, as yet, no mechanism for this risk has been established. Prompted by population-based studies, a series of occupational mortality studies have shown that workers in electrical, electronic, and telecommunications occupations and ham radio operators are at increased risk for ALL, AML, CML, and CLL. Because no viable mechanism has been postulated, there is much controversy over the definition of relevant exposure, although magnetic fields rather than electrical fields are implicated. Exposure metrics under consideration include peak, average, time-weighted average, and variability measures, although the data from different studies are contradictory (see Chapter 33.2).

Two recent expert panel reviews of the EMF issue were conducted in the US.^{73,74} The first,⁷³ under the sponsorship of the National Academy of Sciences, using a consensus process, reported that 'no conclusive and consistent evidence shows that exposures to residential electric and magnetic fields produce cancer', but also asserted that 'an association between residential wiring configurations... and childhood leukemia persists in multiple studies...'. Interpretations of these statements varied. The second panel,⁷⁴ convened by the National Institute of Environmental Health Sciences, using a majority rule process, concluded that 'Extremely low frequency (ELF) EMF are possibly carcinogenic to humans (Group 2B)'. This was based principally on 'the results of studies on childhood leukemia in residential environments and on CLL [chronic lymphocytic leukemia] in adults in occupational settings'. In addition, the participants

stated that the in-vitro and mechanistic data provide weak support based on studies at very high levels of exposures (>100 uT).

To summarize this body of literature analytically, a variety of meta-analyses and pooled analyses were conducted. The most recent meta-analyses^{75,76} reported that the risk for childhood brain tumors was elevated, although not statistically significant, while the risk for leukemia was elevated and marginally statistically significant, particularly at the higher exposure cut points. There was some evidence that supported an exposure-response gradient. The two pooled analyses of childhood leukemia^{77,78} reported no overall effect but, again, elevated risks at the highest exposure categories.

In sum, there still is much controversy over whether exposure to EMFs causes cancer. The strongest and most consistent adverse effect data from EMF exposure are found for childhood leukemia. Although the most common childhood cancer, this is a very rare disease, with an incidence rate of approximately 1.5/100,000. If EMFs are carcinogenic, the excess risk suggested by the combined studies for exposures four times greater than background are in the range 50%–100%. However, there is added concern because exposures are ubiquitous, and rare high residential exposures can be greater than 50 times background while rare high occupational exposures, although typically only short term, can reach 1000 to 40,000 times background.

Asbestos

Beginning in the 1960s, case reports and case series have linked individuals with asbestosis to various immune disorders, both malignant and non-malignant. Clinical epidemiologic studies have linked asbestos exposure and asbestosis to increased prevalences of rheumatoid factor and other indices of immune activation and regulation. Exposure has been linked to NHL, CLL, and acute leukemias, although data are inconsistent and limited (for a review, see Becker et al.⁷⁹). This remains an intriguing area for further investigation, possibly directed at co-factors necessary for an effect to emerge.

Rubber industry and other occupations

Rubber industry workers have been reported to have increased risks for AML, CML, and MM.⁸⁰ The extent to which this factor is independent of benzene exposure has not been definitively worked out due to the complexities of characterization of lifelong retrospective exposure. In this regard, the carcinogenic monomer 1,3 butadiene (see Chapter 41) may be an independent risk factor, although this is not clearly demonstrated.^{81,82}

Chemical workers, machinists, and painters have been reported to have an increased incidence of LH malignancies and, in some cases, to have increased chromosomal abnormalities.^{18,83,84} Especially noteworthy is the suspected relationship between ethylene oxide and AML (see Chapter 40 and Steenland and associates⁸⁵). Although the evidence is not as clear cut as for benzene or radiation exposure, risks have been demonstrated in various

settings and some of the inconsistencies could be explained by exposure misclassification as well as by the more commonly posited causal relationships. Confounding benzene exposures are frequently a problem in the interpretation of this literature based on historical chemical exposures.

Trichloroethylene and other solvent exposures

Several solvents have been investigated for possible carcinogenicity. TCE is an organic chemical that has been used in dry cleaning, for metal degreasing, and as a solvent for oils and resins. It has been shown to cause liver and kidney cancer in experimental animals. Evidence of excess cancer rates among occupational cohorts with the most rigorous exposure assessment is found for kidney cancer (relative risk [RR] = 1.7; 95% CI, 1.1–2.7), liver cancer (RR = 1.9; 95% CI, 1.0–3.4), and NHL (RR = 1.5; 95% CI, 0.9–2.3), as well as for cervical cancer, HD, and MM.⁶⁵ However, since few studies isolate TCE exposure, results are likely confounded by exposure to other solvents and other risk factors. Several studies of communities whose drinking water is contaminated with solvents including TCE show excess rates of leukemia and a few show excess NHL.

30.3 Bladder Cancer

Avima M Ruder, Tania Carreón, Elizabeth M Ward, Paul A Schulte, William Halperin

It is well documented that the etiology of bladder cancer involves environmental risk factors. Occupational risks may account for 21–27% of bladder cancers among men in the United States,^{1,2} an estimated 40,000 cases in 2001,³ and 11% among the estimated 15,000 cases in women in 2001.^{3,4}

Occupational exposure to aromatic amines has been known to cause bladder cancer since Rehn identified the first few cases in workers in the new organic chemical industry in 1895.⁵ Since that time, numerous occupations and specific substances have been associated with an increased risk of bladder cancer (Tables 30.3.1 and 30.3.2). Beyond the certainties that specific aromatic amines have been demonstrated to be human occupational bladder carcinogens and that a broad range of occupations are at risk of bladder cancer, a well-informed approach to the prevention and management of bladder cancer depends on appreciating various controversies involved in its primary and secondary prevention and treatment. The reader is referred to a report of a national conference held in 1989⁶ to delineate these issues. Many of these controversies, such as the relevance to human bladder cancer of findings from animal studies, the line between benign and malignant tumors, the appropriate screening regimen for workers exposed to bladder carcinogens, and whether early detection is worthwhile, remain relevant more than a decade later.

In addition to incidence and survival differences by social class, race, and gender,⁷ new developments in understanding inherited risk factors, such as acetylator status and intermediate biomarkers, influence understanding of etiology, prevention and management.

ETIOLOGY Epidemiology

Bladder cancer is the eighth most common neoplasm worldwide. An estimated 261,000 new cases of bladder cancer occur each year, with four-fifths of the cases occurring in men.⁸ Incidence rates of bladder cancer vary about 10-fold, with higher rates in Western Europe and North America, and lower rates in Eastern Europe and several Asian countries.⁹

Cigarette smoking accounts for 47% of bladder cancer among men and 37% among women; smokers have twice the risk of non-smokers.³ The contributions of coffee drinking and alcohol consumption to bladder cancer are equivocal. The World Health Organization estimates that bladder cancer cases can be subdivided into two broad categories based on etiology. (1) Those caused by tobacco and industrial carcinogens are predominantly transitional cell carcinomas and are common in industrialized countries. (2) Those due to bilharzia, human papilloma virus, and schistosomiasis infection^{10,11} are more likely to be squamous cell carcinomas and are found chiefly in subtropical

and tropical countries. Thus, both types are, in principle, preventable.¹²

Bladder cancer is historically the neoplastic disease most strongly linked to occupational exposure to chemicals. Several occupations have been suspected to increase the risk of bladder cancer, but strong associations only exist for dye workers, aromatic amine manufacturing workers, leather workers, rubber workers, painters, truck drivers, and aluminum workers.¹³ Table 30.3.1 presents the epidemiologic studies of occupational associations. Occupational exposures to chemicals such as arylamines, polycyclic aromatic hydrocarbons and other industry-related agents may explain some of the risk associated with these occupations.¹⁴ Some of the relative risks for exposed workers are substantially higher than the two-fold increased risk for smokers. Table 30.3.2 includes specific chemicals or processes classified by IARC as carcinogenic to the human or canine bladder, combined with data on working populations potentially at risk. Over 200 chemicals have been confirmed as rodent bladder carcinogens; however, rodent bioassays do not appear to be a good model for human bladder cancer¹⁵ (see 'Animal studies' section below).

A relationship between bladder cancer and exposure to chemical dyes was first established in 1895.⁵ In the late 1930s, oral administration of the industrial arylamine 2-naphthylamine was shown to induce bladder cancer in dogs.¹⁶ In 1954, Case et al. reported a 20-fold excess of bladder cancer in arylamine-exposed individuals, compared to the general population of England and Wales.¹⁷ Since then, the most investigated bladder carcinogens have been 2-naphthylamine, benzidine, and 4-aminobiphenyl. Several studies have reported increased risks of bladder cancer in workers exposed to 2-naphthylamine and 4-aminobiphenyl, and have been reviewed elsewhere.¹⁸

One newly recognized factor that may have an occupational component is fluid intake. In a study of about 50,000 men, it was observed that drinking more fluids was associated with a significantly decreased rate of bladder cancer.¹⁹ These results are consistent with the urogenous contact hypothesis, which proposed that the level of DNA adducts to 4-aminobiphenyl (a carcinogenic amine) could be decreased by increased fluid intake.^{20,20a} Occupations that have exposure to carcinogens and limit the workers' ability to drink liquids could be at risk.

There is no known distinctive histologic feature for occupational bladder cancer. However, in some heavily exposed cohorts, cases regularly occur at ages 15 years younger than the median age at diagnosis of the general population,^{17,21} in which the rate of bladder cancer increases substantially with age. Usually, the interval from first exposure to onset of symptoms is decades long; however, occupational cases have occurred surprisingly early after exposure, which substantiates the argument that cases with only a few years of latency may be occupationally induced. It has been estimated that the latency for chemically induced bladder cancer ranges from 4 to 45 years.^{21,22}

Only occupations explicitly mentioned in a study are included. Study types: CC (case-control), C (cohort), NCC (nested case-control), CR (linkage of case registry and census data)

* Dose-response demonstrated

† Higher risks were found for some subcategories of workers

Table 30.3.1 (Cont'd) Occupations associated with increased risk of bladder cancer

Based on mortality data from England and Wales, it was estimated that bladder cancer due to occupational exposures was responsible for half of the rate difference between high and low social classes because these exposures are concentrated in blue-collar jobs.²³ However, no evidence was provided associating the blue-collar jobs with exposure to bladder carcinogens.

Metabolic polymorphisms and bladder cancer

Interindividual variation is common for many metabolic enzymes. In some cases, the variability has been attributed to inherited polymorphisms.²⁴ Phenotypic and genotypic tests have shown that variation in xenobiotic metabolizing enzymes is associated with cancer risk and may have an influence on human susceptibility to genotoxic agents.

A limited number of studies of bladder cancer genetic susceptibility in populations exposed occupationally to arylamines has been published.^{25–29} The results of a meta-analysis of all studies of acetylation status and bladder cancer in the general population suggest that certain groups with the NAT2 slow-acetylation phenotype are at greater risk of bladder cancer.³⁰ Additional studies are needed to establish if individuals could be at higher risk of bladder cancer given the presence of certain alleles that make them more susceptible. In the workplace, various metabolic polymorphisms could be acting in combination with occupational toxicants to produce risk. For occupational bladder cancer, polymorphic genotypes in the NAT (N-acetyltransferase) and GST (glutathione S-transferase) families of genes have been explored. Their joint effect, together with the effect of other genotypes, has not yet

been investigated. Moreover, the metabolic differences between monoarylamines and diarylamines, such as benzidine, warrant careful attention to the specific compounds to which each worker is exposed.

Animal models

Use of animal models to predict human bladder carcinogens has been problematic. Rats and mice are not susceptible to bladder cancer by most aromatic amines, including some highly potent occupational carcinogens. For aromatic amines, the Syrian hamster and dog were found to be better predictors for human bladder cancer than mice or rats, but this may not necessarily be the case for other chemical classes.¹⁵ There has been considerable debate about the relevance to human bladder cancer of bladder tumors associated with urinary calculi in mice or rats or calcium phosphate-containing precipitates in rats. The International Agency for Research on Cancer (IARC), which has a formal program for identification of carcinogenic hazards to humans, has issued a consensus report on this subject.³¹ Based on this consensus report, the IARC monograph program has recently classified saccharin in Group 3 (not classifiable as to carcinogenicity in humans) because the mechanism through which it is thought to cause bladder cancer in rats, formation of a calcium phosphate-containing precipitate, is not relevant to humans.³²

Numerous classes of genotoxic chemicals have been identified as bladder carcinogens in rodents and some of these have been identified in humans, most notably, aromatic amines, nitrosamines, and cyclophosphamide. In contrast, non-genotoxic chemicals appear to be highly specific with regard to species strain, diet, agent, dose, and mechanism.

Compound name [variant name]	CAS#	IARC group	Source(s)	Potentially exposed occupations, numbers*
Aluminum (production)	7429-90-5†	1	Boffetta	al production workers

An RTECS search for substances associated with bladder tumors produced the original list, adapted from Ruder et al., 1990.⁸⁴ IARC classifications are adapted from Wilbourn et al. 1999¹⁵ and Boffetta et al 1997.²³ Updates through Monograph 84 by the authors of this chapter. IARC ratings: 1, definite human bladder carcinogen; 2A, probable human bladder carcinogen. Compounds rated by Wilbourn et al.¹⁵ as canine bladder carcinogens are included, but not those rated as exclusively rodent bladder carcinogens.

* Estimated numbers are from two sources: 1. (NOES) Chemical-specific numbers of workers potentially exposed are from the 1981–1983 National Occupational Exposure Survey. Note that all these workers would be reaching > 20 years latency about 2001–3; 2. (BLS) Estimates of numbers of workers in occupational categories are from the Bureau of Labor Statistics 1999 National Occupational Employment and Wage Estimates (<http://stats.bls.gov/oes>). These data do not consider turnover among employees, which would lead to a greater number of persons exposed than is suggested by estimates from specific points in time.

† These manufacturing processes involve exposure to a number of chemicals.

‡ No study to date has linked passive smoking to bladder cancer; several have found no association.

Table 30.3.2 Known and suspected human bladder carcinogens and estimated numbers of potentially exposed US workers

Use of molecular and genetic mechanism information may be helpful in identifying possible mechanisms involved for these non-genotoxic chemicals and, therefore, can be important for a rational evaluation of human risk.

CLINICAL ASPECTS

Pathology

Transitional cell carcinomas (TCC) are graded by the World Health Organization histologically by the degree of abnormality of the tissues³³ and staged by the American Joint Committee on Cancer – Union Internationale Contre

le Cancer by the extent to which they have spread.³⁴ One problem in the pathology of bladder tumors is the somewhat ambiguous line between the benign and the malignant, distinguishing between a papilloma, a papillary tumor with delicate fibrovascular stroma covered by a layer of epithelial cells indistinguishable from normal bladder mucosa, and a papillary carcinoma. This distinction should be viewed as a region where borders shift between pathologists, between institutions, and given the circumstances, even successive biopsies of the patient.

Some so-called benign papillomas display effects of inflammation and reactive or regenerative conditions so that they are classified by some pathologists as anaplastic,

although most of them do not behave as malignant tumors. To make the situation more complicated, some papillary tumors do become aggressive. Robinson and Hall³³ summarized the results of several studies: about 2–5% of ‘benign’ papillomas progress to carcinoma. The use of biochemical, molecular and genetic characteristics of cells is beginning to provide pathologists with a way to reduce these uncertainties. Strong associations of various markers with progression, invasiveness, and metastatic potential may provide a way to distinguish between pathologic subtypes of bladder cancer in the future.³⁵

Therapy

Strategies for diagnosis and therapy of occupational bladder cancer do not differ from those for bladder cancer resulting from non-occupational etiologies. A comprehensive guide to current treatment options by stage and grade has been assembled by the National Cancer Institute.³⁶ Treatment strategies do not appear to differ by histological type. Occupational bladder cancer does have a public health component: putative bladder carcinogens and high-risk populations that need to be followed with screening have been identified when exceptional cases of bladder cancer (i.e., in young non-smokers) were diagnosed.

Survival

The survival of patients with bladder cancer depends on the grade of anaplasia of the tumor and the stage of tumor invasion at time of diagnosis. SEER 1992–1997 5-year survival rates range from 94.5% for localized disease in white males to 0% for distant disease in African-American males. At each stage, women fare more poorly than men (except African-American women with distant disease) and African-Americans more poorly than whites. From 1974 to 1997 overall survival has improved from 48% to 65% in African-Americans and from 74% to 82% in whites. During the same period, incidence increased slightly overall from 14.6 to 16.7/100,000, in men from 25.6 to 29.0, and in women from 6.3 to 7.4.³⁷

Survival also appears to depend on social class and race, which, of course, are somewhat correlated. A review of five studies on bladder cancer survival found about a 20% discrepancy overall between higher and lower income patients.³⁸ African-Americans are less likely than whites to develop bladder cancer; however, once diagnosed, African-Americans experience poorer survival: 64% 5-year survival vs. 82% for whites.³

PREVENTION

Techniques for early detection

Cytoscopy is effective in identifying visible tumors in the bladder. A cystoscope is a slender tube with a lens and a light that is inserted through the urethra, allowing the physician to visually inspect the urethra and bladder.

Cytoscopy is invasive and not employed for asymptomatic individuals.³⁹

Urine cytology is the accepted technique for detection of bladder cancer in asymptomatic individuals. Urine cytology microscopically identifies the presence of abnormal, malignant cells, which are shed into the urine of patients with bladder cancer.³⁹ Cytologic screening for bladder cancer has a sensitivity of about 70% and a specificity of 90–95%, depending on the grade and stage of the tumor,⁴⁰ which is comparable to screening tests for cervical cancer, breast cancer, and colon cancer.⁴¹ Bladder cytology is effective in detecting preclinical stages of aggressive tumors and is substantially less effective in detecting low-grade tumors. There is widespread agreement that superficial well-differentiated papillary tumors rarely can be diagnosed definitively from voided urine cytology. In summary, cytology may be used to detect aggressive tumors, but these tumors may be advanced by the time they are discovered by this method. Cytology is less effective for low-grade tumors, which, although they are less aggressive, it would be desirable to find.⁴²

The greatest determinant of the sensitivity of urine cytology is the level of cytopathologist expertise. Ancillary techniques have been tested to improve the sensitivity of urine cytology. Of the large variety of methods, the most promising techniques appear to be DNA flow cytometry and image analysis for the detection of nuclear aneuploidy. Other sensitive methods include immunocytochemistry to detect the presence of antigens that are commonly expressed in neoplastic urothelium but not in the normal urothelium, such as the Lewis X antigen, and immunohistochemical analysis for the detection of p53 overexpression.⁴³

Hematuria screening, by urinalysis or by dipstick – a positive reaction for blood on urine-reagent-strip testing of asymptomatic people⁴⁴ – may be a more effective method than cytology for detecting low-grade early stage bladder tumors. The dilemmas with testing for hematuria are: (1) although almost all bladder tumors eventually cause hematuria, an infrequent examination may not be adequately sensitive, and (2) hematuria due to bladder cancer may be intermittent.⁴⁵ Although more frequent examinations increase the sensitivity of the test for bladder cancer, this method decreases the specificity of the test because it will detect other, non-malignant conditions causing hematuria, including cystitis, kidney disease, and urinary calculi.³ The debate then focuses on the predictive value of a positive test result for hematuria or the probability that a positive test result will reflect bladder cancer rather than another problem. It has been suggested that 5–10% of patients with hematuria have bladder cancer and 10–20% have some other serious urinary tract disease. As a condition becomes more prevalent in a population, the predictive value of a positive test increases. Exposure of an individual to an occupational carcinogen, as well as the individual’s age and other risk factors for bladder cancer, should ensure a higher underlying prevalence of bladder cancer and thus increase the predictive value of a screen for hematuria.⁴⁵ The American Urological

Association recommends that asymptomatic microhematuria be evaluated only when associated with a risk (such as occupational exposure to carcinogens) of disease.⁴⁶

Tests of genetic factors are now being developed or assessed for evaluation of risk factors for bladder cancer. In addition to variations in metabolic phenotypes such as *N*-acetyltransferase, there are other genetic factors and acquired factors, such as recessive alleles for oncogenes, mutated tumor suppressor genes, and growth factors, that may place individuals at increased risk for bladder cancer independent of occupational exposure.⁴⁷ These genetic factors could add to any occupational risks for bladder cancer or multiply those risks. It is likely that the rapid pace of research will result in the identification of new predictive or prognostic markers in the near future.

A number of new techniques are being tested for use in bladder cancer screening. Most markers appear to have an advantage over urine cytology in terms of sensitivity, especially for detecting low-grade superficial tumors. However, most markers tend to be less specific than cytology, yielding more false-positive results. This scenario is more common in patients with concurrent bladder inflammation or other benign bladder conditions. A summary of the sensitivity, specificity and limitations of these methods is presented in Table 30.3.3.

The nuclear matrix protein (NMP) 22 test detects and measures urinary levels of a particular NMP called NuMA (nuclear mitotic apparatus). The NMP22 assay appears to be useful only to monitor, with high accuracy, for recurrence in patients with a past history of bladder cancer.⁴⁸

The bladder tumor antigen (BTA) test detects the presence of a bladder tumor antigen in the urine of patients with bladder cancer. The BTA stat and the BTA trak assays are qualitative and quantitative assays, respectively. Both detect a human complement factor H-related protein in the urine, and both accurately identify two-thirds of patients with bladder cancer. Both are limited because of the high number of false-positive reactions compared to urine cytology in low-grade bladder tumors.³⁹

The fibrin and fibrinogen degradation products (FDP) test is positive in two-thirds of patients with bladder cancer. The FDP test detects the degradation product of an

extravascular fibrin clot produced by tumors. It is more sensitive than urine cytology and has a high specificity.⁴⁹

Telomerase is an essential enzyme for cellular immortality and tumorigenesis. The telomeric repeat amplification protocol assay for telomerase in exfoliated cells can be used as a tumor marker. However, the low stability of telomerase in urine affects test sensitivity.⁵⁰ Inflammatory cells and stem cells have telomerase activity, and may be the source of false-positive tests.

Hyaluronic acid is a glycosaminoglycan that promotes tumor metastasis. High levels are detectable in the urine of patients with bladder cancer. Patients with high-grade TCC have elevated urinary hyaluronidase activity. A combination of both tests (HA-HAase test) yields a higher sensitivity than the sensitivity of individual tests,⁵¹ but it has no better sensitivity than urine cytology for detecting low-grade lesions.

Recently, detection of survivin in urine has been suggested as a predictive molecular marker of bladder cancer. Survivin is an enzyme inhibitor of apoptosis that is selectively overexpressed in human cancers, but undetectable in most normal adult tissues. In a patient series, the sensitivity of the urine survivin test for new or recurrent bladder cancer was 100%, and the specificity was 90–100%, depending on the population tested.⁵²

Test batteries

Combining tests can increase their sensitivity and specificity.⁴¹ Series testing is used to increase specificity and reduce the number of false-positive results. Parallel testing is used to increase sensitivity and reduce the number of false-negative results. A new US/European research consortium wants to create a simple, cost-effective, non-invasive diagnostic test to replace cystoscopy and cytology, initiating multicenter trials to find which of seven molecular markers, alone or in combination, is the most accurate detector of bladder cancer.⁵³

Screening programs

There are two reasons for screening a population exposed to a known or suspect bladder carcinogen. First, individu-

Test	Sensitivity	Specificity	Limitations
Urine cytology	17–70%	90–95%	Poor criteria to identify low-grade TCC*
BTA test	29–40%	68–91%	Low detection of grade I TCC. Poorer predictive value than urine cytology
BTA stat test	67–87%	40–70%	High false positive with gross hematuria, prostate cancer, BCG
BTA trak test	72%	43–48%	High false positive with UTI, stones, instrumentation
NMP22	48–80%	64–80%	High false positive with gross hematuria
FDP test	40–68%	80–96%	High false positive with gross hematuria
Telomerase	70–86%	60–90%	False negatives with gross hematuria, false positives with inflammation, complicated assay not widely available
HA-HAase test	90–92%	80–84%	No detection of grade I TCC

Modified from Brown, 2000⁴³
 * Abbreviations: BCG = bacillus Calmette-Guérin, BTA = bladder tumor antigen, FDP = fibrin/fibrinogen degradation products, HA-HAase = hyaluronic acid/hyaluronidase, NMP = nuclear matrix protein, TCC = transitional cell carcinoma, UTI = urinary tract infection

Table 30.3.3 Sensitivity and specificity of non-invasive bladder tumor markers

als may be screened so that their tumors can be detected early when they are more readily treated, resulting in less morbidity and higher survival rates. This type of screening is for the personal benefit of the individuals. The second rationale for screening is to detect disease in a population at the earliest time possible in order to ensure that more primary methods of disease prevention, such as engineering controls and use of personal protective devices, are effectively incorporated to prevent exposure.⁵⁴ The two motivations should be kept in mind in appreciating a consensus view that was reached at the 1989 conference on screening for bladder cancer in high-risk groups. For populations exposed to known carcinogens at high levels, cytologic examination and testing for hematuria was recommended at 6-month intervals. The rationale for including hematuria was to ensure the acceptability of the screening program by ensuring that low-grade tumors would be detected that otherwise may be missed by cytology.

For low-exposure groups, as may be found in patients suffering from conditions as a result of environmental exposures, cytology was recommended 2 years after the first exposure, then every 5 years thereafter. For a suspect carcinogen, at high-exposure levels, cytology was recommended every 6 months, as well as measurement of hematuria to detect low-grade tumors. The argument for detecting low-grade tumors, even though there may be limited personal benefit for the individual because most such tumors are less aggressive, was to provide information that exposure had not been adequately controlled. The panel was not enthusiastic about any recommendations for a suspect carcinogen at low levels of exposure.⁵⁵

When weighing the benefits of a strategy of early detection, be it for the personal benefit of the worker or for the benefit of the workforce, it is necessary to consider the extent to which false-positive findings will be involved. A screening modality that leads to a disproportionate number of unnecessary follow-up and diagnostic procedures may not be cost effective or personally desirable. Moreover, the lengthening of the lead time, although possibly providing an extended opportunity for therapeutic intervention, also could provide a longer period of anxiety and distress for the worker.⁵⁴

In contrast to the recommendations of the bladder cancer conference consensus panel, the US Preventive Services Task Force concluded that there was insufficient evidence that hematuria and cytology screening improved the prognosis for those found to have cancer, even within high-risk groups.⁵⁶ If the efficacy of hematuria and cytology screening is not established, then in monitoring high-risk populations, cystoscopy should be reserved as a diagnostic test in individuals who had positive results on cytology and hematuria. However, it should be remembered that in at least one high-risk group, the MBOCA cohort, bladder cancer was diagnosed in two individuals who had had negative hematuria by dipstick and cytology screening.⁵⁷ Perhaps the non-invasive screening batteries now under development will end this dilemma.

SUMMARY

Despite substitution and process changes to prevent or reduce worker exposure, a substantial number of workers continue to be exposed to bladder carcinogens. Much larger numbers have been exposed to bladder carcinogens in the past. Some of these workers may still be at risk for bladder cancer. Improved screening options for high-risk groups, as well as better treatment options, should continue to improve survival and quality of life for these individuals.

30.4 Renal Cancer

Stuart L Shalat, Sandra N Mohr

Renal cancer is relatively rare, accounting for only 3% of all cancers diagnosed in the US. It is the 10th leading cause of cancer in men and the 14th in women. Perhaps because it has received less attention than other, more common tumors, the etiology of renal cancer, with respect to both general and occupationally related causes, is still not well understood. However, approximately one-third to one-half of all cases of renal cell carcinoma occur in patients with von Hippel–Lindau disease.¹ Other risk factors associated with renal cell carcinoma include smoking, obesity, history of kidney stones, and long-term use of phenacetin.²

Examination of risk of renal cancer in the workplace has included a variety of exposures, including metals (arsenic, cadmium, lead, and uranium), polyaromatic hydrocarbons (PAHs), organic solvents (including chlorinated compounds), asbestos, and other factors. Therefore, although renal cancer may be rare, the exposures that may confer increased risk to workers are not.

In the US in 1996, there were approximately 30,600 incident cases of renal cancer with approximately 12,000 deaths.³ The disease is more common in men than women. Black men and women are at greater risk for the disease than whites. In 1997, age-adjusted incidence rates in the US were 12.2/100,000 in white males, 15.9/100,000 in black men, 6.4/100,000 in white women, and 7.9/100,000 in black women (SEER, 2000). The incidence rates for renal cancer peak in the sixth and seventh decades of life. Epidemiologic data from the National Cancer Institute's Surveillance Epidemiology and End Results (SEER) program followed from 1973 to 1997 suggest that the incidence of cancer in the kidney is rising. There has been an increase of 1.7% per year for men and 2.2% for women. This increase, however, also may be due to improvements in diagnostic records. Only 41% of male cases and 46% of female cases were localized at the time of diagnosis. The 5-year survival rate for renal cancer has shown slight improvement from approximately 50% in the early 1970s (all gender and race groups) to approximately 61% for cases diagnosed in the early 1990s.

CLINICAL ASPECTS

There are no distinguishing characteristics with regard to occupational etiology in the diagnosis and clinical course of renal cell carcinoma. Approximately 60% of cases present with hematuria, either gross or microscopic. The classic triad of flank pain, palpable abdominal mass, and hematuria is found in only 10% of patients. Most of the other presenting symptoms are systemic, including fever, weight loss, anemia, hypertension, and erythrocytosis. At the time of diagnosis, 30% of individuals have extensive metastatic disease. Renal tumors usually are detected by intravenous pyelography with tomography, or by ultrasound, followed up by a computed tomography (CT) scan. The CT scan is considered comparable to renal arteriography for the staging and characterization of the disease.

Classification

Renal cell carcinoma, also known as renal adenocarcinoma or hypernephroma, accounts for 90% of tumors in the kidney. The cancer arises from cells of the proximal convoluted tubule and its associated connective tissue. The Mainz classification is now widely utilized for renal cancer, as a result of several cytogenetic studies.⁴ In this system, there are three histologically distinct forms of renal cell carcinoma:

- clear cell type (cholesterol-filled cells);
- chromophilic (eosinophilic or basophil-staining); and
- chromophobic.

Renal pelvic cancers involve the collecting systems of the kidney, and account for less than 10% of all renal neoplasms. These include collecting duct carcinoma and renal oncocytoma. The cancers usually are morphologically identical to transitional cell carcinomas seen in the bladder, and are associated with them in roughly 50% of cases.

Wilms' tumor, or nephroblastoma, is the third most common form of childhood cancer and represents about 5% of all kidney cancers. These tumors contain a variety of cell types, all derived from the mesoderm. The epithelial cell types may present as immature tubules or glomeruli.

Therapy

As discussed above, the annual number of new diagnoses of renal cell carcinoma is increasing. For patients with localized primary tumors, surgical resection remains the mainstay of therapy. Since renal cell carcinoma is characterized by a lack of early warning signs, a majority of patients present with metastatic disease. Several reviews of available treatment regimens have concluded that renal cell carcinoma is resistant to chemotherapy.^{5–7} The result is that patients with distant metastatic disease (Stage IV) have a 5-year survival of less than 10%.⁸ Recent studies have suggested possible improved survival for advanced renal cell carcinoma from interferon and/or interleukin (IL)-2 therapy, and, more recently, allogeneic stem-cell transplantation; however, far more research is required and new agents and treatment programs need to be considered.^{5,9}

GENERAL EPIDEMIOLOGY

Several epidemiologic studies have attempted to identify risk factors for renal cell carcinoma, which are shown in Table 30.4.1. These risk factors have been evaluated mostly through the use of case-control studies. Because of the high case-fatality rate occurring 1 year after diagnosis, the majority of these studies have had a fairly low response rate of 60% to 73%. In order to prevent a high percentage of non-response, some investigations have used proxy interviews

Established	Suspected	Reported*
Cigarette smoking Phenacetin analgesics Hereditary disorders von Hippel–Lindau disease	Obesity Hypertension and/or antihypertensive medications Northeastern European ancestry Long-term hemodialysis	Meat consumption Kidney infections/stones Acetaminophen analgesics
* Causal association requires further research		

Table 30.4.1 Non-occupational risk factors for renal cell carcinoma

to substitute for deceased patients. This strategy, however, raises the problem of differential recall bias between proxy and direct patient interviews. These issues need to be taken into account when interpreting case–control studies of renal cancer.

Cigarette smoking has been consistently associated with renal cancer across several epidemiologic studies. In a population-based case–control study of 495 cases and 697 controls, McLaughlin and coworkers found an odds ratio for smoking of 1.6 for men, and 1.9 for women.¹⁰ There was also a positive dose–response relationship in both sexes for years of tobacco use. Several other studies also found significant odds ratios for smoking in the 1.5–2.0 range. A large study from Australia recently confirmed the positive association for smoking, and estimated an attributable risk for renal cell cancer of 30% for men and 24% for women.¹¹

Obesity has also been suggested as a risk factor for renal cell carcinoma. In a study by Yu and colleagues which assessed the effect of obesity, as measured by Quetelet's index 10 years before the onset of cancer, significant increases in odds ratios for both men and women were observed.¹² Maclure and Hankinson found that obesity was a predisposing factor for renal cell carcinoma among women in a case–control study of renal cell cancer.¹³ A nested case–control study (cases, $n = 37$; controls, $n = 148$) of refinery and petrochemical workers used body mass index (BMI) and found a statistically significant increase in risk of kidney cancer.¹⁴

A positive association of premorbid hypertension and the risk of renal cell cancer has been demonstrated, but it remains unclear whether the effect is due to an increase in blood pressure or use of antihypertensive drugs. McCredie and Stewart found that both beta-blocker use and hypertension for more than 2 years were independently associated with renal cell cancer, but the use of diuretics was not.¹⁵ In contrast, Yu and colleagues found that hypertension was not significantly associated with renal cell cancer after controlling for diuretic use in women.¹² Several prospective studies have also investigated the relationship of hypertension, antihypertensive medications, and renal cell cancer, but only one of these demonstrated an effect due to antihypertensive medication independent of high blood pressure.¹⁶ In the same occupational study of refinery and petrochemical workers as previously mentioned, high blood pressure resulted in a large increase in risk, even when BMI was taken into account (OR = 4.5; 95% CI, 0.8–26).¹⁴

Phenacetin-containing analgesics have been consistently related to renal cell carcinoma in several epidemiologic

studies. Acetaminophen has not yet been investigated as extensively. While Sandler and colleagues demonstrated an association of acetaminophen with chronic kidney disease, the risk of renal cancer associated with this analgesic is not currently known.¹⁷

Hereditary forms of renal cell cancer have also been identified. These cancers tend to occur earlier and are more likely to be bilateral and multifocal. It has been hypothesized that tumor development in individuals with these cancers may be associated with an alteration of a tumor suppressor gene at the short arm of chromosome 3.

Other risk factors that have been found to be associated with renal cell carcinoma include meat consumption, northeastern European ancestry, and prior kidney stones and infections. Coffee consumption has not been identified as a risk factor. Long-term users of renal dialysis, and those who develop acquired cystic kidney disease, have also been shown to have elevated numbers of renal cell cancer in several recent studies. These latter risk factors suggest that prior injury may predispose an individual to the development of renal cancer.

TOXICOLOGIC STUDIES

Many known carcinogens – for example, asbestos and lead – have been found to cause renal cancer in animals. Animal studies in mice also have shown a clear dose–response relationship between unleaded petrol vapor and renal cell cancer, suggesting a carcinogenic role for gasoline. Several organic compounds have been shown to induce renal cancer in animals, including vinylidene chloride, dichloroacetylene, nitrosamines, PAHs, aromatic amines, coumarins, and various dyes.

A toxicologic study by Walker and associates identified a gene that predisposes rats to develop renal cancer after exposure to a chemical carcinogen.¹⁸ Those rats that carried a single mutation on chromosome 4 had a 70-fold increased risk of developing renal cortical tumors compared with wild rats. These results suggest the involvement of tumor suppressor genes in the development of this cancer; a mutation in one allele predisposes susceptibility to the development of cancer if a spontaneous mutation by an environmental carcinogen occurs in another allele. This study provides valuable insight into the mechanisms of carcinogenesis in kidney cancer. Some studies have examined the role of glutathione S-transferase (GST) and variations in some of the GST genes in the etiology of renal cell carcinoma. A population-based case–control study found that those with GSTT1 null

gene were almost five times as likely to develop renal cell carcinoma.¹⁹

OCCUPATIONAL STUDIES

Epidemiologic research on the role of occupational factors in the development of renal cancer has been conducted through both large occupational cohort studies of cancer mortality and case-control studies. The former have the advantage of relatively specific information on exposure, while usually containing minimal information on potential confounders (i.e., smoking, BMI), while the latter usually are able to address the confounders but are often limited by imprecise information on occupational exposures. In addition, these studies possess other weaknesses, such as difficulty in assessing exposures, recall bias, and lack of statistical power due to the relative rarity of the cancer.

While earlier large occupational cohort mortality studies were suggestive of increased cancer risk, recent studies have specifically addressed this issue. Since these studies have often not distinguished between different types of renal cancer, the following section only discusses occupational factors in relation to renal cell carcinoma. Table 30.4.2 shows the major exposures and occupations that have been examined in relation to renal cell carcinoma to date.

Hydrocarbons

Polyaromatic hydrocarbons

Little direct work has been conducted over the last decade to expand our knowledge on the role of PAHs in renal cell carcinoma. The combustion of organic materials, such as coke or coal, has been associated with renal cancer in several studies. Redmond and coworkers studied men who were employed between 1950 and 1955 at one

of 10 coke plants.²⁰ After adjusting for potential confounders, they observed a relative risk of 7.5 for renal cell cancers among coke oven workers. Those workers were presumed to be exposed to byproducts of coke and coal combustion.

Coal tar pitch and petroleum coke combustion volatiles also appeared to be involved in the high rate of renal cancer mortality seen in Rockette and Arena's study of workers from 14 aluminum reduction plants.²¹ Those individuals who worked in an area where carbon anodes were prebaked were exposed to volatile agents containing PAHs and showed an increased standardized mortality ratio (SMR) for renal cell carcinoma. In a case-control study in Canada, the authors found an increased risk of 1.7 for exposure to burning coal, after controlling for smoking.²² Exposure to coal tar pitch also was found to be significantly associated with increased risk for renal cell cancer.

Petroleum-based hydrocarbons

Since the International Agency for Research on Cancer (IARC) conducted its last comprehensive review of epidemiologic studies of oil refinery workers in 1989, and classified the workplace environment as containing probable human carcinogens, a number of new studies, updates of cohorts, and meta-analyses have been published.^{14,23-27} Petroleum products such as gasoline, chemicals found in distilled fuel oils or oil mist, and PAHs have been suggested as the possible carcinogens. Gasoline, in particular, has been suspected because of its high aromatic content.

Recently, two papers examined both active and terminated workers and retired workers separately.^{23,28} These studies have observed a small increased risk for kidney cancer. In the active and current workers this reached statistical significance, with the point estimates for the SMRs virtually identical (active and terminated workers, SMR = 144; retirees, SMR = 140). A recent case-control

Occupations	Chemicals	Probable	Possible
Aluminum pot-room workers	PAHs	X	
Carbon electrode bakers	PAHs	X	
Coke oven workers	PAHs	X	
Dry cleaners	Perchloroethylene		X
Electric utility transformer repairmen	Organic solvents, PCBs		X
Ferrosilicon and silicon metal workers	Metal fume, organic solvents		X
Formaldehyde production	Formaldehyde		X
Foundry workers	Asbestos, metal fume, PAHs	X	
Gas station attendants	Gasoline	X	
Insulators	Asbestos	X	
Lead battery manufacturing	Lead		X
Lead smelter workers	Lead, arsenic		X
Newspaper pressmen	Lead, organic solvents	X	
Petrochemical and oil refinery workers	PAHs, gasoline, aliphatic hydrocarbons	X	
Phenol production	Phenol		X
Rocket-test stand workers	Hydrazine, TCE		X
Sheet metal workers	TCE		X
Uranium processing workers	Uranium, TCE		X
Welders	Asbestos, cadmium, organic solvents		X

PAHs, polyaromatic hydrocarbons; PCBs, polychlorinated biphenyls; TCE, trichloroethylene

Table 30.4.2 Occupational risk factors for renal cell carcinoma

study of kidney cancer in Canada found odds ratios of 3.9 (95% CI, 1.6–9.8) and 3.6 (95% CI, 1.4–8.8) in workers with an exposure to jet fuel or aviation gasoline.²⁹ Although further investigation is still clearly needed in this area, the available research does suggest that exposure to petroleum products in oil refineries, as well as in distribution, is likely to increase risk of renal cancer.

Organic solvents

A number of case-control studies have also found a positive association between hydrocarbons and renal cell carcinoma. McLaughlin and colleagues demonstrated a statistically significant increased relative risk of 2.6 for workers with 20 years or greater on the job.¹⁰ In a case-control study of 210 cases of renal cell carcinoma, Kadamani and colleagues similarly found increased risk for moderate hydrocarbon exposure, with an odds ratio of 3.5 with high cumulative solvent exposure.³⁰ A greater than 3.4-fold risk was also associated with exposure to mixed non-chlorinated solvents in a large Finnish study of 672 cases of renal cell cancer. Whether other specific organic materials are renal carcinogens in human populations continues to be an area of active investigation. A review of the question of the potential role of trichloroethylene and perchloroethylene in renal cell cancer failed to reach any definitive conclusions.³¹ The authors evaluated seven cohort studies and six case-control studies. Only three of the cohort studies and two of the case-control studies observed an excess, and in only one cohort study was the result statistically significant. It was concluded that future studies need to have large populations and quantitative exposure estimates to further characterize dose-related risk.

Other studies have been conducted with regard to the potential role of gene interaction (GST) in workers exposed to trichloroethylene.³² Elevated odds ratios were observed for both those with GSTM1+ (OR = 2.7; 95% CI, 1.2–6.3) and those with GSTT1+ (OR = 4.2; 95% CI, 1.2–14.9). A more general review of this subject, that examined both the mechanistic issues as well as the occupational epidemiologic data, concluded that the issue was far from settled conclusively.³³

With respect to other specific organic solvents, a cluster of renal cancer cases was observed in a group of workers employed in the repair and refurbishment of electrical transformers.³⁴ The exposures included organic solvent systems used in epoxy coatings for transformers, as well as polychlorinated biphenyls (PCBs), with which the transformers were filled. The authors suggested that the solvents may have acted as initiators, with the PCBs potentially acting as promoters.

A study of mortality in 8854 workers exposed to acrylamide observed only small increases in risk of kidney cancer (SMR 1.1; 95% CI, 0.7–1.6).³⁵ The study also failed to observe a dose response; however, this is not surprising with only 22 cases of kidney cancer in the cohort. Perhaps more importantly, when workers with mean intensity of exposure >0.02 mg/m³ were considered (*n* = 5), the SMR increased to 1.7; although not statistically significant, this is suggestive of a possible causal linkage.

Metals

Cadmium

Cadmium, a potential animal carcinogen and a nephrotoxin, has also been associated with an increased risk of renal cancer. A case-control study by Kolonel identified 64 renal cancer cases in white males admitted to one hospital and 269 controls.³⁶ A relative risk of 2.5 was found for workers exposed occupationally to cadmium. In addition, a synergistic effect was demonstrated between smoking and cadmium exposure, with a relative risk of 4.4. A 1991 study in Finland of 338 cases of renal cell carcinoma also found a suggestion of elevated risks in individuals exposed to cadmium.³⁷ While studies are suggestive of an association of cadmium and renal cancer, further research is required to characterize this risk.

Lead

A mortality study in a cohort of lead smelter workers has been reported by Selevan and coworkers.³⁸ The exposure to lead in the smelting process was considered to be heavy, averaging over twice the consensus standard established in 1965 for air-borne lead exposure of 200 µg/m³. An SMR of 301 (98 to 703), associated with five deaths, was found for kidney cancer in this study. In addition, a significant SMR of 392 for chronic kidney disease was found for exposure lasting more than 20 years. Results for both chronic renal disease and renal carcinoma have been variable in subsequent studies. A recent review and meta-analysis by Steenland and Boffetta of eight studies of lead smelter and battery workers – 40 total cases of renal carcinoma – found little evidence of lead as a risk factor for kidney cancer, observing a relative overall risk of 1.01 (95% CI, 0.7–1.4), with only two of the eight studies demonstrating a risk greater than 1.³⁹ The existing evidence for lead as a renal carcinogen thus remains inconclusive.

Steel, aluminum, ferrosilicon and silicon metal

Studies at steel and aluminum reduction plants have shown elevated rates of renal cancer in some workers. In addition, a recent study of ferrosilicon and silicon metal facilities in Norway observed a small excess of cancer of the kidney and ureter in both furnace (standardized incidence ratio [SIR] = 1.3; 95% CI, 0.66–2.38) and non-furnace (SIR = 1.7; 95% CI, 1.03–2.55) workers.⁴⁰ As discussed earlier, however, these risks are thought to be due to PAHs generated in processing, as well as organic solvents used in cleaning the metals; the role of these metals remains unclear.

Asbestos

A large number of studies have been carried out to examine the mortality of workers exposed to asbestos. While they have primarily focused on lung cancer, a number of studies have observed increased risk of kidney cancer as well. Selikoff's study of 17,800 insulators found 18 deaths due to renal cancer when 8.1 were expected, yielding an SMR of 222, which was statistically significant.⁴¹ These

results were supported by two other long-term cohort studies of use of asbestos products in Italian factory and shipyard workers. A recent meta-analysis of 37 cohort studies was carried out at the IARC.⁴² As is often the case with cohort studies, the actual number of kidney cancer deaths was limited ($n = 169$). The pooled SMR for these studies was 1.1 (95% CI, 0.9–1.6).

The positive epidemiologic studies are supported by several toxicologic experiments of asbestos exposure. It is clear that it is possible for asbestos fibers to reach the kidney, presumably through the blood or lymphatic system. Autopsy studies of individuals have found asbestos bodies in the kidney. Amphibole fibers have also been demonstrated in urine. In conclusion, while there is evidence for a causal association between asbestos exposure and renal cancer, the magnitude of the risk is likely to be relatively small compared with that for lung cancer.

Uranium

There have been two studies that have observed an increased risk of renal cell carcinoma in workers processing uranium.^{43,44} While the former study observed a dose-response association with radiation exposure in general, studies of ionizing radiation have not noted similar increases in risk.^{45–49} In addition to ionizing radiation, other chemical exposures related to the processing may be confounders. Interestingly, in a study of 2514 workers at a uranium processing plant, in addition to renal cell carcinoma, the authors also observed increased mortality for chronic nephritis (OR = 1.9; 95% CI, 0.8–3.8).⁴³

Other associated occupations

Several other occupations have been suggested to be associated with renal cell carcinoma, including ferrochromium workers, rocket-engine test-stand personnel, newspaper web pressmen, printers, and white-collar workers. The excess in kidney cancer (5 versus 1.6 expected) seen in one study of newspaper web pressmen is notable, given the substantial exposure to organic solvents as well as lead in this industry. A study of workers involved in rocket-engine testing found an association between exposure to hydrazine-based fuels and increased relative risk of death from bladder and kidney cancer (RR = 1.8; 95% CI, 0.6–5.1).⁵⁰ The authors indicate that there was significant exposure to trichloroethylene in the same procedures that utilized the hydrazine. The increased risk in white-collar workers, such as physicians, found in several studies, is thought to be related to increased levels of other risk factors associated with renal cell carcinoma, including obesity, meat and fat consumption, analgesic use, as well as increased diagnostic surveillance.

WILMS' TUMOR

The general epidemiology of Wilms' tumor has only recently been understood. There appears to be both a genetic and non-genetic form of this cancer. The genetic cases are more

likely to be bilateral and show nephroblastomatosis on pathologic examination. The genetic form is not familial in nature but reflects mutations in the germ cells before conception.

A case-control study of 88 Wilms' tumor patients identified both maternal and paternal risk factors for Wilms' tumor.⁵¹ The increase was highest in those whose fathers held jobs as machinists and welders during preconception (OR = 5.3; $P = 0.006$). Maternal use of hair dyes in the preconception period revealed a statistically significant odds ratio of 3.6. Other gestational risk factors included hypertension during pregnancy, tea drinking, and vaginal infection. Older maternal age was associated with the genetic form of Wilms' tumor. In a study carried out in England of paternal exposures and childhood cancer, the only statistically significant finding was for exposure to pesticides (proportional mortality ratio [PMR] = 1.6; 95% CI, 1.2–2.2).⁵² A review was carried out of 48 published epidemiologic studies regarding childhood cancer and parental occupation.⁵³ Of the 48 studies, only five addressed the issue of Wilms' tumor, the previously cited Bunin et al. study⁵¹ among them. One study attributed the increased risk to parental exposure to lead, the others to various occupations, including manufacturing of wood and furniture, iron and metal structures, and electrical contracting.⁵⁴ Another study found associations between maternal exposure to PAHs and Wilms' tumor.⁵¹ The overall status of parental exposure and Wilms' tumor, certainly suggestive of an association, warrants further investigation.

30.5 Cancer of the Liver and Gastrointestinal Tract

Howard Frumkin, Patricia Blackwell

The gastrointestinal tract, considered as a whole, is the most common site of cancer incidence worldwide.¹ It is also the most common cause of cancer mortality worldwide, and in the US ranks second to cancer of the pulmonary system in this regard.^{2,3} This chapter considers occupational and environmental contributions to cancers at several sites: the esophagus, the stomach, the colon and rectum, the liver, the gallbladder, and the pancreas. These cancers are summarized in Table 30.5.1.

The cancers discussed in this chapter share several common features. Most are adenocarcinomas, with the exception of esophageal cancer, in which both squamous cell cancer and adenocarcinoma are common. Most of these cancers exhibit strikingly variable incidence rates in geographic comparisons and migrant studies, suggesting substantial contributions from environmental factors. Diet, infectious agents, and alcohol and tobacco use generally have been implicated more than chemical or other workplace exposures. Most gastrointestinal cancers do not cause symptoms until they are relatively far advanced, resulting in poor prognoses. The primary treatment is surgical. Unfortunately, with the important exception of colorectal cancer, effective means of early detection are not available.

SPECIFIC DISORDERS

Esophageal cancer

Etiology

An interesting feature of the epidemiology of esophageal cancer is its tremendous geographic variation, ranging over 500-fold from nation to nation and within nations. The highest rates occur in a belt from the Caspian littoral in Turkey and northern Iran, through the southern republics of Kazakhstan, Uzbekistan, and Turkmenistan, to northern and eastern China, as well as in parts of southern and eastern Africa, India, and Sri Lanka. Rates are much lower in most of Europe and North America. In the US, the incidence is higher in blacks than in whites, and is higher in males than in females. Throughout the world, esophageal cancer rates are higher in lower socioeconomic classes.⁴

This geographic and class variability strongly suggests environmental determinants, and many have been identified. Alcohol consumption and tobacco use are recognized as important causes, especially in developed nations and in Africa. In parts of China with a high incidence of esophageal cancer, domestic fowl also exhibit a high incidence of pharyngoesophageal tumors, suggesting a common environmental cause, perhaps nitrosamine contamination of water, fungal agents, or both. In India, the chewing of betel nuts is associated with esophageal cancer. The use of hot drinks also may be a risk factor. Dietary factors⁵ may play a role; some populations with a high incidence of esophageal cancer eat high-grain diets low in

vegetables, fruits, and animal products. Fumonisin B(1), a mycotoxin produced by *Fusarium verticillioides* that contaminates maize and other grains, especially in Africa, has been linked to esophageal cancer risk. Radiation is carcinogenic to the esophagus, and pre-existing conditions such as achalasia, lye injury, and Plummer-Vinson syndrome also are risk factors for esophageal cancer. Human papilloma virus is a suspected cause of esophageal squamous cell carcinoma, although results across studies have been inconsistent.⁶

Beginning in the early 1980s, a rising incidence of adenocarcinoma of the esophagus was noted, particularly in white males.⁷ While squamous cell carcinoma remains the predominant histologic type for esophageal cancer worldwide, in some centers adenocarcinoma has come to predominate. Most cases of adenocarcinoma of the esophagus occur in individuals with Barrett's esophagus (intestinalized mucosa lining the lower esophagus⁸), related to gastroesophageal reflux. Of possible etiological factors investigated, obesity⁹ is the best established.

Relatively few occupational exposures have been clearly associated with esophageal cancer.¹⁰ Table 30.5.2 shows industries, exposures, and occupations for which such observations have been made. However, few firm conclusions can be drawn at present with regard to the observations in Table 30.5.2 for several reasons: most of the observations are unique and have not been corroborated; opposing evidence exists in some cases; and confounders such as smoking, alcohol use, and social class often were not adequately controlled. Interestingly, several studies have shown that farmers have a lower-than-expected rate of esophageal cancer; the significance of this observation is unclear.

There is relatively more information on asbestos exposure as a cause of esophageal cancer, but the evidence is equivocal.¹¹ Similarly, considerable evidence is available on the rubber industry, but this, too, is equivocal. Because worker exposures often vary within the same facility, exposure misclassification may have obscured a true association in some studies. Straif and collaborators¹² reported increased rates of esophageal cancer in rubber workers exposed to nitrosamines.

Other notable observations include an association between esophageal cancer and two exposures, sulfuric acid and carbon black, in the large case-control study database at Institut Armand-Frappier in Quebec,¹³ an elevation of esophageal cancer among workers with potential exposure to silica dust and chemical solvents or detergents in data from the National Center for Health Statistics,¹⁴ and an association between cutting oils and cancer of several gastrointestinal sites, including the esophagus, in several studies.¹⁵

Diagnosis, treatment, and prognosis

The diagnosis and treatment of esophageal cancer in the workplace do not differ from those of esophageal cancer in

Origin	Approximate US incidence (/100,000)	Major cell type	Five-year survival (%)
Esophagus	3.9	Squamous/adenocarcinoma	14.8
Stomach	6.7	Adenocarcinoma	22.6
Colon-rectum	43.9	Adenocarcinoma	62.0
Liver	4.3	Adenocarcinoma, angiosarcoma	5.5
Gallbladder	1-2	Adenocarcinoma	<10
Pancreas	8.8	Adenocarcinoma	4.6

Table 30.5.1 Cancers of the gastrointestinal tract

Industries and exposures	Occupations
Aluminum reduction plant	Brickmakers and brickmasons
Asbestos	Brewery workers
Automobile repair/body shops	Chimney sweeps
Benzidine	Diagnostic X-ray workers
Biogenic silica (sugar-cane workers)	Dry-cleaning workers
Bitumen	Dye workers
Carbon black	Firefighters
Cutting oils, mists	Janitors and cleaners
Hazardous waste sites	Laborers
Inorganic silica	Painters
Meatpacking	Plutonium workers
Metal working	Police officers
Mineral spirits	Restaurant workers
Nitrosamines	Roofers
Pesticides	Rubber workers
Petroleum products in potable water	Shoemakers
Phenol	Stonemasons
Polycyclic aromatic hydrocarbons	Textile workers
Printing	Wood and forestry workers
Pulp and paper	
Silica dust	
Styrene-butadiene polymerization	
Sulfuric acid	
Synthetic abrasives manufacturing	
Toluene	

Table 30.5.2 Industries, exposures, and occupations in which high rates of esophageal cancer have been reported

the general population, and these topics are beyond the scope of this text.

Opportunities for screening and early detection in the workplace

Screening for esophageal cancer has been attempted in high-incidence areas, using esophageal cytology specimens obtained with brush or abrasive balloon,¹⁶ and in some studies using endoscopy with biopsy. Balloon cytology is more suitable to workplace screening because it is far more rapid and less invasive than endoscopy. However, the Chinese program was conducted as part of a study of the prevalence of epithelial dysplasia, and it did not yield full data on test sensitivity and specificity, opportunities for early treatment, outcomes, or screening costs. Moreover, no occupational groups have been identified with a risk of esophageal cancer even approaching that of northern China. Therefore, workplace screening cannot be recommended based on currently available data.

Gastric cancer

Etiology

Gastric cancer incidence varies substantially from region to region; among nations that collect data, gastric cancer mortality is highest in the Russian Federation, Kazakhstan, Chile, and Japan, and lowest in the US, Canada, New Zealand, and Australia. Migrant studies, especially of Japanese living in the US, have also revealed dramatic decreases in incidence over one or two generations. These observations strongly implicate environmental factors in the etiology of stomach cancer.

Whatever the environmental factors, they are likely to be associated with poverty, because many studies have shown a strong association between low socioeconomic status and gastric cancer incidence. Dietary factors are likely to be important. One dietary risk factor is nitrates and related compounds, which are found in dried, smoked, salted, and pickled foods, cured meats, green vegetables, and, sometimes, drinking water. Nitrates are converted to nitrites by oral bacteria and then to nitrosamines by combining with dietary secondary amines. On the other hand, many studies have found the consumption of fresh fruits and vegetables to be protective. Radiation can cause gastric cancer, whereas the evidence implicating cigarette smoking and alcohol consumption is less consistent. Other risk factors include blood group A, pernicious anemia, and, possibly, gastric ulcer disease. Cancer of the gastric cardia is thought to be similar to esophageal adenocarcinoma in etiology.

Several benign disorders of the stomach are considered premalignant; examples include chronic atrophic gastritis, *Helicobacter pylori* infection, intestinal metaplasia, and gastric dysplasia. When such a condition is associated with an occupational exposure, then the exposure may be considered a risk factor for gastric cancer. For example, methyl methacrylate exposure causes chronic gastritis, and, therefore, it has been considered a risk factor for gastric cancer in Russia.

In individual studies, a wide variety of occupational factors has been reported to be associated with gastric cancer^{10,17,18} (Table 30.5.3). Again, many of these observations cannot support firm conclusions because they are for the most part uncorroborated, and there is opposing evidence in some cases. Most occupational studies have not controlled for social class, a potentially important confounder because both occupational status and the disease are class related.

Industries and exposures	Occupations
Acetylene production	Aluminum reduction workers
Air pollution (petrochemical plants)	Brickmakers
Asbestos	Carpenters
Pulp and paper manufacturing	Ceramic workers
Auto body/repair shops	Chemical workers
Azo dyes	Chemists
Styrene-butadiene polymerization	Concrete workers
Coal dust	Divers
Electronics manufacturing	Dockers and freight handlers
Ethylene oxide	Farmers
Rubber manufacturing	Firefighters
Fertilizer manufacturing	Fishermen
Gasoline (leaded)	Forestry workers
Glass manufacturing	Granite workers
Gold mining	Hematite miners
Halogenated hydrocarbons	Jewelry workers
Hazardous waste sites	Machinists and metal workers
Hydraulic fluids	Painters
Kerosene	Plumbers
Lead	Plutonium workers
Metal dust	Radium-dial painters
Magnesium production	Railroad workers
Silica	Shoemakers
Nickel/chromium plating	Steel foundry workers
Pesticides	Stonemasons
Petroleum refining and petrochemicals	Tin miners
Rock wool manufacturing	Tool and dye workers
Phenoxy herbicides	Truck drivers
Sulfuric acid	
Synthetic abrasives manufacturing	
Wood dust/furniture making	
Wood fuel use	

Table 30.5.3 Industries, exposures, and occupations in which high rates of gastric cancer have been reported

An interesting and frequent observation is the association of dusty work with gastric cancer risk. Data are available for coal dust, silica, and asbestos. *Coal dust* has emerged as a risk factor for gastric cancer in many studies.^{19,20} The mechanism of gastric cancer induction by coal dust is unknown. Constituents such as polyaromatic hydrocarbons (PAHs) and metals may act as carcinogens, or nitrosation of coal dust constituents may create the active carcinogens. The risk of gastric cancer may be confined to coal miners with no or mild pneumoconiosis, perhaps because more severe pneumoconiosis entails defects in respiratory clearance that exposes the gastrointestinal tract.¹⁹ Dusty trades^{21,22} such as cement and quarry work, granite work, and other kinds of mining, many of which entail *silica* exposure, carry an elevated risk of gastric cancer. Finally, *asbestos* exposure has been associated with gastric cancer in numerous studies,^{23–25} although not all studies confirm this association. The best estimate is that lifelong exposure to high levels of asbestos carries a relative risk of approximately 1.3.

Several other exposures deserve special mention. Workers exposed to *wood dust and its derivatives*, such as furniture makers and paper workers,²⁶ have been extensively studied and show a consistent increase in gastric cancer risk. *Farmers* also have higher rates in most studies.²⁷ Lead exposure has been associated with gastric

cancer, but results have been inconsistent across studies.²⁸ *Metalworking and related activities*²⁹ have been associated with an increased risk of gastric cancer in several studies. Although cutting oils have been implicated, other exposures such as solvents, abrasives, metals, and nitrosamine contaminants may play a role as well. Studies of workers in the *rubber industry*³⁰ have shown consistent elevations of gastric cancer.

Diagnosis, treatment, and prognosis

The diagnosis and treatment of gastric cancer in the occupational setting are identical to those occurring in the general population, and they are beyond the scope of this text. Prognosis is affected by the stage at diagnosis. Five-year survival ranges from 78% in AJCC stage IA disease to 7% for stage IV cases.³¹

Opportunities for screening and early detection in the workplace

Several techniques have been considered for gastric cancer screening. Large-scale gastric cancer screening has been conducted in Japan since the 1960s, using image-intensified photofluorography at fixed locations and in mobile vans. Reports of high sensitivity and specificity, earlier average stage at diagnosis, and improved survival³² have appeared. However, even in the high-risk Japanese population, the positive predictive value of the test is probably less than 2%. In China and the former Soviet Union, screening programs have attempted to identify high-risk individuals based on symptoms, history, or both, followed by referral for gastroscopy. The efficacy and cost-benefit features of these programs have not been reported. Other screening methods that have been attempted elsewhere, generally in endemic areas of Asia, include an occult blood detector that is swallowed and extracted from the stomach after a few minutes and tests for monoclonal antibodies. Widely available tests for *H. pylori* may provide a cost-effective screening test to target individuals for antibiotic treatment or gastroscopy. The ratio of pepsinogen type I (PGI) to pepsinogen II (PGII) decreases in proportion to the extent of gastric atrophy, and is a potentially useful test for selecting individuals for cancer screening. However, because no screening method has been sufficiently characterized or subjected to randomized trials, and because no occupational groups in the US are known to have such a markedly elevated risk of gastric cancer, workplace screening for this tumor cannot be recommended at present.

Colorectal cancer

Etiology

Like other gastrointestinal cancers, colorectal cancer has a highly variable incidence across different populations and in migrant studies. Diet is known to play a major etiologic role.³³ High-fat diets confer increased risk, probably mediated by the production of endogenous bile acids. High fiber intake, and perhaps a high intake of calcium, folate, or yellow-green vegetables are associated with decreased

risk. Several studies have shown non-steroidal anti-inflammatory agents to lower the risk of colon cancer. Lichtenstein et al.,³⁴ in a twin study, calculated that 35% of colon cancer risk could be attributed to genetic factors. Several hereditary syndromes, such as familial polyposis, are associated with a substantial increase in the risk for colon cancer. Other risk factors for colorectal cancer include inflammatory bowel disease, ureterosigmoidostomy, *Streptococcus bovis* bacteremia, and, perhaps, cholecystectomy. Most colonic cancers arise from polyps, and the presence of polyps may be an independent risk factor.

Colon cancer rates vary by subsite of origin, and the incidence of cancer at different subsites varies by age, gender, race, and geographical region.³⁵ Recent evidence suggests that colorectal cancers arising at different sites within the colon may represent genetically distinct diseases. Consistent with this theory, several investigators have found that work-related elevations in colorectal cancer tend to be site specific. Advances in molecular biology and epidemiology may clarify this finding in coming years.

The level of physical activity is a risk factor for colorectal cancer, and may be work related. Numerous studies have demonstrated that sedentary employment is associated with an increased risk of colon cancer, whereas high levels of physical activity seem to be protective. Interestingly, the protective effect seems most striking in the proximal colon, whereas results are less consistent with regard to rectal cancer.

Beyond this observation regarding physical activity, few workplace exposures have been consistently linked with cancer of the lower gastrointestinal tract.⁹ One exception is *asbestos*.³⁶ Frumkin and Berlin, in a meta-analysis,²³ calculated that substantial asbestos exposure confers a relative risk of about 1.6 for colorectal cancer, consistent with the value seen in the largest ongoing cohort study of asbestos workers. Smaller cohorts and studies of less intensely exposed workers have yielded less clear results. While evidence suggests that asbestos is a colorectal carcinogen, there remains some disagreement on this point.

Studies of the *rubber industry* have revealed a slightly elevated risk of colorectal cancer, although the risk is well below the relative risk for gastric cancer among rubber workers. Studies of *printers* and *pressmen* have shown a fairly consistent increase in colorectal cancer, as have studies of *automotive pattern and model makers*. *Wood dust* exposure in furniture makers has also been associated with colon cancer.³⁷ Other reports of exposed groups with increased colorectal cancer rates are shown in Table 30.5.4.

Diagnosis, treatment, and prognosis

The diagnosis and treatment of colorectal cancer are well described in standard texts and are not covered here. The prognosis depends upon how advanced the tumor is. Superficial tumors that do not cross the submucosa (stage A) have a 5-year survival better than 90%. Stage B tumors that infiltrate the muscularis or penetrate the bowel wall but do not involve lymph nodes have a 70% to 85% 5-year survival. Tumors that involve lymph nodes (stage C)

Industries and exposures	Occupations
Abrasives manufacturing	Accountants and auditors
Arsenic	Artists
Asbestos	Brewery workers
Automobile engine and parts manufacturing	Chemical workers
Bearing manufacturing	Chemists
Bitumen	Designers and draftsmen
Chlorination byproducts	Dockworkers
Clothing manufacturing (small intestine)	Farmers (small intestine)
Coke byproducts	Firefighters
Communications	Forest and soil conservationists
Copper smelting	Fur dressers and dyers
Crude oil	Janitors and housekeepers (small intestine)
Diesel exhaust	Lawyers and judges
Dry cleaning (small intestine)	Leather workers
Dyes	Machinists
Electronics manufacturing	Millwrights
Food manufacturing	Pattern and model makers
Formaldehyde	Plutonium workers
Fuel oil	Police officers
Gasoline exhaust	Printers and pressmen
Glass manufacturing	Radium-dial painters
Grain dust	Salesmen and sales clerks
Grinding wheel dust	Tailors and furriers
Hazardous waste sites	Textile workers
Meatpacking	Veterinarians
Metal dust	Waiters
Metal-working fluids	White-collar workers
Methyl methacrylate, ethyl acrylate	Woodworkers, furniture makers
Optical manufacturing	
Paint and coating manufacturing	
Pesticides	
Petroleum products trade	
Petroleum refinery	
Polypropylene manufacturing	
Rubber manufacturing	
Solvents	
Stress	
Synthetic fiber dust	

Table 30.5.4 Industries, exposures, and occupations in which high rates of colorectal cancer have been reported

have a 35% to 65% 5-year survival rate, and those with distant metastases have less than a 5% 5-year survival. Carcinoembryonic antigen (CEA), which is elaborated by colorectal and other tumors, may have a role in monitoring patients postoperatively for tumor recurrence.

Opportunities for screening and early detection in the workplace

For persons at average risk for colorectal cancer, the US Preventive Services Task Force³⁸ recommends home fecal occult blood testing annually, or periodic flexible sigmoidoscopy, or a combination of these approaches. While the Preventive Services Task Force does not specify the frequency of sigmoidoscopy, other groups^{39,40} recommend 5-year intervals. According to Preventive Services Task Force recommendations, colonoscopy may be substituted for flexible sigmoidoscopy. Again, the test interval is not specified, but other groups^{39,40} recommend every 10 years.

Double-contrast barium enema is considered a less effective option, and digital rectal examination has not been

shown to be of use. Although flexible sigmoidoscopy may miss some proximal lesions, the increased expense and complication rate of colonoscopy render it a less cost-effective screening option. Insufficient data exist at present to evaluate the effectiveness of newer technologies, such as virtual colonoscopy or stool screening for DNA abnormalities.

Some workplace screening programs for colorectal cancer have been implemented, not because of any presumed job-related increase in risk, but because such screening was considered generally advisable and the workplace was a convenient screening site. Certainly, the workplace may be a suitable venue for cancer screening and other health interventions that are generally beneficial.

In specific industrial settings believed to confer increased risk – most notably among pattern makers, asbestos workers, and polypropylene manufacturing workers – screening programs have been implemented. These programs have generally achieved participation rates of 50% or less. Non-participants identified various reasons for their reluctance, including inconvenience, embarrassment, anxiety, a belief that the procedure was unnecessary, and a belief that they were at low risk, factors generally similar to those cited by non-participants in screening programs in the general population. Moreover, there is no evidence that colorectal cancer screening in any specific occupational group (beyond that recommended for the general public) results in decreased morbidity and mortality. Firm recommendations on workplace screening must await further data on the general utility of colorectal cancer screening and on specific risks of various occupational exposures.

Liver cancer: hepatocellular carcinoma

Etiology

Liver cancer is one of the most common cancers in Africa and Asia, although it is relatively uncommon in Western countries. The usual cell type is hepatocellular carcinoma (or hepatoma). Liver cancer is two to three times more common in men than in women, probably reflecting greater male exposure to the causative agents and perhaps hormonal factors as well. Three risk factors account for most hepatocellular carcinoma worldwide:

- hepatitis B or C⁴¹ virus;
- alcohol; and
- aflatoxin.

Recent advances in molecular epidemiology have permitted investigation of possible interactions among these risk factors.⁴² About 75% of cases occur in patients with cirrhosis. Hepatitis D virus is considered to contribute little if any risk of hepatocellular carcinoma.

Agents that induce liver cancer may do so by acting as initiators or promoters. Few occupations, industries, or environmental agents have been consistently associated with elevations of hepatoma incidence.^{10,43} Steenland and Palu⁴⁴ reported an increase in liver cancer among painters.

Industries and exposures	Occupations
Abrasives manufacturing	Accountants
Aflatoxin-contaminated dust (oil mills, livestock feed processing)	Bartenders
Arsenic	Brewery workers
Arts, theater and recreation	Business executives
Asbestos	Chemical plant maintenance workers
Auto repair shops	Chimney sweeps
Automobile engine and parts manufacturing (machining/assembly plant)	Construction workers
Benzene	Diagnostic X-ray workers
Chemical industry	Farmers
Diesel exhaust	Fishermen
Dry cleaning	Grain millers
Dye, paint and oil stores	Insulation workers
Flower shops	Insurance agents
Formaldehyde	Jewelry workers
Gasoline service stations	Metal workers
Shoe manufacturing	Painters
Highway construction	Physicians
Incinerators, solid waste	Plumbers and pipefitters
Metal product manufacturing	Police officers
Nickel and chromium plating	Pressmen
Nickel alloy production	Rubber workers
Paper and graphics industry	Salesmen (travelling and door-to-door)
Pesticides	Service workers
Polychlorinated biphenyls	Slaughterhouse workers
Restaurant and hotel industry	Waiters
Retail foods	Woodworkers
Rubber manufacturing	
Solvents	
Wool manufacturing	

Table 30.5.5 Industries, exposures, and occupations in which high rates of liver cancer have been reported

Cirrhosis was also increased within this group, but it was felt that alcohol consumption only partially accounted for the increased cancer incidence. Workers in nuclear weapons production plants have been reported to experience an increased incidence of liver cancer.⁴⁵ Although increases in liver cancer have been seen in some studies of rubber workers and asbestos workers, these findings are not consistent across most studies. A recent study of women workers found little evidence of occupational liver cancer increases.⁴⁶ Other observed elevations of liver cancer, mostly isolated, appear in Table 30.5.5.

Some occupational groups are heavily exposed to agents that are known to cause liver cancer but that are not normally considered occupational carcinogens. Thus, brewery workers show an increased risk of liver cancer, probably related to increased alcohol consumption. Similarly, healthcare workers and prostitutes may be exposed to hepatitis B virus, and grain handlers and other food preparation workers may be exposed to aflatoxin. Premalignant conditions also should be considered. Solvent-exposed workers have been shown to develop hepatic necrosis and potentially fibrosis, at least after massive accidental exposure; in such uncommon cases, occupational liver cancer must be considered a possibility, even if no risk has yet been demonstrated for the solvent, per se.

Diagnosis, treatment, and prognosis

Useful diagnostic measures include radionuclide scans, ultrasound examinations, and computed tomography (CT) and magnetic resonance imaging (MRI) scans, but the most informative non-invasive test is angiography. Both hepatomas and hemangiosarcomas are hypervascular, as distinguished from hepatic metastases. Tissue diagnosis is made following biopsy, either with a percutaneous needle or at surgery. The only definitive treatment is surgical excision, but this is often precluded by an underlying illness such as cirrhosis and by the extent of the disease. The prognosis is poor, with median survival well under 1 year.

Opportunities for prevention, screening and early detection in the workplace

The hepatitis B vaccine represents an important opportunity for primary prevention of hepatitis B in healthcare workers at risk for occupational exposure to the virus. In these workers, both standard medical practice and Occupational Safety and Health Administration (OSHA) requirements⁴⁷ dictate that the vaccine should be routinely offered. In addition, serologic testing of workers with documented exposure to body fluids infected with hepatitis A or B may identify individuals requiring follow-up.

Early detection of hepatoma has been attempted in high-risk populations in China, Taiwan, South Africa, Italy, Alaska, and elsewhere. In most cases, screening has been targeted at chronic carriers of hepatitis B antigen and patients with cirrhosis, groups with substantially elevated risk. Two tests have received the most attention: alpha-fetoprotein and high-resolution ultrasonography. Alpha-fetoprotein alone is less than 50% sensitive in detecting small hepatomas. Even in the setting of large tumors, the sensitivity is only 85% to 90%. The specificity is well under 50% in some studies, because alpha-fetoprotein may increase in hepatitis and for other unknown reasons. These values can be varied considerably by redefining the upper normal limit of the test. Ultrasound alone is about 90% sensitive and 70% specific. The most successful programs have used both tests sequentially, following up abnormal alpha-fetoprotein values with ultrasonographic examination. Most studies have been unable to demonstrate any improvement in resectability or survival following screening. Therefore, routine screening for liver cancer in occupational groups, most of which have much lower risk than populations of cirrhotics and hepatitis carriers, cannot be recommended at this time.

Liver cancer: hemangiosarcoma

Etiology

A second form of liver cancer, hepatic hemangiosarcoma, is much rarer than hepatocellular carcinoma and is much more closely identified with occupational causes.⁴⁸ The world literature includes several hundred cases to date. Non-occupational causes include *thorotrast* (thorium dioxide), an alpha-emitter that was used as a radiographic

contrast agent from about 1930 to 1955, and *steroid medications* (both anabolic steroids and estrogen preparations). There are two major occupational and environmental causes: *vinyl chloride* and *arsenic*. An Egyptian report⁴⁹ suggests that organophosphate and organochlorine pesticides may be associated with hepatic angiosarcoma, but because the patients described also were exposed to arsenicals, the other pesticides could not be clearly implicated.

Arsenic exposure (see Chapter 39.2) has occurred following the use of Fowler's solution for medical purposes; following contamination of drinking water in Mexico, Taiwan, Chile, China, Argentina, and elsewhere; and following occupational exposure in agriculture, smelting, and wine making. Many studies of arsenic-exposed populations have described elevations of rates of liver cancer, mostly hemangiosarcoma but also including hepatomas.

Vinyl chloride exposure (see Chapter 41) was first associated with hemangiosarcoma when an alert clinician noted a cluster of cases in a polyvinyl chloride plant in Louisville in 1974.⁵⁰ Since then, numerous studies have confirmed an increased risk of hemangiosarcoma and of hepatoma in exposed workers and in animals. Recent evidence suggests a role for specific *k-ras-2* and *p53* mutations.^{51,52} Following deep reductions in occupational exposure to vinyl chloride in the US and Europe in the 1970s, hemangiosarcoma and hepatoma related to this substance have declined dramatically.

Diagnosis, treatment, and prognosis

Angiosarcoma is associated with non-specific symptoms such as anorexia, malaise, nausea, weight loss, and right upper quadrant pain. Physical examination usually reveals hepatomegaly by the time of presentation, and often reveals fever, jaundice, ascites, splenomegaly, and a liver bruit as well. Laboratory studies reveal abnormal liver function tests and often normochromic, normocytic anemia. Liver scan or ultrasound shows single or multiple filling defects, CT scan shows mixed-attenuation tumor mass, and hepatic angiography shows a hypervascular lesion.

Needle biopsy is risky because of the vascularity of the tumor, so open liver biopsy often is necessary to reach a diagnosis. Angiosarcoma arises from the endothelial or Kupffer cells that line the hepatic sinusoids, and it has a variable microscopic appearance (Fig. 30.5.1). In areas of the liver that are minimally involved, dilated sinusoids are lined by hypertrophied endothelial cells with atypical hyperchromatic nuclei. As the tumor advances, the sinusoids dilate and fill with malignant endothelial cells. Eventually, hepatocytes may be entirely replaced by massed tumor cells with extensive vascular channels. The malignant cells may have an epithelioid appearance similar to poorly differentiated carcinoma or a spindled appearance similar to fibrosarcoma, making microscopic diagnosis difficult.

Hepatic angiosarcoma can progress to hemorrhage, disseminated intravascular coagulation, or renal failure, and is rapidly fatal. Chemotherapy and radiotherapy have

Figure 30.5.1: Histology of angiosarcoma of the liver. Solid cellular masses are separated by blood spaces. The tumor cells are elongated with pleomorphic, hyperchromatic nuclei and ill-defined cytoplasm (hematoxylin–eosin stain, $\times 250$). (Courtesy of Dr Swan Thung.)

not been found to be helpful, and the role of local tumor resection and liver transplantation has not been defined.

Opportunities for screening and early detection in the workplace

Early detection of hemangiosarcoma has been attempted in vinyl chloride workers, but there is no evidence that outcomes are altered by such an effort. Primary prevention through containment of exposure rather than secondary prevention has proved feasible and extremely effective in the US; consequently, it is the preferred approach.

Gallbladder and biliary tract cancer

Cancer of the gallbladder and biliary tract is extremely rare in the US, and it is not generally considered occupational or environmental in origin. Cholangiocarcinoma has been induced experimentally in animals by feeding 3-methyl-4-dimethyl-aminoazobenzene.⁵³ Isolated observations⁵⁴ appear in Table 30.5.6, which cites reports of increased risk among forestry workers, rubber workers, automotive workers, textile workers, chemical workers, and shoemakers. Other industries in which some increase in risk has been observed include metal fabricating, aircraft, wood finishing, petroleum refining, and paper mills. Because workers in forestry, wood finishing, and paper mills have been

Industries and exposures	Occupations
Aircraft manufacturing	Automotive workers
Heavy metals	Chemical workers
Metal fabricating	Forestry workers
Paper mills	Shoemakers
Petroleum refining	Textile workers
Rubber manufacturing	
Wood finishing	

Table 30.5.6 Industries, exposures, and occupations in which high rates of biliary tract cancer have been reported

mentioned in this regard, it is interesting to speculate that a wood product may be specifically carcinogenic to the biliary tract. Shukla et al.⁵⁵ studied the relationship of biliary heavy metal concentrations and gallbladder cancer in an area of India with high drinking water concentrations of heavy metals. Thirty-eight patients with gallbladder cancer were found to have significantly elevated biliary levels of cadmium, chromium, and lead, compared with a control group of 58 patients presenting with benign cholelithiasis. This difference was particularly marked for biliary lead, with cases having a mean lead level of 58.38 mg/l, as compared with 3.99 mg/l for controls ($P < 0.001$).

Pancreatic cancer

Etiology

Cancer of the pancreas varies among populations relatively less than other gastrointestinal cancers, ranging from a high incidence of 20.8 per 100,000 per year among black men in central Louisiana⁵⁶ to a low incidence of 1.4 per 100,000 per year among women in Mauritius. Most populations have an incidence of between 5 and 10 per 100,000 per year. Because it is almost invariably fatal, pancreatic cancer is the fourth leading cause of cancer mortality in the US.

Pancreatic cancer is clinically associated with diabetes, pancreatitis, and gallbladder disease, although the nature of these associations is unclear. Both demographic (advancing age, black race, male gender, Jewish religion) and dietary (carbohydrates, cholesterol, meat, salt, dehydrated food, preservatives, refined sugar, nitrosamines) factors have been associated with an increased risk of pancreatic cancer.⁵⁷ A protective effect has been reported for dietary fiber, vitamin C, fruits and vegetables, pressure cooking, and microwave cooking. Cigarette smoking increases the risk of pancreatic cancer several-fold.

Few occupational exposures have been clearly and consistently associated with pancreatic cancer.^{10,58,59} Garabrant⁶⁰ reported a relative risk of 5 for *chemical workers* exposed to dichlorodiphenyltrichloroethane (DDT) and its metabolites. Several studies of *chemists* have shown an increased risk, all with relative risk less than 2. Workers in *petroleum refineries*, the *chemical industry*, and the *rubber industry* also have demonstrated an increased risk of pancreatic cancer, although results have been inconsistent in both settings. Finally, several studies of *mechanics* have suggested an increased risk of pancreatic cancer. Although each of these findings suggests a risk for chemical exposures, specific etiologic agents have not been identified. Other isolated occupational associations with pancreatic cancer are shown in Table 30.5.7.

Diagnosis, treatment, and prognosis

The diagnosis of pancreatic cancer is well described in standard texts and is not covered here. The only definitive treatment is surgical resection, either pancreaticoduodenectomy (the Whipple procedure) or total pancreatec-

Industries and exposures	Occupations
Acetylene production	Automobile assembly workers

Table 30.5.7 Industries, exposures, and occupations in which high rates of pancreatic cancer have been reported

tomy, but these are rarely possible because of tumor spread by the time of diagnosis. The prognosis is poor, with a median survival of less than 6 months.

Opportunities for screening and early detection in the workplace

No screening tests have proved useful in the early detection of pancreatic cancer.

30.6 Thyroid Neoplasia

Thomas E Hamilton

Thyroid cancer continues to be one of the most uncommon forms of carcinoma, although the prevalence has been increasing, with now over 15,000 cases and 1200 deaths annually in the US.¹ However, this information is misleading in terms of the impact of the condition on clinical practice. Thyroid carcinoma usually presents as a thyroid nodule, one of the most common clinical problems that physicians and healthcare professionals encounter. The prevalence of palpable thyroid nodules is as high as 4%–7% in the general population, thus making the evaluation of thyroid cancer common and important to understand.

In addition, during the last two decades, there has been increasing public interest and concern about the potential hazards of environmental exposures, particularly from radioactive iodine, stemming from nuclear accidents or nuclear weapons development. This concern was heightened in 1986 after the accident at the Chernobyl nuclear power facility, which released approximately 1.8×10^{18} becquerels (48 million curies) of radioactive iodine into the atmosphere. During that same year, the US Department of Energy revealed that large amounts of radioactive iodine (subsequently estimated to be 2.74×10^{16} becquerels [740,000 curies]) had been released into the atmosphere from the Hanford Nuclear Site in Washington State during plutonium production in the 1940s and 1950s.

CLINICAL EVALUATION

History

The evaluation of a thyroid nodule of environmental origin does not differ from that of a nodule found in general practice. Although most people presenting with thyroid nodules are asymptomatic, a complete history pertaining to the thyroid gland should be gathered, including time of onset, recent change in nodule size, and symptoms related to compression of vital structures in the neck, such as dysphagia and hoarseness.

Patients should be asked about past exposures to ionizing radiation, especially those that occurred 10 to 40 years prior to presentation. The most common risk to the thyroid gland involves prior head and neck treatment with external beam radiation therapy for disorders of childhood. These radiation exposures resulted from treatment of presumed enlargement of the thymus gland, facial acne, tonsillar enlargement, fungal infections of the scalp, and various infections of the cervical lymph nodes such as tuberculosis.² These treatments should be distinguished from diagnostic X-ray studies of the head and neck, which constitute little or no clinical risk for adults. Prior history of radiation treatment for non-thyroid malignancies such as for Hodgkin's lymphoma should also be obtained, since such exposures can also confer an increased risk of thyroid neoplasia.

Medications that may exert an indirect effect on the induction of thyroid neoplasms via the action of thyroid-stimulating hormone (TSH) include lithium and amiodarone. A family history of thyroid neoplasms should be obtained, and, if positive, specific inquiry for medullary histology should be made. Ethnic background and past residential history are important in determining the likelihood of dietary iodine that may promote the induction of thyroid neoplasia via TSH stimulation of the thyroid gland.

There is very little information about the effects of occupational, environmental, and medical exposures on thyroid cancer induction other than ionizing radiation. Although the evidence linking the risk of thyroid carcinoma to environmental radioiodine exposure has been mixed, a residential history should be obtained with emphasis on residence locations or military service around atmospheric nuclear test sites (e.g., Nevada Test Site, Marshall Islands), locations near nuclear weapons production facilities, or childhood residence near the Chernobyl reactor accident.

Physical examination

The thyroid gland is one of the more challenging areas of the body to examine and several important features deserve mention. The most important aspect of the examination is to have the patient swallow water. A full swallow enables the thyroid examiner to inspect the thyroid gland and to palpate the body of the gland more completely as it moves under the examiner's fingers, allowing the size, shape, and consistency of the gland to be noted. If discrete nodules are present, they should be described in detail and the size of each nodule recorded. A complete evaluation for thyroid abnormalities also should include listening for hoarseness; carefully examining the cervical lymph glands, eyes, skin, and hair; examining the deep tendon reflexes; and observing for the presence of tremor.

Laboratory examination

Routine thyroid function testing is generally normal in persons presenting with either a benign thyroid nodule or thyroid carcinoma. However, because 5% to 10% of thyroid nodules may function autonomously, measurement of TSH is indicated. Although thyroglobulin levels are important in detecting recurrent carcinoma after surgery and radioiodine therapy, this measurement is not sufficiently specific to warrant its use as an initial screening test. Use of fine needle aspiration for histologic assessment of suspect nodules is discussed in evaluation and treatment, below.

CLASSIFICATION

A general classification of malignant thyroid neoplasms is listed in Table 30.6.1. This classification belies the com-

Type	Prevalence (%)	Radiation association
Papillary adenocarcinoma	80–85	Yes
Follicular carcinoma	10–15	Yes
Medullary carcinoma	2–10	No
Undifferentiated (anaplastic) carcinoma	<5	Uncertain
Lymphoma	<1	No

Table 30.6.1 Pathologic classification of thyroid carcinoma

plexity of differentiating between benign and malignant lesions as well as among the subtypes within these categories. In addition, the international distribution of papillary and follicular histology is highly dependent on iodine sufficiency. Because the majority of thyroid carcinomas are papillary or follicular in histology and the association of nearly all environmental or occupational exposures is with papillary, the focus of the subsequent sections is on papillary and follicular carcinomas.

Papillary and follicular carcinomas

Etiology and epidemiology

Papillary and follicular carcinomas are both the most common thyroid cancers and also the ones most notably associated with occupational or environmental exposures, particularly ionizing radiation. These carcinomas comprise nearly 90% of all thyroid cancers.

Non-occupational factors

Age and sex are the two most important non-occupational risk factors for thyroid neoplasms. The prevalence of solitary thyroid nodules (both benign and malignant) is reported to be 2% to 4% in the US, with this number increasing to 7% to 8% in the seventh and eighth decades of life.³ The common occurrence in women has been a consistent finding, with a female-to-male ratio of at least 3:1 in most studies. There is no clear evidence that ethnic background is an important risk factor for thyroid neoplasia, although individuals of Jewish descent have been shown to have a higher risk of radiation-induced thyroid neoplasms.

Although data exist to suggest that familial factors may be involved in the pathogenesis of thyroid carcinoma,

this issue is far from settled. It remains uncertain whether the presence of a papillary or follicular thyroid neoplasm in a person with a family history of thyroid carcinoma is any more frequent than in age- and sex-matched members of the general population without a family history of thyroid neoplasm. There does appear to be an increased risk of papillary thyroid cancer in persons with colonic adenocarcinoma.

MEDICAL RADIATION EXPOSURES

External gamma or photon radiation

The most thoroughly studied etiologic agent of thyroid cancer is ionizing radiation. The evidence that most strongly supports ionizing radiation as a cause of thyroid cancer has arisen from historic cases in which children were treated with external gamma radiation for benign diseases of the head and neck (Table 30.6.2). The first such case, reported in 1907, involved a young boy whose pre-sumed enlarged thymus gland was thought to be the cause of respiratory distress; he responded after treatment with external X-irradiation. Over the next several decades, external beam radiation therapy was given for tonsillar enlargement, fungal infections of the scalp, facial acne, and cervical adenitis from tuberculosis. During the 1950s, several retrospective analyses indicated that adults with a history of childhood radiation exposure had a high prevalence of thyroid cancer.^{4–6} Since these initial reports, multiple cohort studies have clearly established that childhood exposure to external gamma radiation is a risk factor not only for papillary and follicular thyroid carcinoma but also for benign nodules of the thyroid.^{7–9} The magnitude of the risk has been estimated to be linearly dose dependent, with an excess relative risk per gray of 7.7 and highest for those exposed at young ages.¹⁰

Although most of these therapeutic regimens were abandoned by the late 1960s, the risk is still present because the latency for developing radiation-induced thyroid neoplasms has been shown to be 40 years or longer.

Therapeutic radioactive iodine

Much less information is available regarding the induction of thyroid carcinoma from medical uses of radioactive

Agent	Source	Mean thyroid dose estimate (Gy)	Effect	Reference
External gamma or photon radiation	Head and neck radiation treatments	0.09–1.36 (range)	Linear dose–response*	10
Diagnostic I-131	Diagnostic thyroid scans	1.1	No clear excess risk†	17
Therapeutic I-131	Patients with hyperthyroidism	na‡	No clear excess risk‡	12,13,15

† See text: excess risk documented but thought to be due to underlying condition
‡ See text: excess risk documented; however, it is uncertain whether it is related to I-131 exposure
¶ Doses not available; thyroid dose was generally targeted to be 60–100 Gy

Table 30.6.2 Risk of thyroid neoplasia from medical radiation exposures

iodine as compared with gamma or photon radiation. Large therapeutic doses of radioactive iodine have been used to treat Graves' hyperthyroidism. A large multicenter cooperative study in the 1970s assessed the long-term carcinogenic effects on the thyroid of iodine-131 (I-131) treatment in over 20,000 persons with Graves' disease and found no increase in thyroid cancer when compared with individuals who were treated with thyroidectomy (Table 30.6.2).¹¹ More recently, Ron and colleagues extended the follow-up of that cohort until 1990.¹² The mean age at radioiodine treatment was 46 years and the mean length of follow-up was 21.2 years. Although no excess risk was found in total cancer deaths, an increase in thyroid cancer was detected in patients treated with I-131 (standardized mortality ratio [SMR], 3.94; 95% confidence interval [CI], 2.52–5.86). However, the absolute risk was quite low, with few thyroid cancer deaths, and the increase was most pronounced in patients with toxic nodular goiter. Limitations of the study included treatment based on the medical condition, multiple statistical comparisons, and lack of individual dosimetry. The authors concluded that the increase in thyroid cancer deaths might reflect an association with thyrotoxicosis rather than I-131 treatment.

In a Swedish mortality study, which has also been extended, cancer mortality was evaluated in 10,552 hyperthyroid patients who were treated with I-131 between 1950 and 1975. Patients were matched with Swedish registry data and were followed for a mean of 15 years. The targeted thyroid dose was between 60 and 100 Gy. Ninety-five percent of the patients were older than 40 at the time of exposure. No increased risk of thyroid cancer was detected for persons followed for more than 10 years, with an SMR of 0.66 (95% CI, 0.08–2.37).^{13,14}

The most recent investigation of the risk of thyroid cancer following radioiodine treatment of hyperthyroidism involved a population-based cohort of 7400 patients treated with I-131 between 1950 and 1991.¹⁵ All cancer diagnoses and deaths from this cohort were compared with registry data for England and Wales. Overall cancer incidence and mortality were decreased; however, thyroid cancer incidence and mortality were increased (standardized incidence ratio [SIR], 3.25; 95% CI, 1.69–6.25; SMR, 2.78; 95% CI, 1.16–6.67). As in the study by Ron et al., there were

small numbers of both thyroid cancer cases and deaths. The authors could not distinguish between thyrotoxicosis or radioiodine as the cause of the increased thyroid cancer incidence and mortality.

Diagnostic radioactive iodine

Although not in use now, I-131 was used previously at low doses for diagnostic thyroid scans to evaluate nodules or hyperthyroidism. Swedish investigators followed over 35,000 persons who had had diagnostic I-131 scans for a mean follow-up period of 20 years.¹⁶ The average thyroid dose was 0.5 Gy. No significant increase in thyroid carcinoma was detected in this group when compared with expected rates for the general population. This cohort study has subsequently been extended through a follow-up period of 40 years.¹⁷ The results of the extended follow-up differed in that an increase in thyroid cancer incidence was detected (SIR, 1.35; 95% CI, 1.05–1.71). However, the excess cases were apparent only among patients referred for suspicion of a thyroid tumor; no increased risk was found among those referred for other reasons. In addition, risk was not related to thyroid radiation dose, time since exposure, or age at exposure. The authors concluded that the excess appeared related to the underlying thyroid condition rather than radiation exposure. It should be noted that 93% of the cohort were over age 20 years when I-131 was administered. Thus, while this study shows little, if any, detectable risk of thyroid cancer in adults after exposure to low dose I-131, it likely cannot be used to assess the risk of similar doses to infants or children.

ENVIRONMENTAL EXPOSURES

As with medical exposures, the most common environmental agent thought to cause thyroid neoplasms is ionizing radiation. However, in contrast to studies of persons exposed to medical radiation, studies of environmental radiation exposure have been more difficult, primarily because of the difficulty in determining who was exposed and estimating individual thyroid radiation doses. The following sections characterize studies of populations exposed to environmental radiation and are summarized in Table 30.6.3.

Agent	Source	Mean thyroid dose (Gy) (range)	Effect	Reference
External gamma radiation	Japanese atomic bomb survivors	0.27 (0.01–3.99)	Linear dose–response*	10,19
Nuclear fallout (mixed radioiodines and external gamma)	Utah; weapons test fallout Chernobyl accident Marshall Islands; weapons test fallout	0.17 (0–4.6) 0.15–1.0 2.8–21 [¶]	ERR 0.7%/mGy [†] Dramatic increase in children [‡] Dose–response for total thyroid nodules**	29–32,34 20,24–26
Iodine-131	Hanford nuclear reservation; plutonium production	0.186 (0–2.8)	No effect detected	35

* Thyroid cancer only
[†] Excess relative risk for benign neoplasms and cancer combined
[‡] Risk estimates not yet available; doses highly dependent on multiple factors, including region of residence
[¶] Mean population estimated doses: 2.8 Gy for Utrik islanders, 21 Gy for Rongelap islanders
** No individual dosimetry available; strong linear dose–response using distance from test site as proxy for dose

Table 30.6.3 Risk of thyroid neoplasia from environmental ionizing radiation exposures

Natural background radiation

Although information is limited about the risk of thyroid cancer from variations in background radiation exposure, one study from China assessed thyroid nodularity in a region of high background radiation and compared it to a region with low background radiation exposure.¹⁸ In 2000 elderly women, there was no difference in thyroid nodularity in women from high (14 cGy) and low (5 cGy) radiation areas.

External gamma or photon radiation

Persons exposed to atmospheric nuclear fallout from nuclear weapons testing or from nuclear attack such as in Hiroshima and Nagasaki may also be at increased risk for developing benign or malignant thyroid neoplasms. The increased risk of thyroid carcinoma from external gamma-radiation exposure among the Japanese survivors is well documented.^{10,19} This exposure, resulting from an air burst of an atomic bomb, produced external whole-body penetrating photon radiation nearly instantaneously. A linear dose-response relationship was shown, with an increased relative risk for thyroid cancer. An age-related effect was also demonstrated, with those exposed before the age of 15 having the greatest risk and those exposed after age 15 having little or no increased risk of thyroid cancer.¹⁰

Radioactive iodine

The most widespread population exposures to radioactive iodine have occurred in the following locations:

- the Marshall Islands, where nuclear weapons were tested;
- the state of Utah and areas surrounding the Nevada test site, from US nuclear weapons testing;
- eastern Europe near the Chernobyl accident; and
- the United States Pacific Northwest, where nuclear weapons were produced at the Hanford test site.

Numerous other populations have been directly exposed (as opposed to indirect exposure from worldwide fallout) to weapons test fallout, such as at Semipalatinsk in the Kazakhstan area in the former Soviet Union, the Mayak nuclear power station, and the aboriginal population in Australia.

Marshall Islands

The Marshall Islanders represent one of the most intensively studied populations exposed to weapons test fallout. In contrast to the external gamma radiation from the atomic bomb attacks on Japan, the Marshall Islanders were exposed to particulate fallout radiation. Of at least 66 atomic tests detonated in the Marshall Islands between 1946 and 1958, the BRAVO thermonuclear test on March 1, 1954, produced the largest single radiation exposure to the Marshallese people. Extensive evaluation of this population by Brookhaven National Laboratory has shown an increase in benign and malignant thyroid nodules in persons living on the northern atolls of Rongelap and

Utrik.²⁰ Thyroid doses have been estimated to be primarily from a mixture of the short-lived radioiodines and, to a lesser extent, I-131 and external gamma radiation.^{21,22}

Although the Brookhaven studies had maintained that fallout exposure from the BRAVO test affected only the Rongelap and Utrik atolls, additional dosimetry studies have suggested a much wider area of fallout exposure.^{23,24} In addition, a retrospective cohort study of over 7000 Marshall Islanders showed that the prevalence of palpable thyroid nodularity (≥ 1.0 cm) decreased linearly with increasing distance from the Bikini test site.²⁵ These results were highly statistically significant and strongly suggested that fallout radiation affected a much wider region of northern and central atolls, including those used by Brookhaven as a control population.

Takahashi and colleagues recently attempted to independently assess the prevalence of thyroid nodularity in the Marshall Islanders and compare their results with those of the above 1987 study.²⁶ They reported a much higher prevalence of thyroid nodules in the population but only a borderline significant relationship between prevalence of thyroid nodules and distance to the Bikini test site. However, the authors' first result can be partially explained by the inclusion of ultrasound abnormalities in addition to palpable nodules in their criteria of thyroid nodules. Also, the very small numbers of persons screened from each atoll in the Marshall Islands produced unstable point prevalence figures and can explain the failure to find a relationship between thyroid nodule prevalence and distance from the Bikini test site.

Dose reconstruction for Marshall Islanders exposed to nuclear fallout is difficult. Because adequate individual dosimetry information was either not obtained or not available during the actual exposures in the 1950s, it is unlikely that future dose reconstruction efforts will be successful in further elucidating the risk of radiation-induced thyroid cancer in this population.

Nevada test site

Over 100 atmospheric nuclear tests were detonated at the Nevada test site between the years 1951 and 1958. Although recent reports have suggested that persons throughout the US might have been exposed to small amounts of radiation from radioiodine during the 1950s, the persons with some of the highest exposures were from southwestern Utah. Early studies of thyroid disease in Utah schoolchildren appeared to show no difference in thyroid disease outcomes compared to children from unexposed areas.²⁷ However, extension of this cohort study showed an excess of thyroid neoplasms which was associated with exposure to radioiodine from the Nevada test site.²⁸

In that study, a relative risk of 3.4 for the period prevalence of thyroid neoplasms during 1965–1986 was observed for persons exposed to >400 mGy. A statistically significant excess relative risk of 0.7% per mGy was observed for total neoplasms, which included both benign follicular adenomas and thyroid cancers. Although positive dose-response trends were noted for total nodules or thyroid carcinoma, these were not statistically significant. The mean dose in

the Utah exposed children was 170 mGy. Although the dose was reported to be primarily from I-131, the contribution of external radiation or short-lived radioiodines is uncertain.

Chernobyl

The 1986 accident at the Chernobyl power station near Kiev in the Ukraine is the most recent event that involved environmental exposure to radioiodine. Beginning in 1992, reports began to show increased rates of thyroid cancer in children who were exposed to radiation from the Chernobyl accident.^{29,30} A marked increase in childhood thyroid cancer has since been documented in areas surrounding the Chernobyl reactor, especially in Belarus and Ukraine.³¹⁻³³ Pacini et al. have evaluated thyroid cancer registries in Belarus since 1986 and compared them with presumably unexposed cases from registries from France and Italy.³² Of 472 cases of thyroid cancer from the six regions in Belarus, 52% were from the most exposed region of Gomel; the numbers of cases of thyroid carcinoma throughout Belarus roughly correlated to the degree of radioactive contamination. In addition, the cases from Belarus were younger, more aggressive at initial presentation, and more likely papillary in histology than the thyroid cancer cases from France and Italy. Similar increased rates of thyroid cancer occurring at young ages at exposure have been reported in the Ukraine.³⁴

To date, there is limited individual thyroid dosimetry and therefore little published information assessing a dose-response relationship between Chernobyl radiation exposure and thyroid cancer. The type of radiation exposure presumably is largely due to I-131, although external radiation as well as short-lived radioiodines also contributed to the dose.

Hanford nuclear reservation

A second large population from the United States Pacific Northwest was exposed to atmospheric radioiodine during the 1940s and 1950s from the Hanford nuclear site. This information, released in 1986 by the US Department of Energy, resulted in the funding of two studies: the Hanford Environmental Dose Reconstruction project and the Hanford Thyroid Disease Study (HTDS), designed to determine whether or not thyroid disease, including thyroid neoplasia, was increased among individuals exposed to environmental I-131 from Hanford.

Results from the HTDS have found no evidence of an increase in thyroid neoplasia as a result of Hanford radiation exposure.³⁵ This study was based on the results of comprehensive thyroid evaluations in 3441 persons who were aged 0–7 years at the time of the radiation exposures, including duplicate thyroid physical examinations, thyroid ultrasound scans, and thyroid function testing. In addition, individual thyroid radiation doses were estimated for each person. In contrast to most of the above exposures involving mixtures of I-131, other short-lived radioiodines, and external gamma radiation, the Hanford exposures were primarily I-131 alone. No increase was found for either benign or malignant thyroid

neoplasms in relation to radiation dose from radioiodine exposure. Factors that might have contributed to lack of a radiation effect include low thyroid doses, and chronic rather than acute exposures to radioactive iodine.

OCCUPATIONAL EXPOSURES

The risk of thyroid cancer in occupations involving ionizing radiation has not been well studied because the mortality rate is low and, therefore, is not detected in occupational mortality studies. One incidence study showed that thyroid cancer incidence in 27,000 medical diagnostic X-ray workers in China was significantly increased when compared with 25,000 physicians who did not use X-rays.³⁶ Although previous studies have not shown occupational exposures to diagnostic X-rays to be a risk factor for thyroid cancer, the patterns of risk associated with age, calendar time of employment, and duration of employment suggested that the excess thyroid cancer in this study might be caused by occupational exposure to X-rays. Although an increased risk of thyroid cancer has most commonly been the result of acute high doses of gamma radiation, this study suggests that chronic low doses of X-ray exposure may also confer excess risk.

More recently, several studies have assessed the risk of thyroid cancer in workers exposed to ionizing radiation. Fraser and colleagues analyzed a cohort of 39,718 atomic energy employees in the UK based on deaths from 1946 to 1986; they found no increase in thyroid cancer prevalence or mortality.³⁷ A second study of 95,217 radiation workers in the UK did show an increased SMR for thyroid cancer; however, there was no evidence for a trend with external radiation dose.³⁸ In a study of Danish employees in two radiotherapy departments, Andersson et al. found no increase in thyroid cancer among 4151 workers compared to the general population.³⁹ Antonelli and colleagues evaluated thyroid nodularity in 50 medical workers from a Pisa hospital who worked in high radiation exposure units and compared them to unexposed male workers. They found an elevated relative risk for thyroid nodularity in the exposed group and concluded that occupational exposure to radiation might be a risk factor for thyroid nodules. These results are somewhat limited by lack of individual dosimetry, small numbers of exposed workers, and diagnostic criteria for thyroid nodules which rely primarily on ultrasound abnormalities. No thyroid cancer was found in either the exposed or control group.⁴⁰

The risk of thyroid cancer from radiation exposures from the Chernobyl accident in workers at the nuclear power station as well as those involved in clean-up has also been studied. Inskip and colleagues screened 2400 Estonian clean-up workers using ultrasound and needle biopsy of thyroid nodules.⁴¹ They found no increase in thyroid disease that could be correlated with radiation dose.

Even less is known about occupational risks of thyroid cancer other than ionizing radiation, again because of the low incidence and mortality rate of the disease. In a

study from Sweden, a record linkage between the Swedish Cancer Registry and census data reported an increased incidence of thyroid cancer in men working in petroleum refineries.⁴² The association was found only in occupations working with crude oils and not in those involving volatile petroleum products. Whether this represents a real association from a hypothesis-generating study remains unclear.

A more recent case-control study (1272 cases, 2666 controls) from Canada explored the etiology of thyroid cancer and occupational exposures.⁴³ An adjusted odds ratio of 2.54 (95% CI, 1.11–5.83) was found for wood processing, pulp, and papermaking workers, who have multiple chemical exposures, including hydrocarbons. The authors concluded that additional studies with better exposure characterization would be warranted.

EVALUATION AND TREATMENT

The evaluation (and usually the treatment) of suspected environmentally or occupationally related thyroid neoplasms is not different from that of those which occur sporadically. The advent of fine-needle aspiration (FNA) has significantly changed the approach and evaluation of a thyroid nodule over the last 20 years, and now it is usually the initial diagnostic test following a TSH determination. There is controversy about the ability of thyroid ultrasound to predict histology, and the sensitivity and specificity of this modality are not adequate to reliably distinguish malignant from benign neoplasms.^{44,45} Therefore, thyroid ultrasonography, as well as thyroid nuclear scans, are adjuncts to an experienced physical examination and FNA of nodules.

The treatment of thyroid carcinoma includes thyroidectomy and usually radioiodine ablation. The indication for radioiodine ablation is not influenced by whether the carcinoma is caused by an environmental or occupational exposure. Regardless of the extent of the initial thyroidectomy or whether radioiodine ablation and therapy is employed, the administration of thyroid hormone is indicated on a lifelong basis for thyroid hormone replacement and for TSH suppression, which decreases recurrence rates. The dose of thyroid hormone should be high enough to suppress TSH but to avoid clinical symptoms of hyperthyroidism.

External beam radiotherapy usually is reserved for palliative treatment of progressive or widely metastatic disease, for persons with focal bone metastases, and for those patients whose disease is inoperable. Clinical decisions in these cases must be made in consultation with the endocrinologist and radiation oncologist.

Chemotherapy (except radiosensitizers in conjunction with I-131 or X-ray therapy) has generally not been used in well-differentiated papillary or follicular carcinoma, primarily because most patients do well with the therapeutic regimens discussed earlier. Although chemotherapeutic regimens have been tried in widely metastatic disease, it is unclear whether they add any benefit beyond external beam radiotherapy.

Benign thyroid nodules

Any discussion regarding the management of thyroid carcinoma is incomplete without reviewing the management of benign thyroid lesions, because ruling out carcinoma confirms a benign lesion, which may occur in 2% to 4% of the general population. Two important issues are the management of benign nodules, and whether occupational or environmental causation changes the management.

The management of benign nodules can be difficult because of the possibility of false-negative FNA results and the question of whether TSH suppression with thyroid hormone is effective in causing regression of nodules. It can be difficult to decide whether a nodule is truly benign because FNA cytology cannot reliably distinguish follicular carcinoma from follicular adenoma. Because studies have shown that 10%–20% of follicular neoplasms diagnosed by FNA cytology are malignant, most authorities recommend thyroidectomy in persons with such cytology. The beneficial effect of TSH suppression on benign nodules is questionable both because of unproven effectiveness and also because of potential symptoms and long-term adverse effects of TSH suppression. Typically, benign thyroid nodules can be managed by periodic examinations to ensure that the nodule is not enlarging or causing compression symptoms. In persons with enlarging nodules or compression symptoms, thyroidectomy should be considered.

Evaluation of thyroid nodules in radiation-exposed patients

Does a history of prior head and neck radiation exposure change the management (or evaluation) of a thyroid nodule? Such a history has in the past compelled many clinicians to recommend thyroidectomy regardless of cytology or in lieu of biopsy. It is clear that a prior history of head and neck radiation exposure from X-rays increases the risk that a person will develop thyroid nodularity (both benign and malignant neoplasms). However, it is less clear whether such nodules are more likely to be malignant than are sporadic thyroid nodules. In addition, with the possible exception of carcinomas developing in children from the exposure at Chernobyl, there is no convincing evidence that radiation-induced thyroid carcinomas are more aggressive than those arising spontaneously. In fact, the majority of radiation-induced cancers have been of papillary histology, which has the best prognosis. Although persons with a benign nodule who have a history of radiation exposure should have careful and experienced lifelong yearly examinations of the thyroid, these nodules can generally be evaluated and managed in the same manner as the spontaneous nodule found in a person without prior radiation exposure.

Prognosis

The prognosis of well-differentiated thyroid carcinoma, in general, is good, and the long-term survival is in excess of 90%–95% of patients. Three prognostic factors have

proved to be predictors of poor outcome: age at diagnosis, local tumor invasion, and distant metastases. The age range when prognosis worsens is probably between 40 to 50 years and less than 20 years. Except for poorly differentiated tumors, minor differences in tumor grade do not appear significant. To date, there is no strong evidence that the prognosis of papillary and follicular carcinomas that are caused primarily by ionizing radiation is different from the prognosis of sporadic carcinomas.

Screening of radiation-exposed populations

Persons having a history of environmental or occupational radiation exposures (including medical exposures) should be considered for routine thyroid surveillance. The question of who should have routine screening is complex because the documentation of increased risk has not been shown for all types of radiation exposures and depends on multiple factors, including age at exposure, thyroid dose, and perhaps whether the exposure was acute or protracted. Clearly, those individuals with a history of prior head and neck X-ray treatments for benign childhood conditions, as well as those with prior external gamma or photon exposures (including persons given radiation therapy for non-thyroid primary malignancies), should be screened. In addition, persons having documented exposures from nuclear weapons attack (e.g., Hiroshima or Nagasaki) or who received high doses from nuclear weapons testing (Marshall Islands, Nevada test site) should be screened.

Recommendations for screening after exposures to I-131 are much less clear. There is no convincing evidence that the medical use of I-131 in the treatment of hyperthyroidism or the diagnostic doses of I-131 formerly used in thyroid scans have caused an increased risk of thyroid neoplasms.

The largest screening programs have included the Marshall Islanders, who have been screened every 1 to 2 years with careful palpation of the thyroid gland and thyroid function testing. Screening programs in the US Midwest were performed in persons having a prior history of head and neck radiation treatments in childhood. Although these programs have increased the detection rate of thyroid nodules, it is not clear that detecting the nodules earlier has improved morbidity or mortality rates. Nonetheless, it seems prudent to screen on an annual basis persons who have been exposed to external gamma radiation, especially given the long latency of thyroid neoplasms.

The question of how exposed individuals should be screened is controversial, and screening is performed differently throughout the world. Certainly, a careful and experienced thyroid physical examination is important to detect clinically significant thyroid neoplasms (as well as thyroid function tests to detect hypothyroidism). The question of whether adjunctive diagnostic tests, such as thyroid ultrasound and thyroid nuclear scans, should be used is less clear. Ultrasound of the thyroid gland is definitely a more sensitive technique compared with

physical examination. This increased sensitivity may increase the number of clinically palpable nodules that might be missed without ultrasound; however, a large number of non-palpable ultrasound-detected abnormalities will also be detected. The number of such ultrasound-detected abnormalities in the general population is estimated to be at least 5% to 10%, and in some studies, as high as 40% to 50%.^{46,47} The biologic significance of these small non-palpable ultrasound findings is unclear, but such lesions are unlikely to represent important clinical neoplasms.

A recent study followed the natural history of thyroid ultrasound abnormalities identified 5 years earlier from random screening of an adult population in Finland.⁴⁸ In the original survey, 69 of 253 persons (27%) had ultrasound abnormalities. At follow-up, 35% of the nodules had grown, 24% of the nodules had diminished or disappeared, and 12% of persons screened had new nodules. Biopsies were performed in 10 of 12 persons with growing lesions, and in five of seven persons with new lesions. All biopsied lesions were benign. No malignancies were detected at follow-up. The authors concluded that thyroid ultrasound abnormalities occurring in a random adult population are unlikely to be clinically important. Because most clinically significant thyroid nodules are palpable and because false-positive ultrasound findings may lead to increased medical intervention, including thyroid surgery, the use of thyroid ultrasound as a screening test is generally not warranted at the present time.

Although thyroid nuclear scans may be useful as an adjunct to the physical examination, this test also is unwarranted as a screening diagnostic test. Although malignant neoplasms usually do not take up the tracer isotope, the finding of a cold nodule on a thyroid scan does not distinguish between a benign and a malignant lesion. In fact, more than 80% to 90% of such lesions found on thyroid nuclear scanning are benign.

The question of how long to screen exposed individuals is uncertain. However, because studies have shown the latency of thyroid neoplasia to be at least 40 years,¹⁰ screening should be conducted annually on an indefinite basis.

In summary, persons with a clear history of external gamma or photon radiation to the head and neck should have lifelong screening for thyroid neoplasms. This should be conducted on an annual basis and include careful thyroid physical examination by an experienced thyroid examiner. Although thyroid ultrasound can improve sensitivity over thyroid palpation, it should be used only in this context and not as a general screening tool because of the high rate of ultrasound-detected abnormalities that have unclear clinical significance.

Persons who have a history of I-131 exposure need not have routine screening if this exposure was from a diagnostic thyroid scan. Persons with prior radioiodine therapy for Graves' disease will likely be followed for that problem. Persons who have a history of environmental exposure to I-131, especially if the exposure was during childhood, may benefit from screening. It would be reasonable for

individuals who have a concern about such exposure to have a careful thyroid evaluation.

UNCOMMON THYROID CARCINOMAS

Of the uncommon types of thyroid carcinoma listed in Table 30.6.1, the most frequent is medullary thyroid carcinoma, which occurs in 2% to 10% of all cases. Medullary thyroid carcinoma has not been found to result from exposure to ionizing radiation or other occupational or environmental exposures.

The small- and large-cell anaplastic thyroid carcinomas are considered undifferentiated or poorly differentiated carcinomas and are highly lethal. One of their unusual features is that they may occur by transformation from well-differentiated papillary or follicular carcinomas. Although the factors involved in this transformation are not known, there has been some suggestion, although unconfirmed, that ionizing radiation might be a factor. This lesion has a very poor prognosis, with a survival time of usually 3 to 6 months.

Lymphomas of the thyroid gland are rare (less than 1% of all thyroid malignancies) and usually occur beyond the sixth or seventh decade of life. A strong association with autoimmune thyroiditis (Hashimoto's thyroiditis) has been found with thyroid lymphoma. The basis for this association is currently unknown. Again, no association has been found between lymphomas of the thyroid and ionizing radiation or other environmental or occupational exposures.

The clinical evaluation, treatment, and prognosis of these malignancies are beyond the scope of this text.

30.7 Cancer of the Reproductive Organs

Lora E Fleming

INTRODUCTION

Although an area of increasing scientific interest, there is relatively little information on the role of occupational and environmental exposures in reproductive cancers. In particular, these exposures have not been closely studied in women because women traditionally were not believed to be at risk for major chemical or physical occupational or environmental exposures. For men, the lack of study has been, in part, because the incidence of testicular cancer peaks at a young age and that of prostate cancer peaks at an advanced age – patients that constitute populations predominantly outside the workforce.

Although all of the reproductive cancers have been found to have familial predispositions suggestive of genetic risk factors, recent work by Verkasalo et al¹ has shown the importance of environmental (and occupational) exposures in the development of cancers over a purely genetic predisposition. Verkasalo et al¹ used the Finnish Cancer Registry, Twin Cohort Study and Central Population Register to evaluate cancer risk among monozygotic versus dizygotic twins. Based on genetic modeling, inherited genetic risk factors accounted for 18% (95%CI = 4–32%) of cancer risk while unique environmental factors accounted for 75% (95% CI = 65–85%). In particular, the risk from unique environmental factors for prostate cancer was 58% (95% CI = 33–89%), and for breast/ovarian cancer 77% (95% CI = 52–96%). This chapter reviews the current knowledge of the contribution of occupational and environmental factors to the risk for reproductive cancers, summarized in Table 30.7.1.

In general, reproductive cancers due to workplace exposures present with the same signs and symptoms as the same type of cancer would in the general population (i.e., with a bleeding, growing mass; irregular menses; and localized pain), and they are diagnosed the same way. Differing age distributions from those found for the same cancer type in the general population may be a clue to an occupational or environmental exposure etiology. In addition, as far as we know, workplace reproductive cancers should be treated therapeutically in the same way, and should have a similar prognosis as these same cancers in the general population.

A unique aspect of reproductive cancers in the workplace is the possibility of primary and secondary prevention. Primary prevention can be practiced in those workplaces in

which known or suspect reproductive carcinogens are used. This type of prevention can be accomplished by industrial hygiene and engineering, as well as by education of the workforce, to prevent exposure to potential carcinogens.

For those workers who appear to be at high risk for a particular reproductive cancer, or even for workers in general, the workplace also provides an unique venue for screening and education of at-risk workers where appropriate programs exist.^{2,3} For example, both the testicular and breast self-examinations may be taught to all workers whether or not they are exposed to suspect reproductive carcinogens.

Endocrine disrupters

Before beginning a review of specific reproductive cancers, a brief discussion is necessary of recent research concerning chemicals that can act as endocrine disrupters and their possible role in the etiology of reproductive cancers, both occupationally and environmentally. A more detailed discussion of this topic is provided in Chapters 45 and 27.1.

It has been demonstrated that various natural and synthetic exogenous substances, such as the previously widely used organochlorine pesticide DDT, can bind and functionally interact with endogenous receptors. An environmental endocrine disrupter is an exogenous agent that interferes with the synthesis, secretion, transport, binding, action, or elimination of natural hormones in the body that are responsible for the maintenance of homeostasis, reproduction, development, and/or behavior.^{4,5} Recent in-vitro and in-vivo studies have demonstrated that some exogenous substances can have estrogenic (xenoestrogens) and antiandrogenic effects.^{4,5}

In the case of the organochlorine pesticide, DDT, the first interpretation of an estrogen-like action of DDT was noted in 1950, when the inhibition of testicular growth and secondary sexual characteristics of cockerels was reported.⁶ Furthermore, it was subsequently demonstrated that both DDT and its metabolites were estrogen receptor agonists^{7–9} and androgen receptor antagonists.¹⁰ Numerous in-vitro testing procedures indicate that DDT is not a mutagen.⁶ There is evidence, however, that DDT can act as a promoter of carcinogenesis. Specifically o,p'-DDT can support the growth of an estrogen-responsive tumor⁶ in a specific and dose-dependent manner, and at a rate similar to estradiol⁷.

The chronic effects of these chemicals are of particular concern. These compounds are highly persistent in the environment and have been found in animals¹¹ and in tree bark in the most remote locations worldwide.¹² The more volatile compounds have been found to globally redistribute to colder, higher latitudes by a distillation effect.¹² These compounds can have a half-life of the order of several years, and are resistant to the natural degradation pathways.¹¹ Their highly lipophilic properties and environmental persistence

Female	Male
Breast cancer	Testicular cancer
Ovarian cancer	Prostatic cancer
Uterine/endometrial cancer	Male breast cancer
Trophoblastic disease (choriocarcinoma & hydatidiform mole)	

Table 30.7.1 Cancers of the reproductive organs

result in their bioconcentration in the food chain.¹¹ Concern about chronic effects in humans, including cancer, is reasonable considering the ubiquity of exposure to these agents.

Initial evidence supported a possible role for endocrine disruptors such as DDT in the etiology of breast cancer.¹³ However, as discussed below, more recent evidence not only does not uphold this association, but rather may focus future attention on the possible role of these endocrine disruptors in the male reproductive cancers.

CANCERS OF THE REPRODUCTIVE ORGANS IN THE FEMALE

Female breast cancer

Breast cancer is predominantly a disease of women. It will develop in at least 1 out of 11 women in the United States during their lifetimes. Each year in the United States, it accounts for over 30% of newly diagnosed cancers among women, with over 100,000 new cases and over 33,000 deaths. Throughout the world, it is very rare in girls before they reach menarche and until age 30, with a significant increase in incidence among postmenopausal women. Factors such as a high-fat diet and obesity appear to play an important role in breast cancer in postmenopausal women, whereas genetic (especially a history of premenopausal and/or bilateral breast cancer in a close female relative) and endocrine factors appear to be important for breast cancer in premenopausal women. Identification of BRCA gene mutations and associated breast cancer risk underscores the importance of genetic factors. Increased rates of breast cancer are found in industrialized countries, in urban areas, and in higher socioeconomic classes. Early first pregnancy and lactation appear to be protective factors.^{14,15}

Ramazzini¹⁶ noted in 1713 that certain groups of women (e.g., nuns) have a greater susceptibility to breast cancer; this susceptibility is probably related to lack of parity. In large epidemiologic studies of occupation and cancer, jobs with higher education were associated with increased breast and decreased cervical cancer rates;¹⁷ this finding may have been confounded by socioeconomic class.¹⁸ For example, King et al¹⁹ found increased risk for

breast cancer for teachers (proportionate mortality rate (PMR) 1.68) and registered nurses (PMR 1.20) in British Columbia from 1950 to 1984. Rix et al²⁰ found an increased risk among 1.4 million Danish working women since 1970, particularly among women professionals (lawyers, medical doctors, dentists, physiotherapists, and nurses), as did Morton²¹ using the National Cancer Institute Surveillance, Epidemiology and End Results (SEER) program in the US, and Pollan²² among Swedish working women. Coogan et al,²³ using a population-based case-control study in the US, found an increased risk only for administrative support occupations; Gunnarsdottir²⁴ found an increased risk of breast cancer for Icelandic nurses. Threlfall and associates²⁵ have suggested that this association with socioeconomic class and higher education may be due to low parity and older age at first birth, which are both risk factors associated with these types of jobs. Other reported occupational and environmental causes for female breast cancer are summarized in Table 30.7.2.²⁶

Cantor et al²⁷ used mortality records from 24 states from 1984 to 1989 in a case control analysis of breast cancer risk, using a job matrix after adjusting for socioeconomic class. They found an increased risk of breast cancer with probable occupational exposure to styrene, several organic solvents (methylene chloride, carbon tetrachloride, formaldehyde), several metals/metal oxides, and acid mists. Petralia et al²⁸ found an association between the risk of estrogen receptor-positive breast cancers and occupational exposure to benzene. Aschengrau et al,²⁹ in a case-control study, found an insignificant increase in breast cancer among women with drinking water contaminated by tetrachloroethylene from the lining of drinking water pipes.

Ionizing radiation exposure is an established risk factor for breast cancer. This has been shown in a number of different exposure cohorts, including women who received repeated fluoroscopy for pulmonary tuberculosis, women receiving radiation treatments for mastitis, and survivors of the atomic bomb blasts in Hiroshima and Nagasaki, where marked increases in breast cancer were seen in women exposed to 10 rads or more (with peak at 100 rads and latencies typically of more than 10 years from exposure).^{30,31} All of these cohorts demonstrated evidence of a linear

Possible causes/contributing factors	Occupation/group	References
<i>Exposures</i>		
External ionizing radiation	Survivors of Hiroshima and Nagasaki; flight attendants	30, 31, 35, 37, 41
Radium	Radium-dial painters	32, 33, 34
Permanent hair dyes, hair dyes	Cosmetologists	22, 63, 64, 65
Anti-rust oil (N-phenyl-1-naphthalene)	Factory workers	67
Various exposures	Ethylene oxide, styrene, several organic solvents, several metals/metal oxides, and acid mists	27, 28, 68
<i>Occupations/industries</i>		
Lamp manufacturing (methylene chloride, trichloroethylene, resin)	Factory workers (coiling and wiredrawing area)	66
Various occupations	Nuns, employers, managers, clericals, nurses, teachers, sales clerks, professionals (lawyers, medical doctors, dentists and physiotherapists), skilled tobacco workers, book binders, meat wrappers and cutters, secretaries and typists, radio and telegraph operators, pharmaceutical workers	

Table 30.7.2 Breast cancer: occupational and environmental causes

dose–response relationship between radiation exposure and risk of breast cancer. There also appears to be a significantly increased risk in women irradiated during adolescence; this finding is postulated to be due to increased sensitivity of stem cells in the developing and adolescent breast to ionizing radiation exposure.

There is a controversial relationship between radium dial painting and increased breast cancer.^{32,33} In a cohort of women radium dial painters in the United States who were exposed before 1930,³⁴ breast cancer risk was increased with a highly significant dose–response relationship at high radium intake, but there was no indication of an association with duration of employment or any suggestion of the importance of age at first exposure (e.g., <20 years of age). Other factors in this controversy concern whether or not the increased risk of breast cancer is due to external exposure to ionizing radiation in the workplace or to the radium absorbed by work practices such as ‘tipping’ (placing the brushes in the mouth).

Whether or not women exposed to low-level ionizing radiation (such as occupational exposure to radiation for technicians or nurses) are at increased risk for breast cancer is not known. For example, Pukkala et al³⁵ found a statistically increased risk of breast cancer incidence (standardized incidence ratio (SIR) = 1.87; 95% CI 1.15–2.23) among Finnish flight attendants, but Boice et al³⁶ did not find a significant risk among certified women radiologic technologists in the US.³⁷ In a death certificate study, Loomis et al³⁸ found an increased risk of breast cancer mortality (odds ratio (OR) = 1.38; 95% CI = 1.04–1.82) among female electrical workers in the US. In particular, significant increased risks were reported for electrical engineers (OR = 1.73), electrical technicians (OR = 1.28), and telephone installers, repairers, and line workers (OR = 2.17).

With respect to non-ionizing radiation, Tynes et al³⁹ found an increased risk of breast cancer among Norwegian female radio and telegraph operators. Feychting et al⁴⁰ performed a case-control study of male and female breast cancer risk and residential magnetic field exposure. Female breast cancer risk was particularly increased for women diagnosed at <50 years of age with estrogen-positive tumors, however, with wide confidence limits (relative risk (RR) = 7.4; 95% CI = 1.0–178.1). However, this suggests at least a theoretical possibility of increased breast cancer risk associated with non-ionizing radiation, and has raised concern regarding low-level radiation for women who have undergone repeated mammographic examinations.⁴¹

Brainard et al⁴² evaluated the hypothesis that breast cancer risk may be associated with a decrease in melatonin production secondary to increased exposure to artificial light at night and electromagnetic fields (EMFs). The authors concluded that there is no strong evidence of such an association, though they cautioned that even a small risk would have a substantial public health impact.

Male and female breast cancer incidences were both increased among employees in a Danish pharmaceutical plant where sex hormones, antibiotics, insulin and enzymes were produced.⁴³ Breast cancer incidence among female employees was significantly elevated (SIR = 1.5), particularly

for the subgroup that started work at aged 30–39 for at least 1–9 years (SIR = 2.8).

As discussed above, early age at first pregnancy and breast feeding have long been observed to be protective factors in the development of breast cancer. While this is likely due to hormonal influences, this may have an impact on the body burden of fat-soluble environmental toxicants. Repeated breast feeding, as well as pregnancy itself, leads to a mobilization of a woman’s fat stores, including any lipophilic substances such as the organochlorines, leading to a decrease in stored levels (and an increase in their breast-feeding infants).⁴⁴ This suggests that breast-feeding may be an important ‘detoxification mechanism’ for organochlorines and possibly explains in part the decreased risk of breast cancer associated with lactation.^{13,44–46} In addition, various authors have proposed that pregnancy itself may protect against breast cancer due to the excretion of lipophilic organochlorines by the mother through the fetal fat and vernix caseosa.^{46,47}

Several small studies have evaluated organochlorine levels in breast cancer tissue with variable results.^{48–51} Westin and Richter,⁴⁵ among others, have argued that changing breast cancer trends over time in Israel may be related to changes in pesticide contamination in breast milk and other sources of milk, and the banning of organochlorine use in Israel. Wolff et al^{13,52} showed a strong statistical association between DDE levels and breast cancer in a nested case-control study of women in New York City, even when controlling for a variety of other variables. However, the actual mean levels of DDE were quite low (11.0 ± 9.1 ng/mL cases vs 7.7 ± 6.8 ng/mL controls), presumably because women in New York City have had relatively little exposure to DDT and other organochlorines, even historically; similarly low levels were found in the nested case-control study of Kreiger et al.⁵³ Thus, the possible association found between DDE levels (and other similar organochlorine compounds with possible estrogenic action) and breast cancer needs to be investigated in populations with historically high organochlorine use. Wesseling et al⁵⁴ found significantly increased rates of breast cancer incidence in allegedly high pesticide use areas compared to low pesticide use areas in Costa Rica; no increased risk was found among women in North Vietnam, where there had been extensive use of DDT for malaria control.⁵⁵ To date women potentially exposed occupationally to organochlorines have in general not been found to have increased risks of breast cancer.^{56–62}

A variety of studies have examined the possible relationship between breast cancer and exposure to permanent hair dyes.^{63,64} Occupational exposure to hair dyes has also been examined. Among others, Pollan²² and Teta et al⁶⁵ found significantly increased risk of cancers of the breast among cosmetologists, while other studies have found no increase among cosmetologists, hairdressers, manicurists, and beauticians. An increased frequency of the regular use of permanent hair dyes was found among those with breast cancer as opposed to controls in two studies. Of interest, in the past certain hair dyes (permanent and semi-permanent) were strongly mutagenic in the Ames test. A significant

excess of chromosomal damage (mainly chromosomal breaks) has been reported in women with dyed hair, although this has not been found in those with occupational exposures (except when the hairdressers dyed their own hair) or in men with dyed hair.

A follow-up study of a cluster of tumors in women workers in a lamp manufacturing plant found increases in ovarian, uterine, and breast cancer in the coiling and wire drawing area of the plant, without identifying a definite exposure.⁶⁶ Women workers exposed to anti-rust oil, in particular N-phenyl-1-naphthalamine or its nitroso derivatives, were observed to have an increased rate of cancer, including uterine, ovarian, and breast cancers.⁶⁷ Breast cancer incidence was increased in a cohort of workers in an ethylene oxide plant, although there was no increase associated with cumulative exposure.⁶⁸ Pulp and paper industry workers in Spain had an insignificantly increased of breast cancer mortality.⁶⁹

Prevention and early detection are best served by following the recommendations and schedules of the American Cancer Society for breast self-examination and mammography. Workplace screening may be an effective and under-utilized setting for breast cancer screening.² Particular attention should be paid to women with environmental or occupational exposure to ionizing radiation in terms of primary and secondary prevention.

Ovarian cancer

The lifetime risk of ovarian cancer among white women is 1–2% (less among African-American and Hispanic women), and the risk increases sharply with age. There are several different cell types (including germ cell, stromal and epithelial tumors), with different types predominating in different geographic populations. A variety of risk factors have been identified. In animals, oocyte loss is a prerequisite for tumor production, as well as gonadotropin stimulation. Low fertility is a risk factor, although there appears to be some protection with the use of birth control pills. There may be increased risk in humans and animals after the use of diethylstilbestrol (DES). There is a strong familial risk of ovarian cancer.^{15,70}

In a review of occupation and mortality from reproductive cancers among women from 24 US states from 1884 to 1993,⁷¹ ovarian cancer mortality risk was increased for certain professional groups, including managers, teachers, librarians, office workers, financial workers, and religious workers. Technical writers had the highest risk with a mortality odds ratio of 6.1. Among other occupations, waitresses, dental assistants, electricians and bus drivers had excess risk. Among African-American women, financial managers, elementary school teachers, librarians, designers, health technicians, administrative support occupations, child care workers and machine operators had the highest risk, with the occupation of financial managers demonstrating the greatest risk of mortality (MOR = 20.9). Industries with the highest risk included printing, publishing, soap and cosmetic manufacturing, machinery manufacturing, utilities, retail trade, finance, healthcare, legal services, education, professional services, and government. Rix et al²⁰ found an increased risk of ovarian cancer among 1.4 million working Danish women since 1970 among clerks. In a proportionate mortality study, King et al¹⁹ found an increased risk for ovarian cancer for teachers (PMR 1.48) and registered nurses (PMR 1.56) in British Columbia from 1950 to 1984 (Table 30.7.3).

Shen et al,⁷⁰ reviewing the experience in European countries, observed an increased risk for ovarian cancer among hairdressers, beauticians and women employed in the printing industry, but concluded that the data were insufficient to conclude an occupational association. The authors judged that only exposure to talc had sufficient evidence for a modest to moderate increased risk. Vasama-Neuvonen et al⁷² used the Finnish cancer registry to evaluate risk by occupational exposure of ovarian cancer using a job-exposure matrix. Occupational exposures to aromatic hydrocarbon solvents, man-made vitreous fibers, high levels of asbestos, diesel and gasoline engine exhausts were associated with insignificant increases in cancer risk; hairdressers and women in the printing industry were also at increased risk.

Exposure to ionizing radiation appears to be a risk factor for ovarian cancer (Table 30.7.3). Studies by Doll and Smith⁷³ of women who underwent radiation for ostensibly benign pelvic conditions showed a small increased risk for

Possible causes/contributing factors	Occupation/group	References
<i>Exposures</i>		
Ionizing radiation	Women survivors of atom bomb blast	74
Asbestos and talc	Gas mask assemblers, asbestos workers	72, 75, 76, 77, 78
Talc	Cosmetologists, hairdressers, pulp and paper workers	65, 70, 72, 79, 80, 81, 82, 83, 84
<i>Occupations/industries</i>		
Lamp manufacturing (methylene chloride, trichloroethylene, resin)	Factory workers (coiling and wire)	66
Various professions	Managers, teachers, librarians, office workers, financial workers, religious workers, waitresses, dental assistants, electricians, bus drivers, nurses, clerks, aerospace workers	19, 20, 70, 71, 85
Various industries	Printing, publishing, soap and cosmetic manufacturing, machinery manufacturing, utilities, retail trade, finance, health care, legal services, education, professional services, and government	71

Table 30.7.3 Ovarian cancer: occupational and environmental causes

developing ovarian carcinoma. This increased risk also was seen in a case-control study⁷⁴ of the atomic bomb survivors (6 versus 3.3 expected) in Hiroshima, but the risk did not appear in Nagasaki. The latter finding was possibly due to increased neutron exposure in Hiroshima.

Asbestos and talc exposures, both occupationally and environmentally, have been related to an increased risk of ovarian cancer; in the past, talc has been contaminated with asbestos. Women who worked as gas mask assemblers and with other asbestos products during World War II had an increased risk of ovarian cancer. This risk appears to be associated most strongly with crocidolite exposure. Asbestos can reach the ovary, and high fiber counts have been seen in women with para-occupational exposure to asbestos.^{75–78}

An increased risk for ovarian cancer was reported in a study of female cosmetologists and hairdressers in British Columbia, a study of cosmetologists in Connecticut, and reviews of national cancer registries in Europe for cancer risk among hairdressers.^{65,79–81} A NIOSH⁸² retrospective survey of cancer in relation to occupations also found an increased relative risk for hairdressers and cosmetologists for ovarian cancer. In the case of cosmetologists, talc has been a hypothesized etiology. Langseth⁸³ found a significantly increased risk of ovarian cancer incidence (SIR = 1.5; 95% CI = 1.07–2.09) among Norwegian pulp and paper workers with possible exposure to talc and paper dust; Bulbulyan et al⁸⁴ also found an increased risk of ovarian cancer mortality (standardized mortality ratio (SMR) = 2.9; 95% CI = 1.50–5.00) among women in the Russian printing industry with possible talc exposure. Of interest, talc particles have been found more frequently in ovarian tumors than in normal ovarian tissue. Several areas of controversy still exist. First, talc, including cosmetic talc, was contaminated with asbestiform fibrous particles in the past (including exposures in the 1970s); non-fibrous talc does not cause cancer in experimental animals. Furthermore, it is possible that the ovarian cancers actually represent undiagnosed mesotheliomas of the peritoneum.

A follow-up study⁶⁶ of a cluster of various tumors in women workers in a lamp manufacturing plant found increases in ovarian cancer in the coiling and wire drawing area. The etiologic agents are unknown; occupational exposures included methylene chloride, trichloroethylene, and various resins. Morgan et al⁸⁵ found an insignificant increased risk of ovarian cancer relative risk among aerospace workers with increased trichloroethylene exposure using job exposure matrix.

Wesseling et al⁵⁴ found significantly increased rates of ovarian cancer incidence in reported high pesticide use areas compared to low pesticide use areas in Costa Rica. However, other studies of pesticide-exposed working populations have not found an increased risk of ovarian cancer.^{59–61,86}

Endometrial/uterine (corpus) cancer

The risk factors for uterine cancer resemble those of breast cancer except for the peak age incidence. The age-adjusted incidence for uterine cancer is approximately 30 per

100,000 women. However, the age-specific incidence peaks around 55–60 years, and the amount of uterine cancer is apparently increasing worldwide, although mortality has decreased substantially. There is an increased incidence of uterine cancer among higher socioeconomic classes, and in industrialized countries. Obesity (or increased estrogen production from non-ovarian sources) and endogenous estrogen are known risk factors for uterine cancer. There also is an increased risk with nulliparity. Uterine cancer originating from the endometrium (adenocarcinoma) is much more common than that originating from the myometrium (sarcoma); uterine sarcoma is very rare, although it is increased among African-American women in the United States.¹⁵

In a review of occupation and mortality from reproductive cancers among women from 24 US states from 1884 to 1993,⁷¹ highest risk of endometrial cancer were seen among teachers in special education (MOR = 3.7), with increased risk also observed in public relations specialists (MOR 2.8) and religious workers (MOR = 2.7). Among African-American women, librarians, clergy and hand packers had the highest risks. By industry, endometrial mortality was highest in fishing and trapping (MOR = 4.8) and optometry (MOR = 4.8); manufacture of paper, metal products; education, and public administration. Rix et al²⁰ found an increased risk of uterine cancer among 1.4 million working Danish women since 1970 among traveling saleswomen, furriers, hairdressers, nurses and clerks. Dalager et al⁸⁷ reported that US military nurses who served in Vietnam had increased risk of uterine cancer mortality compared to other US military nurses. King et al¹⁹ found an increased risk for ovarian cancer for teachers (PMR 1.56) in British Columbia from 1950 to 1984 (Table 30.7.4).

As discussed above with breast cancer, exposure to lipophilic organochlorines with estrogenic action theoretically may be associated with an increased risk of uterine cancer. As in the case of ovarian cancer, Wesseling et al⁵⁴ found significantly increased rates of uterine cancer incidence in high pesticide use areas in Costa Rica. However, to date women potentially exposed occupationally to organochlorines have not been found to have increased risks of uterine cancer.^{57–60,88}

Possible causes/ contributing factors	Occupation/group	References
<i>Occupations/industries</i>		
Various professions	Teachers in special education, public relations specialists, religious workers, nurses, traveling saleswomen, furriers, hairdressers, clerks	19, 20, 21, 87
Various industries	Fishing and trapping; employment in optometry; manufacture of paper, metal products; education; and public administration	71

Table 30.7.4 Uterine cancer: occupational and environmental causes

Several studies of occupation and cancer have revealed a number of job categories with statistically increased risk for uterine cancer.⁸⁹ A NIOSH⁸² retrospective survey of cancer in relation to occupation found an increased relative risk for hairdressers and cosmetologists for uterine body cancer, although this was not seen in other studies. A cohort study of cosmetologists⁶⁵ in Connecticut also observed a significant increased risk for cancer of the uterus.

In a large Swedish cohort study from 1971 to 1984, Floderus et al⁹⁰ analyzed jobs for possible occupational exposure to magnetic fields using a job matrix. An association was noted for uterine cancer among women workers with those jobs judged to have more definite occupational electromagnetic field exposures.

Prevention and early detection are best served by following the recommendations and schedules of the American Cancer Society for uterine biopsy. Particular attention should be paid to women with environmental or occupational exposure to estrogens in terms of primary and secondary prevention, although no increase in uterine cancer has been noted in workers such as farmers and pesticide applicators possibly exposed to estrogen analogues.

Cervical cancer

The peak in incidence for cervical cancer is around age 30, with a reported age-specific incidence of approximately 110 cases per 100,000 women. Cervical cancer is very rare in women who are not sexually active (e.g., nuns). The most important risk factors are increased and early sexual behavior, i.e., young age at first intercourse and high number of sexual partners. There is a more modest risk associated with exposure to sex hormones (prolonged use of combined oral contraceptives, injectable progesterones) and lower socioeconomic class. Worldwide, there has been a decrease in incidence, especially in developed nations, which is believed to be due to improved standards of living, as well as increased routine screening through the Pap smear. Cigarette smoking may be a risk factor, however smoking is also associated with lower socioeconomic class, a major confounder. Squamous cell cancer accounts for 85–90% of invasive cancers of the cervix, whereas 5–8% are adenocarcinomas (non-clear cell). Clear cell adenocarcinoma is seen almost exclusively in association with maternal DES exposure. Finally, several viruses have been studied for their possible oncogenic role in cervical cancer, including papilloma and herpes (especially HSV-2). The data strongly indicate that papilloma virus is the major risk factor for cervical cancer.^{15,91}

A controversy has developed concerning the role of occupation (especially husband's occupation) and cervical cancer. Several researchers have noted that occupation (of the woman or spouse) is too closely associated with socioeconomic class to draw environmental inferences. However, widely different rates have been reported for cervical carcinoma of women classified by their spouse's occupation within the same socioeconomic class. Spouses of men with jobs involving exposures to dust, metals, chemicals, tar, and machine oil appear to have higher rates of cancer,

possibly due to indirect para-occupational genital exposures via the husband, but socioeconomic status continues to be a significant confounder.⁹²

In a review of occupation and mortality from reproductive cancers among women from 24 US states from 1884 to 1993,⁷¹ the highest risks were seen for cervical cancer among actors and directors (MOR = 4.1), typesetters and compositors (MOR = 3.3), and artists and performers (MOR = 3.1). Cervical cancer mortality risk was increased for certain service occupations: maids, cleaners, waitresses, and nursing aides. Increased risk among manufacturing occupations was observed for molding machine operators, printers and textile machine operators. Similar results in a proportionate mortality study were found by Alterman et al⁹³ using mortality data from the National Occupational Mortality Surveillance System from 1985 to 1990 for 27 states, and by Rix et al²⁰ among 1.4 million Danish working. Cellulose triacetate fiber workers exposed to methylene chloride with 20 or more years of employment were at increased risk of mortality (SMR = 8.02; $P < 0.01$) from cervical cancer⁹⁴ (Table 30.7.5).

Florida women pesticide applicators and farmers^{59,60} had an increased risk of cervical cancer incidence (SIR = 3.69; 95% CI = 1.84–6.61), without increased mortality. Sala et al⁷¹ and Alterman et al⁹³ observed that among African-American women, farmers had a significantly increased risk for cervical cancer mortality (MOR = 1.7; 95% CI = 1.2–2.4). Other studies have also observed increased cervical cancer risk among farmers,^{95,96} although not in all studies.^{61,97}

A study of nurses found an increased risk of cervical cancer as well as other lower genital tract cancers with hair dye use; this risk persisted despite adjustment for smoking.⁸⁹ Increases in cancer of the cervix uteri and of the genitals (unspecified) were reported in a case-control study of female laundry and dry cleaning workers even after adjusting for socioeconomic class. Cervical cancer was increased (SIR = 1.71; 95% CI = 1.3–2.3) among waitresses in Norway,⁹⁸ particularly in the subcohort working in restaurants with liquor licenses. Of note, waitresses have been at particularly high risk for both passive and active smoking exposure.

Prevention and early detection are best served by following the recommendations and schedules of the American

Cancer Society for PAP smear. Of note, a study by Savitz et al⁹⁹ comparing the risk of invasive carcinoma versus carcinoma in situ identified maids, cleaners and cooks as a group at particularly increased risk for invasive cervical cancer.

Miscellaneous: choriocarcinoma and hydatidiform mole

Choriocarcinoma, which arises from the trophoblastic epithelium of the placenta, usually is seen after hydatidiform mole, but can occur after a normal pregnancy (either aborted or progressing to term). Choriocarcinoma is very rare; in the US the incidence has been estimated at 1.4/million population. The risk of choriocarcinoma is about 1000 times greater after a pregnancy with hydatidiform mole than after normal pregnancy (choriocarcinoma is seen in 3% of hydatidiform moles). There also are increased risks associated with increasing maternal age, increasing parity, lower socioeconomic status, and exposure to exogenous sex hormones.^{15,100}

An increased incidence of hydatidiform mole and choriocarcinoma has been reported among Southeast Asians (1 in 200 deliveries versus 1 in 2000 in Europe and the United States). Ha et al¹⁰¹ examined the increased risk for gestational trophoblastic disease (hydatidiform mole and choriocarcinoma) in Vietnam since the spraying of the dioxin-contaminated Agent Orange as a case-control study. Adjusted odds ratio was increased among agricultural workers breeding pigs (OR = 5.7; 95% CI = 1.27–27.6) as well as increased meat intake, but no difference was noted for residence history with Agent Orange exposure or agricultural use of pesticides.

In a Japanese study,¹⁰² cosmetic salespersons and beauticians were reported at increased risk for hydatidiform mole. It has been hypothesized that the increased risk of cancer may be related to exposure to a red pigment commonly used in Japan as a cosmetic. The same study also

reported significantly increased risks of hydatidiform mole for textile dyers, printers, chemical workers, and fishermen.

CANCERS OF THE REPRODUCTIVE ORGANS IN THE MALE

Testicular cancer

Testicular cancer accounts for less than 1% (0.2% lifetime risk for US white males) of all male cancer deaths; nevertheless, it is the most commonly diagnosed malignancy in men aged 20–34 years with a 50% increase noted in the age-adjusted incidence between 1973 and 1990. The young age of onset tends to cast doubt on an occupational etiology, unless para-occupational factors such as indirect para-occupational exposures from parents are the cause. However, the incidence of testicular cancer has been rising over the last 50 years in industrialized countries (England, the United States, Japan, and Denmark), without an obvious connection to increased screening. There appears to be an increased risk with upper socioeconomic class (up to 2.5 times). Race still appears to be an important risk factor; it is generally rare among black populations. Other risk factors include higher socioeconomic class, testicular trauma, mumps, testicular atrophy, the solvent dimethylformamide, and radiation exposure.^{15,103–105}

In several large epidemiologic studies examining occupation, an increased risk for testicular cancer has been found among a variety of disparate occupational groups (Table 30.7.6).^{106,107} Paternal occupational exposure to metal or the food and beverage industry may be related to an increased risk of testicular cancer in Ontario.¹⁰⁸ In particular, non-seminoma tumors were associated with male parents who were miners, food and beverage processors, utilities employees, and other service workers, while seminomas were associated with male parents who were leather industry employees.¹⁰⁸

Possible causes/contributing factors	Occupation/group	References
<i>Exposures</i>		
Dimethylformamide (DMF)	Navy aviation mechanics, leather tanners, US Navy personnel, British Navy airmen	135, 136, 137, 138, 139, 142, 145
Chromates, metal protective primers (zinc chromate, solvents)	Painters in Geneva	141, 145
Agricultural chemicals	Farmers, pesticide applicators, agricultural workers	59, 105, 131

Table 30.7.6 Testicular cancer: occupational and environmental causes

A variety of other occupational and environmental exposures have been associated with an increased risk of testicular cancer. An increase in cancer of the testis was seen among 39,546 employees of the United Kingdom Atomic Energy Authority between 1946 and 1979.¹⁰⁹ Stenlund and Floderus¹¹⁰ found a significantly increased risk for testicular cancer with occupational electromagnetic field exposure in a Swedish case control. Floderus et al,¹¹¹ in a large Swedish cohort study from 1971 to 1984, analyzed jobs for possible occupational exposure to magnetic fields using a job exposure matrix. An association was noted for testicular cancer among young male workers judged to have more definite occupational electromagnetic field exposures, although the authors noted that occupational heat exposure might also be an important factor. In a separate case control study¹¹⁰ an increased risk, predominantly for non-seminoma tumors was noted with increased electromagnetic field occupational exposure.

In controlled studies, occupational exposure to temperature extremes was associated with increased risks of testicular cancer incidence.¹¹² Hobbesland et al¹¹³ studied cancer incidence in 8 ferrosilicon and silicon metal plants in Norway. Testicular cancer incidence (SIR = 2.30) was elevated among the furnace workers. Metal workers had a significantly increased risk of testicular cancer (OR = 2.05; 95% CI = 1.17–3.58) in Germany.¹¹⁴

Although controversial, an increased risk of testicular cancer has been associated with exposure in utero to estrogens (such as DES) in animals and possibly in humans.^{103,115–117} Of note, cryptorchidism, the only established risk factor for testicular cancer, is associated with in utero estrogen exposure. Cryptorchidism appears to also have an increasing incidence, especially in the more developed nations, paralleling the increase noted in testicular cancer incidence.^{115,118}

Recent reports have raised the question of an overall worldwide significant decrease in human sperm counts, possibly related to the use of certain pesticides and their estrogen effects.^{115,119–125} The latter issue has been given further credence by the historical link between profound male infertility and occupational exposure to the pesticide dibromochloropropane (DBCP). The pesticide dibromochloropropane (DBCP) causes sterility in human males exposed occupationally. It also is very toxic to the testis in animals (causing atrophy and degeneration), and it is carcinogenic (although not to the testis) in a variety of animal species. However, so far, DBCP has not been demonstrated to be carcinogenic to the testis (or other organs) in humans.^{126,127} More recently, some of the organochlorines have been shown in animal models to be powerful antian-drogens.¹¹⁵ These chemicals and their derivatives are environmentally persistent, and extremely lipophilic, leading to lifetime body burdens. Therefore, this is an area of great research interest.¹²⁸

Several studies have found increased risks for testicular cancer among agricultural workers.¹²⁹ These include a case control study¹³⁰ of 347 people with histologically confirmed germ cell tumors of the testis, that demonstrated a significant odds ratio of 6.27, and a large case-control

study (2434 cases) in England and Wales, that observed increased testicular cancer rates (OR > 3) among farmers. Fleming et al^{59,60} performed a retrospective cohort study of 33,658 pesticide applicators licensed in Florida. Testicular cancer incidence was significantly elevated compared with the general population (SIR = 2.49; 1.58–3.74). In a cohort study in Sweden^{56,131} an elevated, but non-statistically significant increase for testicular cancer was found among both agricultural workers and pesticide applicators. Mills¹³² found a significant correlation ($r = 0.41$) for testicular cancer incidence in Hispanic males with atrazine occupational pesticide exposure. In a case-control study of testicular cancer, Hardell et al¹³³ found that embryonal testicular cancer, but not seminoma, was associated with reported history of farming (OR = 3.1; 95% CI 1.03–9.1) and exposure to farm animals (OR = 3.3; 95% CI 1.00–10.9); Kirstensen et al¹³⁴ found increased risk of seminoma associated with parental exposure to specific fertilizer regimens on farms. However, several other studies among agricultural workers do not support this finding.^{54,56}

Occupational exposure to the bipolar solvent dimethylformamide (DMF) has been implicated as a suspect risk factor for testicular cancer in a variety of studies. This association was first seen in a cluster and subsequent retrospective cohort among navy aviation mechanics who used DMF and other solvents.¹³⁵ Boice et al¹³⁶ found significantly increased risk of testicular cancer associated with exposure to mixed solvents among aircraft manufacturing workers; Ryder¹³⁷ found significant increases in testicular cancer risk in a case-control study of the UK Royal Navy, particularly among Fleet Air Arm (OR = 1.90; 95% CI = 1.04–3.48), air engineers (OR = 2.32; 95% CI = 1.20–4.48), and aircraft handling (OR = 7.31; 95% CI = 1.81–29.53). Another cluster of testicular cancer was identified among leather tanners in a follow-up case-control study;^{138,139} increased risk for development of seminoma was also found in male parents who had been involved in leather tanning.¹⁴⁰

Increased testicular cancer was observed in two retrospective cohort studies: one among US Navy personnel with exposure to chromate-based paints and solvents (including possible DMF exposure),¹⁴¹ and another study of painters in Geneva who were exposed to metal protective primers containing zinc chromate and a variety of solvents.¹⁴² DMF is neither a known animal carcinogen nor mutagen, but it can cause testicular damage in animals. In a study conducted by a DMF manufacturer,^{143,144} of 2530 potentially exposed employees, no increase in testicular cancer was observed. This has led Ducatman and others to hypothesize that DMF (a highly polar solvent) may act to increase tissue absorption of direct carcinogens such as chromates, cadmium, and other heavy metal pigments.^{145,146}

Mesothelioma of the tunica vaginalis from the head of the epididymis (i.e., primary malignant testicular mesothelioma) has been reported in asbestos workers with 20 years of regular exposure and a latency period of greater than 20 years from first exposure;^{147,148} no asbestos fibers were identified in the tumors.

Hardell et al¹⁴⁹ observed an increased risk of testicular cancer with self-reported polyvinyl chloride exposure; the odds ratio was 6.6 (95% CI = 1.4–32) with the majority seminomas. Cancer of the genital organs was moderately increased among men exposed to tetrachloroethane exposure during World War II in the impregnation of clothing for protection against mustard gas.¹⁵⁰ Testicular cancer was noted to be increased in a study of cancer mortality among Northern Georgia carpet and textile workers.¹⁵¹ There have been two separate clusters reported of testicular carcinoma among podiatrists, with no obvious etiology.¹⁵²

In certain working populations, such as those exposed to DMF, teaching testicular self-examination and testicular cancer screening may be warranted, given the markedly increased survival rate with early detection and treatment of this disease and its peak occurrence among working-aged men.

Prostate cancer

Prostate cancer is common, and is responsible for at least 27.5% of cancer cases among males and 13% of cancer deaths in the US. The highest rates are reported in industrialized Western countries. In 1981 in the United States, 70,000 men were newly diagnosed and 22,700 men died of prostate cancer. As a subgroup, African-American men in the United States have the highest incidence and mortality in the world. Because this incidence is not seen among African black men, some other risk factor such as dietary influences (e.g., fat intake) and occupational and environmental exposures may be involved. Prostate cancer is very rare in men younger than 50 years of age, and it is chiefly seen in older men. There appears to be an association with sexual behavior, in that the risk increases with an increase in the number of sexual partners and a history of repeated venereal infections. Ninety-five per cent of prostate cancers are adenocarcinomas.^{15,153}

Hanchette and Schwartz¹⁵⁴ performed an ecological study of the geographic distribution of prostate cancer mortality

within the US. Data on prostate cancer mortality for white men in 3073 counties in the continental US were compared to UV radiation levels at the county level and as a geographic trend. The authors demonstrated a significant north–south trend in mortality; higher mortality was demonstrated in the north and with lower levels of UV radiation. These results have been interpreted as providing possible support for a role of vitamin D as an antitumor agent in prostate cancer.

Farmers, teachers, welders, metal workers, mechanics, plasterers, textile workers, transport workers, fire fighters, nitrate workers, and rubber workers exposed to heavy metal oxides have all been reported to be at an increased risk of prostate cancer (Table 30.7.7). Cadmium is one of the few chemicals predominant in occupational exposures clearly associated with prostate cancer.^{103,155–163}

An increased risk in cancer of the prostate has been reported among employees of the United Kingdom Atomic Energy Authority between 1946 and 1979; of interest, those with radiation monitoring showed a significant dose–response relationship.^{109,164} At both Hanford and Oak Ridge National Laboratory, there were increases in prostate cancer without a dose–response relationship. Increases in cancer of the prostate have not been seen in other populations exposed to high doses of ionizing radiation, such as the atomic bomb survivors.^{165,166} Increased risk of prostate cancer mortality was found among workers exposed specifically to kerosene during uranium processing.¹⁶⁷

Prostate cancer has been suspected among workers exposed to cadmium, although this association is still somewhat controversial.¹⁶⁸ Potts¹⁶⁹ first reported on 74 men exposed for over 10 years to cadmium as battery workers, with three out of eight deaths due to prostate cancer. There are several small positive cohort studies. Holden¹⁷⁰ reported one case among 42 workers with 2–40 years of exposure to cadmium oxide occurring more than 20 years after first exposure; Kipling and Waterhouse¹⁷¹ retrospectively studied 248 workers with at least 1 year of cadmium exposure and observed four deaths (0.58 predicted). A retrospective study by Lemen¹⁷² of 292 workers with at least 2 years of exposure

Possible causes/contributing factors	Occupation/group	References
<i>Exposures</i>		
Cadmium	Battery workers, other workers, nickel-cadmium battery workers	169, 170, 171, 172, 173, 174, 175

Table 30.7.7 Prostate cancer: occupational and environmental causes

in a cadmium smelter observed four deaths (versus 1.88 expected). In a meta-analysis, available data from the most recent follow-up of causes of death among cadmium workers in six different cohorts identified 28 cases among 522 nickel-cadmium battery workers (SMR = 162); a possible additional role of nickel was suggested. Two case control studies^{173,174} of prostate cancer have found the relative risk to be about 1.7 for work in the cadmium trades.

In animals, there is definite evidence of carcinogenicity with cadmium exposure.¹⁷⁵ It also is hypothesized that prostate cancer may be related to crucial zinc-calcium interactions in the prostate. Of note, there has been no further evidence of an association between occupational exposure to nickel-cadmium batteries (cadmium oxide) and cancer of the prostate in longitudinal follow-up of a cohort, with four cases reported by Kipling,¹⁷¹ nor in the United States cadmium production workers. However, this finding may be related to more recent lower occupational exposures.¹⁷⁶

A number of studies have observed an association between working with metals and prostate cancer.^{177,178} A review of studies of metal workers and repairmen by van der Gulden¹⁶³ found a slight but consistent excess of prostate cancer. An increased incidence of prostate cancer was found in a retrospective study of male workers producing ferrosilicon and ferrochromium; in another study of ferrochromium workers, a similar increase was observed. Hobbesland et al¹¹³ studied prostate cancer incidence in eight ferrosilicon and silicon metal plants in Norway; prostate cancer incidence was increased among the blue-collar non-furnace workers. Costantino et al¹⁷⁹ reported that coke oven workers have an increased risk of prostate cancer as much as 4.45 times greater than non-coke oven workers, even as their risk of respiratory cancer is decreasing. Firefighters in Washington State were found to have an increased risk of prostate cancer incidence (SIR = 1.45; 95% CI 1.1–1.7) compared to the general population.¹⁸⁰

Farmers and agricultural workers are the occupational groups most studied for prostate cancer risk. Compared with other occupational groups, farmers are reported to have a lower risk of cancer from all causes combined and most of the major types of cancer.^{181–184} The observations that farmers have an elevated risk of prostate cancer, and are exposed to greater than average amounts of UV radiation, are at odds with the suggested protective effect of UV radiation, and thus vitamin D, on prostate cancer.¹⁵⁴ It is possible, however, that some environmental factor associated with farming and prostate cancer may be responsible and identifiable. For example, increased nitrate levels in drinking water in Spain were associated with an increased risk of prostate cancer mortality.¹⁸⁵

A number of studies have examined the issue of increased prostate cancer among farmers and pesticide applicators.^{162,186,187} One study¹⁵⁶ suggested that 38% of the excess prostate cancer mortality among African-Americans could be due to farming-related occupations. Mills¹³² found a significant correlations for prostate cancer incidence and black males with atrazine ($r = 0.67$) and captan ($r = 0.49$) occupational pesticide exposure. In a case-control study of Checkoway et al,¹⁸⁸ farming was the most common occu-

pation among the prostate cancer patients (75% cases vs 38% controls). This association persisted even when adjusted for education, age, race and county of residence. Another case-control study of farming and prostate cancer risk in Iowa¹⁸⁹ observed an increased risk (RR = 1.7; 95% CI = 1.0–2.7%) of prostate cancer among farmers after adjustment for age, smoking, alcohol, and diet, compared to cancer-free controls selected from the cohort. The relationship was strengthened (RR = 2.0; 95% CI = 1.1–3.6) when localized well-differentiated tumors were excluded. Adjusting for family history only slightly attenuated the association. Iowa cancer mortality data has demonstrated that the risk of prostate cancer in farmers may have increased from 1971 to 1986.¹⁸⁹

A number of literature reviews and meta-analyses of farming and cancer risk, including prostate cancer risk, have been performed with variable results.^{54,157,181,190–193} Internationally, prostate cancer risk for farmers has been found to be consistently but only slightly elevated, with some variation across countries. Some of the variation is believed to be associated with differing types and amounts of pesticide and other farming exposures.

Two recent studies of pesticide applicators found positive associations between this occupational category and prostate cancer.^{59,60,158} Dich and Wiklund¹⁵⁸ studied the cohort of 20,025 Swedish pesticide applicators. The total standardized incidence ratio (SIR) for prostate cancer was significantly but only mildly elevated at 1.13 (95% CI = 1.02–1.24). Fleming et al^{59,60} performed a retrospective cohort study of 33,658 pesticide applicators licensed in Florida. Prostate cancer mortality [SMR = 2.38 (95% CI = 1.83–3.04)] and prostate cancer incidence [SIR = 1.92 (1.73–2.14)] were both significantly elevated. An investigation of golf course superintendents found a significantly increased risk of prostate cancer mortality (PMR = 2.93; 95% CI = 187–460).¹⁹⁴

There is an ongoing controversy as to whether an increase in cancer of the prostate noted among butchers and meat cutters in the United Kingdom could be due to occupational exposure to androgens.^{195,196} However, the levels of androgen exposure are believed to be insignificant, and increased prostatic cancer was not noted in a large cohort study of abattoir workers in the United States.^{197,198}

An increase in prostate cancer was found among 857 Swedish chemists.¹⁹⁹ Chen and associates^{200,201} noted an increase in prostate cancer in production workers exposed to DMF and acrylonitrile; this risk was not observed in workers who were exposed to only DMF. Of interest, an unexpected increase was seen previously in a cohort of acrylonitrile workers.²⁰² Whorton et al²⁰³ observed a significant increase in prostate cancer mortality (SMR = 3.30; 95% CI = 1.21–7.19) among workers in a chemical plant making acetic acid and acetic anhydride for the synthesis of cellulose triacetate fibers. Textile workers have been noted to have an increased risk of prostate cancer in large epidemiologic surveys. However, in a case-control study in South Carolina, no relationship except among African-American males was found between working in the textile industry and prostate cancer.²⁰⁴

In the past, studies of rubber workers have shown an increase in the rates of cancer of the prostate, although no specific carcinogens were causally identified.²⁰⁵⁻²⁰⁹ A recent meta-analysis by Stewart et al²¹⁰ concluded that occupational exposure to rubber and tire manufacture did not result in an increased risk of prostate cancer.

Although controversial, workplace sponsored prostate cancer screening can be instituted based on the length of employment and possible occupational risk factors of employees.³

Male breast cancer

Male breast cancer is rare, and studies have been very limited. Female to male incidence ratios vary from 70:1 to 130:1 around the world. It is known that males with altered estrogen, orchitis or orchiectomy, gynecomastia, and Klinefelter's syndrome are at greatest risk of developing breast cancer; there are also reports of familial clusters and an association with higher reported weight during adolescence. The strongest risk factors appear to be higher socioeconomic class, estrogen and radiation.^{15,211}

A Swedish Cancer Environment Registry study²¹² found increased incidences of male breast cancer in several occupations. The highest risk was found among men employed in making soap and perfume and among newspaper printers. Other increased rates were seen among a variety of occupations. In a large US national mortality study, Cocco et al²¹³ observed a significantly increased risk for employment in blast furnaces, steel works and rolling mills (OR = 3.4; 95% CI = 1.1-10.1) as well as motor vehicles manufacture (OR = 3.1; 95% CI = 1.2-8.2). Occupational exposures to electromagnetic fields, PAHs, herbicides and pesticides, and organic solvents were not associated with an increased risk.

Male and female breast cancer incidences were both increased among employees in a Danish pharmaceutical plant where sex hormones, antibiotics, insulin and enzymes were produced.⁴³ There were three male breast cancer cases with 0.4 expected. Hansen²¹⁴ also found an increased risk for male breast cancer incidence among workers potentially exposed to gasoline vapors and combustion products. The odds ratio for men potentially exposed more than 3 months ranged from 2.5 (95% CI = 1.3-4.5), to 5.4 (95% CI = 2.4-11.9) for men with first employment potential exposure before age 40.

Robinson et al²¹⁵ found a significantly increased risk of male breast cancer (PMR = 4.69; 95% CI = 128-720) among white male carpenters. This risk was associated with last employment in wood machining trades. Forastiere et al²¹⁶ found an increased risk of male breast cancer mortality (SMR = 14.36) based on only two cases.

An increase in male breast cancer has been observed in men with a variety of occupational exposures to electromagnetic fields in both the United States and Norway.²¹⁷ Demers and coworkers²¹⁸ reported the highest risk among electricians, telephone linemen, and electric power workers in a population-based case-control study. Rosenbaum et al²¹⁹ performed a case-control study using the New York

State Tumor Registry between 1979 and 1988, with 71 male breast cancer cases. No increased risk was found for electromagnetic field exposure, although an increased risk was associated with occupational heat exposure. Stenlund and Floderus¹¹⁰ did not find an increased risk for male breast cancer with occupational electromagnetic field exposure in a Swedish case-control study. Feyshting et al²²⁰ performed a case-control study of male and female breast cancer risk and residential magnetic field exposure with a non-statistically significant increased relative risk of 2.1 (95% CI = 0.3-14.1) for male breast cancer incidence.

30.8 Brain Neoplasms

Paul A Demers

In this chapter the classification, occurrence, and suspected occupational and environmental causes of intracranial neoplasms are discussed. Although even a benign tumor occurring in the enclosed space within the skull may eventually prove fatal if untreated, this chapter is concerned primarily with malignant brain tumors. Malignant tumors identified in epidemiologic studies and case series have often been found to be gliomas of the astrocytic series and, in particular, glioblastoma multiforme. However, most studies have not had the ability to differentiate between brain tumors of different histologies so that common non-malignant neoplasms, such as meningiomas, also are discussed. Extracranial nervous system tumors are not considered in this chapter because they are both extremely rare and have, in general, not been associated with occupational or environmental agents. Although the brain is a frequent site of metastasis, most commonly from the lung or breast, tumors whose origin is outside the brain also are not considered in this chapter.

CLASSIFICATION

Nervous system tumors are primarily classified according to the presumed cell type of origin. Table 30.8.1 presents the most common brain tumor histologic types. Gliomas are the most common malignant brain tumor. The majority of gliomas belong to the astrocytic series, of which grades 1 and 2 are referred to as astrocytoma, whereas grades 3 and 4 are referred to as malignant astrocytoma or glioblastoma multiforme. Lymphomas also may arise within the brain and are sometimes referred to as microgliomas. Meningiomas are the second most common brain tumor (after gliomas) and the most common non-malignant tumor. Nerve sheath tumors, also referred to as neuromas, are usually benign.

DESCRIPTIVE EPIDEMIOLOGY

The age-adjusted incidence rate for brain neoplasms in the United States is 7.0 per 100,000 people for men and 5.0 for women.¹ The corresponding mortality rates are 5.1 and 3.5, respectively. Although the incidence varies somewhat by country, Western Europe and Canada have rates similar to that of the United States, while Japan and some Asian countries have lower rates.² In the United States, the risk of brain cancer is higher among whites than blacks, Asians, and other racial groups.¹ In the US all women and African-American men appear to have lower rates of gliomas and higher risk of meningioma than white men.³ The reason for the gender and racial differences is not known. A higher risk of brain tumors among men relative to women also has been observed in a number of other countries.²

Among adults, brain cancer incidence peaks between the ages of 65 and 75.¹ Brain cancer is the second most common malignancy in children (after leukemia). Approximately a fifth of both incident and fatal childhood cancers arise in the brain, and some histologic types occur

almost exclusively in children. For example, medulloblastomas (primitive neuroectodermal tumors) account for almost a quarter of brain tumors among children but less than 2% of brain tumors among adults.

Five-year survival from brain cancer has improved in recent years and is approximately 30% for all malignant brain and central nervous system neoplasms in the US.¹ Survival is primarily determined by the histology of the tumor and the age at diagnosis rather than stage at diagnosis. Only 2% of persons diagnosed with glioblastoma multiforme survive 5 years, with younger individuals having a better prognosis.³ Brain neoplasms may metastasize to other sites within the brain but rarely metastasize outside the central nervous system. However, the brain is a relatively common target of metastasis from other sites, such as the lung and breast.

The etiology of brain neoplasms is poorly understood. Although some genetic factors are suspected, only a small percentage of brain tumors are currently believed to be due to inherited factors. Head injuries, exposure to x-rays, and viruses are suspected of causing brain tumors, whereas intracranial lymphomas have been associated with immunosuppression.³ Brain cancer rates have been rising in many industrialized countries in recent decades.⁴ The increase has been observed primarily among individuals over 65 and has occurred in both males and females. It is unclear whether the increasing rates are due to changes in diagnostic practices or reporting procedures alone, or whether the true incidence is rising.

ENVIRONMENTAL AND OCCUPATIONAL CAUSES

The higher incidence of brain neoplasms observed in men relative to women, as well as the positive results of animal studies of chemical agents, have raised the suspicion that environmental exposures, possibly of occupational origin, may increase the risk of brain cancer. Based on the results of experimental studies using rodents, many occupational and environmental exposures are suspected of increasing the risk of brain neoplasms. In addition, epidemiologic studies have identified a wide range of occupations and industries with a higher risk for brain neoplasms than the general population, often without implicating any specific exposures. However, the results of many of these studies have been inconsistent and there are no occupational or environmental exposures widely accepted as causing brain neoplasms.

EXPERIMENTAL STUDIES OF ANIMALS

Animal experimentation with carcinogens has not always been useful in predicting the target organ for carcinogenesis in humans. However, in the case of brain neoplasms atten-

Gliomas
 Glioblastoma multiforme
 Astrocytoma
 Primitive neuroectodermal tumors
 Oligodendroglioma
 Ependymoma
 Pineal tumors
 Lymphoma
 Meningeal tumors
 Meningiomas
 Meningeal sarcomas

 Acoustic neuromas
 Pituitary tumors

Table 30.8.1 Histologic classification of common primary brain tumors

tion has focused on animal studies in the hope of identifying the agent or agents responsible for the excess risks observed among workers exposed to multiple chemicals, such as in the petrochemical and rubber industries. The basis for such anticipation is that humans share common mechanisms with other mammals for excluding many foreign substances from the central nervous system. A large number of agents that can produce brain neoplasms under experimental conditions have been identified. These belong to a wide variety of families and include nitrosoureas, triazenes, hydrazines, and various polycyclic aromatic hydrocarbons.⁵ In addition, there is evidence that lead acetate and subacetate may cause gliomas in rats. Although early experiments used direct implantation of chemicals into the intracranial space, later studies used systemic administration, which may be more relevant for assessing occupational or environmental risks. Agents that have produced brain tumors in animals after inhalation, ingestion, or exposure through the placenta are listed in Table 30.8.2.

Generally, there is insufficient epidemiologic evidence to either support or refute an association between these chemicals and brain cancer in humans. However, we have learned from animal experiments that the tissues of the central nervous system are susceptible to chemical carcinogens and that, despite the protection afforded by the blood-brain barrier, chemical agents that have been introduced via inhalation and ingestion have been able to produce intracranial tumors.

EPIDEMIOLOGIC STUDIES

Despite the availability of data from a large number of epidemiologic studies, the relationship between brain neoplasms and occupational and environmental exposures has not been clearly defined. There are a number of reasons why this is true. First, because of the rarity of brain cancer, most studies of occupational groups have lacked the statistical power to detect excesses, whereas those with a sufficient number of cases, such as case control or very large cohort studies, have typically lacked relevant exposure information. Second, many studies have historically relied on death certificates, which often lack the histologic type and also may not specify whether the brain tumor was malignant or benign. There is evidence that brain

Vinyl chloride

Table 30.8.3 Chemicals, physical agents, occupations, and industries suspected of increasing the risk of brain cancer

cancers of different histologic types have different risk factors and, thus, the combination of all histologies could obscure existing associations. Last, some studies have found the incidence of brain cancer to be positively associated with higher socioeconomic status.³ Whether this association is due to the fact that these individuals have a greater likelihood of diagnosis or autopsy or whether the actual risk of disease is different is not known, but socioeconomic status may be a potential confounding factor in some studies. Table 30.8.3 lists chemicals, physical agents, occupations, and industries reported to be associated with an increased risk of brain cancer in humans. However, in all cases there are conflicting studies, making it difficult to draw conclusions regarding causal relationships.

AGENTS AND OCCUPATIONS ASSOCIATED WITH NEOPLASMS

Vinyl chloride

In 1976, Maltoni reported on a relationship between inhalation of vinyl chloride and brain tumors in rats.⁶ Around the same time, epidemiologic studies found an excess risk of brain cancer in exposed workers.^{7,8} In general, the relative risks observed in these studies ranged from 1.5 to 2.5.⁹ Among the few studies that have collected histologic information, a large proportion of the brain tumors were found to be glioblastoma multiforme. It is important to note that not all investigators have found an association. For example, a large collaborative study conducted by the International Agency for Research on Cancer did not find a strong association between brain neoplasms and exposure

to vinyl chloride, and an update of one of the original cohorts observed only a small excess that was not associated with exposure.^{10,11}

Formaldehyde

High rates of brain neoplasms have been seen in professional occupations potentially exposed to formaldehyde, such as embalmers, pathologists, morticians, and anatomists.¹² However, most studies of industrially exposed workers have not found an elevated risk.^{12,13} Socioeconomic status has been suggested as a possible confounder, although one analysis that compared anatomists to psychiatrists, an occupational group with similar social and economic status, still found an elevated risk among anatomists.¹⁴

Inorganic lead

Several epidemiologic studies have observed an association between the risk of brain cancer and occupational exposure to lead. Anttila and colleagues found an excess risk of glioma among a large cohort of Finnish workers biologically monitored for blood lead.¹⁵ An excess associated with both elevated blood lead and duration of lead exposure was observed. Cocco and colleagues found an association between brain cancer and intensity of lead exposure in a death certificate study using a job exposure matrix.¹⁶ However, excesses have not been observed in most other studies of workers in lead exposed industries.¹⁷ The studies which have observed an association have been given greater attention because the central nervous system is the target organ for other toxic effects of lead and because some lead salts have been found to be carcinogenic to animals.⁵

Organic solvents

Thomas and Waxweiler have suggested that organic solvents be considered as possible brain carcinogens because they are exposures that are held in common by several of the occupational groups identified as being at higher risk.¹⁸ Heineman and colleagues observed an association between the risk of astrocytic brain cancers and exposure to methylene chloride, carbon tetrachloride, tetrachloroethylene, and trichloroethylene assessed through a job exposure matrix.¹⁹ Rodvall and colleagues observed an excess risk associated with exposure to solvents, degreasers, and cleaning agents in a Swedish case-control study of gliomas.²⁰ Some studies of childhood cancer have observed an association between brain cancer and paternal exposure to paints.²¹ However, evidence for an association between hydrocarbon exposure and childhood cancers appears to be less consistent.

Ionizing radiation

Exposure to ionizing radiation frequently has been reported to increase the risk of brain neoplasms. Studies of individuals who received scalp irradiation or full-mouth dental x-ray studies as children have found a higher risk of

brain tumors.³ Airline pilots, who are exposed to cosmic radiation during high altitude flights, have also been observed to be at an increased risk of brain cancer.²² High rates of brain neoplasms also have been observed among workers at plants producing nuclear fuels or weapons in some studies.²³ Histology was reported for two of these studies, and gliomas were the predominant type observed. It is important to note that no association with radiation exposure was found in the nuclear industry studies, and it is unclear whether radioactive materials or some other exposure common to the plants is responsible.

Electromagnetic fields

A potential association between occupational exposure to electromagnetic fields (EMF) and brain neoplasms was first reported by Milham, who found a high rate in men whose usual occupation (from death certificate) involved potential exposure to EMF.²⁴ An association between employment in these occupations, which include electricians, utility workers, communications workers, welders, and electrical or electronic equipment repairers, technicians, and engineers, has been observed in a number of subsequent studies.³ More recent studies have attempted to assess quantitative exposure to magnetic fields. The results of these studies have been mixed and the potential for confounding due to chemical or other exposures remains a limitation.²⁵ A recent meta-analysis of five studies which had used quantitative estimates of magnetic field exposure to estimate dose-response found evidence consistent with a small overall increase in relative risk.²⁵ Some studies have observed an increased risk of brain cancer among the children of men employed in operations with potential EMF exposure but a recent Swedish study which attempted to assess exposure quantitatively did not find an association.^{21,26}

Agricultural work

Farmers and other agricultural workers are at lower risk than the general population for most types of cancer (other than possibly multiple myeloma and lymphomas), but a number of studies have found them to be at higher risk for brain neoplasms.²⁷ For example, Musicco and colleagues found an excess of gliomas among farmers in Northern Italy.²⁸ The excess was limited to those who had worked in the 1960s or later, leading the authors to speculate that it might be due to the introduction of pesticides, fertilizers, and herbicides around the same time. Excesses also have been seen in other studies among farmers or farm workers, and potential excesses also have been observed among other agricultural occupations such as pesticide applicators and agricultural extension agents.^{27,29} Agricultural workers are potentially exposed to a variety of exposures including fertilizers, fuels, vehicle exhausts, organic dusts, and zoonotic bacteria and viruses, as well as insecticides, fungicides, and herbicides.³⁰ Some case control studies and a number of large state or national studies have found excess risks in various subpopulations of agricultural workers, but a consistent pattern has yet to

emerge.^{3,29} Several studies have also observed an association between paternal exposure to pesticides or employment in agricultural occupations prior to birth and the risk of childhood brain cancer.³¹

Firefighting

Smoke is a complex mixture of combustion products. Although the exact composition may vary significantly from fire to fire, smoke commonly contains a number of carcinogens such as polycyclic aromatic hydrocarbons, benzene, formaldehyde, and others.³² Several studies have observed a two-fold excess of brain tumors among firefighters.^{18,33–35} Several have not observed an association.^{5,26} In addition, the relationship with duration of employment and other indicators of exposure in the positive studies has been weak, but given the variability in smoke exposure between fires these may only be poor surrogates for smoke exposure. The only study that examined the risk by number of fires fought observed a pattern that was compatible with a dose-response, but there were too few cases to draw firm conclusions.¹⁸

Rubber industry

Rubber manufacturing was one of the first industries to come under suspicion for an excess of brain cancer based on evidence that Ohio workers producing tires had a higher risk of brain neoplasms.³⁶ Although early studies implicated the tire curing and building processes, few studies have examined the risk among subpopulations defined on the basis of potential exposure. Most ensuing investigations have not found an excess of brain neoplasms among rubber workers, possibly indicating that exposure may have changed over time.³⁷ However, a case-control study of Shanghai women observed a five-fold excess among rubber workers and a five-fold excess was also observed among male rubber workers from Moscow.^{38,39}

Petrochemical industry

Suspensions that petrochemical workers are at higher risk for brain neoplasms were raised in 1978 when a large cluster of cases was reported among former employees of a petrochemical company in Texas.⁴⁰ Following the discovery, a series of studies were initiated in order to determine whether or not an excess risk truly existed. In general, the results of the initial studies sponsored by government agencies and the Oil, Chemical, and Atomic Workers Union were consistent with a two-fold excess, and the histologies of the majority of tumors reported were either astrocytoma or glioblastoma multiforme.⁴¹ However, studies sponsored by the industry at the same time generally found no excess risk. Much of this disparity may have been due to differences in study design (proportionate mortality versus cohort studies) and populations studied (all workers versus workers most likely to be exposed). More recent cohort studies have continued to yield mixed results and to suffer from the same limitations.⁴² Several case control

studies have also observed an association between employment in the industry and brain neoplasms, but no association with any specific chemical exposure has been found.^{43,44}

Parental exposure and childhood cancer

Numerous epidemiologic studies have examined the relationship between parental occupation and childhood brain cancer. Although no firm causal relationships have been established, suggestive associations have been observed with paternal exposure to paints, hydrocarbons, ionizing radiation, electromagnetic fields, and pesticides.^{21,31,45} The degree to which a father's exposure may influence an offspring's cancer risk is unclear, and few studies have examined maternal occupational exposures. Experimental studies have found animals that were exposed to carcinogens transplacentally or at young age to be particularly susceptible to brain neoplasms. However, it is unclear whether these studies are relevant to adult or childhood cancer in humans because of the long induction times observed in animal experiments.

CLINICAL EVALUATION

The diagnosis, clinical course, treatment, and prognosis of brain tumors associated with occupational or environmental exposures are no different from their non-occupational counterparts. Patients initially may present with a variety of symptoms including headache, seizures, personality changes, vomiting, loss of sensory functions, hemiparesis, hemiplegia, or ataxia depending on the tumor type and location.⁴⁶ Tumors are detected after the onset of symptoms using computed tomographic (CT) scanning or magnetic resonance imaging (MRI). Treatment may require surgery, radiotherapy, or chemotherapy, or some combination of these methods depending on the histology or location of the tumor.

Screening for brain neoplasms cannot be recommended at this time. It would be very difficult to identify a group of individuals who are clearly at higher risk given the ambiguity of much of the epidemiologic evidence, and unfortunately, there are no appropriate screening tests available. The utility of advanced diagnostic techniques, such as MRI, for improving or prolonging the life of asymptomatic patients when used for screening has yet to be proved, and the financial costs would be substantial.

30.9 Skin Cancers

David E Cohen, Shirley Bassiri, Brian G Forrester, James Nethercott

INTRODUCTION

The skin is the largest organ of the body and a critical interface with the environment. During activities of routine daily living, work, and recreation, the integument is subjected to a legion of chemical and physical assaults that are typically neutralized through metabolic and homeostatic mechanisms. When these systems are overwhelmed, cutaneous and systemic disease may result. When evaluating occupational and environmental dermatoses, a variety of inflammatory, neoplastic, and infectious diseases may be encountered. Irritant and allergic contact dermatitis are the most common occupational dermatoses, and benign and malignant neoplasms may be associated with a variety of exposure patterns. Malignancies of the skin represent the most common human cancers.

The major divisions of the skin are the epidermis (comprising the outermost layer), the dermis (composed of collagen, elastin, and appendageal structures), and the subcutis (principally composed of fat). Cutaneous neoplasms may be encountered in all layers of the skin but the epidermis is the most common site.

The epidermis is subdivided into four histologically defined sections that represent the differentiation pathways of a mature skin surface: basal, spinous, granular, and cornified layers. The basal layer, or stratum germinativum, abuts the dermis and is composed principally of epidermal progenitor cells. These cells divide constantly to replenish those lost on the surface and consequently maintain epidermal integrity. One daughter of this mitotic activity will move upward toward the surface as it undergoes morphologic and biochemical changes in a process called terminal differentiation. These cells from the mitotic layer first move into the stratum spinosum, where they begin to differentiate, developing more extensive intracellular filaments and pronounced intercellular attachments at desmosomal junctions with adjacent cells.

With further upward movement toward the surface, the cells reach the granular layer, where they begin to accumulate keratohyalin granules in their interstices. Membrane-coating granules attach to the outer cellular membrane and can secrete substances into the intercellular space. This process begins to isolate the cells from one another. Finally, the cells reach the outer layer of the epidermis. The cells in the granular layer metamorphose from living nucleated cells to become dead cells filled with filaments and keratohyalin with only a faint outline left of residual intracellular organelles such as the nucleus. This outer layer of cells, the stratum corneum, forms the principal barrier to the loss of fluids and electrolytes from the body, and is the major barrier to percutaneous absorption of environmental agents and adverse effects from physical trauma and ultraviolet (UV) light.

The vast majority of the cells in the epidermis are keratinocytes in the various stages of differentiation outlined earlier. In addition, melanocytes or pigment cells

are resident in the normal epidermis. The cells reside along the basement membrane, sharing the basal layer with the dividing keratinocytes. They have dendrites that contact and transfer melanin to keratinocytes in the epidermis above them. Melanin, the main pigment in skin, is produced in two forms: eumelanin, a brown pigment, and pheomelanin, a red-yellow pigment, that is produced in a specialized organelle called a melanosome. The melanin is formed via a series of enzymatic steps that begins with the conversion of tyrosine to dopaquinone. As the melanin is produced, it accumulates within the melanosome until the structure is mature. The melanosome is then transferred from the melanocyte dendritic tip to a keratinocyte via an incompletely characterized mechanism that may involve membrane fusion. Each melanocyte has a population of keratinocytes that it serves and to which it transfers melanin.

Melanosomes are larger in black skinned people compared to Caucasians, and the amount of melanin and melanosome is greater in black skin. Facultative increases in pigmentation are accomplished by increases in melanin and melanosome production typically after stimulation with UV light or local inflammation or hormone fluctuations (e.g., sun tanning, post-inflammatory hyperpigmentation). Physiologically, melanin is an effective ultraviolet light chromophore, protecting the epidermal and underlying dermal cells from UV radiation. Melanin confers this protection by absorbing photons of UV light and dissipating the energy absorbed through the melanin polymer structure so that damage to cellular structures and DNA is avoided. The melanocyte may undergo transformation, forming a variety of benign and malignant neoplasms ranging from benign nevi to malignant melanoma.

In addition to melanocytes and keratinocytes, the epidermis contains immunocompetent cells called Langerhans' cells. These cells are distinctive in that they stain selectively with gold salts and contain distinctive intracellular granules demonstrable by transmission electron microscopy called Birbeck's granules. They function as antigen-processing cells and transmit signals to lymphocytes, allowing the development of immune responses to antigens that they encounter. Langerhans' cells also produce lymphokines, which will activate other immunologically active cells (e.g., T cells, natural killer cells). The Langerhans' cells are susceptible to malignant transformation, which results in the T-cell lymphoma of the skin known as mycosis fungoides.

Finally, there is another cell found in the epidermis, known as the Merkel cell, whose function is unknown. Rarely, tumors of the skin arise from this enigmatic cell.

PATHOPHYSIOLOGY

Subcellular and cellular events are necessary prerequisites in the transformation of a normal skin cell to a malignant cell. Such a transformed cell ignores internal and environmental

messages, becoming a malignant cell that grows to become a collection of cells with no defined borders or lifespan. This process in the pathogenesis of cancers such as squamous cell carcinoma (SCC), basal cell carcinoma (BCC) and malignant melanoma (MM) is referred to as carcinogenesis and is thought to involve multiple steps of assault to the cell and damage to cellular deoxyribonucleic acid (DNA).

Ultraviolet (UV) radiation plays a pivotal role in the initiation of skin damage and photocarcinogenesis. The basic mechanism of phototoxicity lies in DNA damage resulting in a mutation-like genetic change. It may involve mutation of tumor suppressor genes, oncogenes, and genes directly involved in control of the stability of the genome, such as the mismatch repair (MR) genes. The UV radiation forms dimers in DNA between adjacent pyrimidine residues. Damaged cells normally will respond to injury either by arresting cell growth to repair the damaged DNA or by inducing apoptosis (programmed cell death). The failure of these processes results in a proliferation of abnormal cells bearing genomic mutations. Consequent to the DNA alteration, this change is irreversible and persists throughout the subsequent life of the altered daughter cells. Three to seven mutations at different loci are estimated to be required for the transformation of a normal cell to a cancerous one. Besides UV radiation, polycyclic aromatic hydrocarbons (PAHs) are also well-known mutating agents.

Alterations in the expression of various tumor suppressor genes and oncogenes have been reported in skin carcinogenesis. The *P53* tumor suppressor gene, which is frequently mutated in human cancers, appears to be an early target in the development of UV radiation-associated skin cancers, and plays an important role in the development of BCC. Various studies have reported that 40–90% of BCCs show at least focal immunopositivity for *P53*. It is thought that UVR can result in mutations of *P53*, which stabilize the protein and are therefore detected by increased immunoreactivity. It is not known whether BCCs arising largely as a consequence of exposure to agents other than UVR that share the same disruption of *P53* function and, in particular, the same spectrum of mutations. In cutaneous melanoma, UVB has been shown to increase collagenase IV activity and angiogenesis, thereby promoting tumor aggressiveness, and *P53* involvement has been linked to melanocyte malignant transformation.

The instability of microsatellites (short repetitive DNA sequences) is a common event in the carcinogenic process, resulting in mutation in genes responsible for the mismatch repair process. Such mutated genes contribute to the control of cellular proliferation by regulating growth control genes, the prototype of which is the *hMSH2* gene. This gene, situated on chromosome 2p21-22, has also been implicated in the pathogenesis of UV-associated skin cancers.¹

NON-MELANOMA SKIN CANCER

Premalignant skin lesions

Actinic, or solar, keratoses (AKs) most commonly have the appearance of warts (Fig. 30.9.1), but are occasionally flat.

Figure 30.9.1: Actinic or solar keratosis.

These lesions develop on the sun-exposed skin and are usually evident on the face, hands, and non-hair-bearing scalp. Occasionally, they are exophytic and grow to form an excrescence or cutaneous horn. A variant of this occurs on the vermillion border of the lip as a focal area of thickening or erosion and is referred to as actinic cheilitis. It has been estimated that up to 20% of those persons with multiple AKs eventually develop one or more SCCs. Although the risk of metastases from SCCs evolving out of AKs on the skin is small (i.e., 0.5%), the risk is 11% in instances from actinic cheilitis.

While AKs are benign lesions, some have argued that they may be thought of as evolving lesions of squamous cell carcinoma in situ in which the altered keratinocytes remain restricted to the epidermis. The differentiation between SCC and AK may be very difficult, illustrating the continuum between these two entities; however, there is no dermal invasion in AK. There is evidence of actinic damage to the dermal tissue in AK, such as solar elastotic degeneration. The presence of degeneration of the elastin in the dermis allows one to conclude that there has been significant sun damage.

Common clinical forms of non-melanoma skin cancer

The most frequently occurring skin cancers known to be of environmental and occupational origin are the non-melanoma skin cancers (NMSC) that are derived from keratinocytes.² These include basal cell carcinoma and squamous cell carcinoma.

Basal cell carcinoma

BCC is a common tumor thought to be derived from an adult progenitor epithelial cell (either an altered basal cell in the epidermis or precursor cell from cutaneous adnexal structures) or, rarely, an aberrant primary germ cell in the case of the basal cell nevus syndrome (BCNS). There is experimental evidence derived from transplantation of BCCs that they need connective tissue stroma to be successfully transplanted.

BCCs can be relatively slow growing. For instance, it has been shown by using ^3H -thymidine uptake by BCC tumors harvested from nude mice that there are large areas of quiescence or very slow growth in the tumor cell mass, with growth occurring mainly at the tumor nodule periphery. In addition, approximately 5% of BCCs demonstrate areas of spontaneous regression, although this process is almost always incomplete. The presence of amyloid in such tumors also suggests cell death is occurring, accounting for the slow progression of growth. The presence of Councilman's bodies in such tumors also suggests a significant role for cell degeneration in limiting tumor growth.

Metastasis of BCC is rare, with reported incidences of 0.0028–0.4%.³ Of BCCs that metastasize, 70–86% occur in the head and neck region. Lesions in the ear and scalp region have been cited as the most likely to metastasize. Larger, more invasive tumors have a greater tendency to metastasize. Tumors smaller than 1 cm rarely metastasize. A history of radiation therapy may also be a risk factor for metastasis. The risk of metastases is greater in men than in women (2:1), and affected persons tend to be younger than other patients presenting with BCCs. However, there are no absolute prerequisites for metastasis.

Clinical variants of BCC correspond closely to their histologic subtypes. Although as many as 26 different categories of tumor have been described based on histologic appearance, they are often subdivided into four major variants: nodulocystic, adenoid, morpheaform, and superficial.

Nodulocystic BCC (Fig. 30.9.2) is the most common form and accounts for approximately 70% of all cases. It characteristically presents as a dome-shaped papule with superficial telangiectasia, raised, rolled margins and a 'pearly' translucent border. There are frequently signs of actinic damage on surrounding skin. It also may appear as an

erosive, pimple-like or pigmented lesion. The pigmented sub-variant is not uncommon, particularly in skin of color, and may be clinically suggestive of malignant melanoma. Histologically, nodulocystic BCC is characterized by cellular clusters with peripheral palisading, whereby a parallel alignment of peripheral tumor cell nuclei occurs at right angles to nuclei of cells at the center of the nodule. Connective tissue stromal retraction at the periphery of the tumor is usually apparent. The tumor cells are uniform in size, polygonal in shape, and have scanty cytoplasm and variable mitotic activity. Typically, separation of the tumor cells from the stroma leaves gaps, related to a paucity of desmosomal junctions joining tumor cells to the underlying stroma as well as gaps in the basement membrane.

Adenoid BCC occurs in approximately 20% of cases and displays a gland-like growth pattern in tumor cell clusters. In contrast to true glandular tumors of the skin, adenoid BCC retains the typical peripheral nuclear palisading seen in nodulocystic BCC. Clinically, both adenoid and nodular BCCs have a similar appearance.

Approximately 5% of all BCCs are termed *morpheaform*, or sclerotic, BCCs because of intense connective tissue stromal proliferation characterizing the tumor's architecture. Clinically, it presents the greatest diagnostic challenge, as it may be difficult to detect. They either exhibit an irregular, scar-like appearance or present as a firm, yellowish, plaque-like lesion. The margins of the tumor are often difficult to determine clinically. Histologically, stromal retraction and peripheral palisading are not readily apparent. Unlike other BCCs, this type produces a cytokine that stimulates the synthesis of glycosaminoglycan by surrounding fibroblasts. The marked fibrotic response makes treatment more challenging by protecting the tumor cells so that total excision or Moh's chemosurgery is often required to eradicate the lesion.

The fourth type, the *superficial* BCC, presents as an erythematous faintly scaly patch with a subtle 'rolled' edge often only seen when the lesion is stretched manually on clinical examination. It may be mistaken for a benign dermatosis such as nummular eczema, dermatophytosis or psoriasis. It is the least common of the four main subtypes and has been associated with exposure to arsenic. Individuals with superficial BCC due to arsenic exposure usually also have arsenical keratoses, which have a distinctive histologic appearance due to the presence of vacuolated keratinocytes in the proliferating epidermal cells, as discussed in further detail later in the chapter. Superficial BCCs are more likely to be pigmented and, in a high percentage of cases, are multifocal and show a downward, bud-like growth of tumor nodules from the basal epidermis.

Variants of basal cell carcinoma Basal cell nevus syndrome and linear unilateral basal cell nevus with comedones are distinctly different from common BCCs in their appearance, natural history, and etiology. Although they may be of some importance in elucidating the underlying pathogenic mechanisms in BCC, they are not environmentally caused per se. BCNS may predispose an individual to an increased risk for the development of BCCs with x-ray exposure.⁴

Figure 30.9.2: Nodulocystic basal cell carcinoma.

Squamous cell carcinoma

SCCs have the capacity to metastasize locally and to distant sites. Although the capacity for metastasis in SCC is greater than that of BCC, it is less than that of many cancers. It is estimated that only 0.5% of all SCCs derived from solar keratoses metastasize. For SCCs developing on skin that is not exposed to the sun the risk is 2–3% with a fatal outcome in 75% of cases. For SCCs of the lower lip (Fig. 30.9.3), the risk is even greater, with 16% metastasizing and half the patients succumbing to the disease.

The histologic variants of SCC include the conventional, adenoid, spindle-pleomorphic, small cell, clear cell, and verrucous forms. Only the two main subtypes, the conventional and adenoid forms, are discussed. Conventional SCCs display a connecting growth pattern of cords and nests of polygonal-shaped cells with enlarged nuclei and amphophilic cytoplasm. They are usually categorized by Borders' grades of differentiation as well differentiated, moderately differentiated, and poorly differentiated. Well-differentiated SCC tumor cells often are arranged in a concentric pattern enclosing keratin pearls, which are masses of enucleate keratin. Moderately differentiated SCCs are more deeply invasive, have greater mitotic activity, and have less propensity for keratin pearl formation. Poorly differentiated SCCs have little, if any, keratin formation and often are noted to have infiltrated the subcutis at the time of diagnosis. Adenoid SCC is a variant that exhibits a combination of glandular and squamous differentiation, and often is associated with AKs. The principal differentiating feature is the lack of invasion of epidermal cells into the reticular dermis in the AK.

Variants of squamous cell carcinoma *Bowen's disease* is exhibited as a single lesion on sun-exposed or unexposed skin. It is a slow growing, erythematous patch that is often mistaken clinically for a superficial BCC. The histology is that of an AK but without evidence of solar degeneration in the dermis if the lesion is not in a sun-exposed area. The risk of metastases is higher than for SCCs associated with AKs, with percentages varying from 3% to 11% in reported series. Arsenic exposure is known to be associated with the

Figure 30.9.3: Squamous cell carcinoma of the lip.

Figure 30.9.4: Keratoacanthoma.

development of BD lesions on skin that is not exposed to the sun.

Keratoacanthoma (KA), or self-healing squamous cell carcinoma, may occur as a solitary event or, rarely, affected individuals may develop multiple KAs. The lesion has a crater-like appearance, with the central portion filled with keratinous debris (Fig. 30.9.4).

In the more common solitary KAs, the lesions occur in older persons at a sun-exposed site. They erupt suddenly and grow rapidly for 4–6 weeks, following which they involute spontaneously to leave a depressed scar. It may take up to a year for complete resolution to occur. Larger lesions may cause severe disfigurement and fail to involute. Differentiation from an SCC may be difficult or impossible and occasionally, such lesions have metastasized. In the latter instances, it is suggested that the KAs were, in fact, SCCs.

Epidemiology of non-melanoma skin cancer

NMSC is the most common malignancy in the United States, accounting for one-third of all diagnosed cases of cancer. The American Cancer Society estimated that there are 1.3 million cases of NMSC diagnosed in the United States alone each year, with nearly 75% presenting as BCCs. The incidences of both SCC and BCC have been rising at an alarming rate.⁵ Between 1980 and 1994, incidence rates of SSC rose by 235–350%, and those of BCC increased by 80%.

Basal cell carcinoma is the most common skin cancer in the United States, with an estimated 900,000 cases per year. It represents 75% of all cutaneous neoplasms and outnumbers squamous cell carcinoma by 3.3–4.5 to 1. It has also become the most commonly diagnosed malignancy in the world, with the highest annual incidence in Australia. The incidence of BCC is higher in men than in women and increases with age, usually occurring between the ages of 40 and 60 years. However, there has been a

Host factors	
Fair skin	
Blue eyes, blond or red hair	
Skin sensitivity to sun	
Older age	
Immunosuppression	
Photochemotherapy (PUVA)	
Occupational and environmental factors	
UV radiation	Typical exposure settings
	Outdoor workers: construction workers, roofers, agricultural workers, telephone- repair workers, highway workers, sailors, fishermen
Ionizing radiation	Radiation workers: uranium miners, radium workers, nuclear energy workers
	Medical uses: x-ray technicians, therapeutic radiation
Skin trauma	Construction workers, machinists, agricultural workers
Arsenic	Pesticide, herbicide workers, copper smelter workers
	Contaminated food, water, medicinals, treated wood
Polycyclic aromatic hydrocarbons (PAH)	Coal tar workers, petroleum workers, chimney sweeps, foundry workers, diesel engine workers

Table 30.9.1 Risk factors for non-melanoma skin cancer

rise in the number of cases among younger patients. Approximately 80% of BCCs occur in the head and neck. The nose is the most common site of occurrence, followed by the cheeks and forehead.

Risk factors for NMSC are listed in Table 30.9.1. Numerous studies have documented a particular phenotype that appears to be associated with NMSC. Important constitutional risk factors include fair skin, blue eyes, blond or red hair, childhood freckling, skin sensitivity to the sun, and an inability to tan. Darkly pigmented skin appears to be more resistant to the effects of UV radiation because of the protection of epidermal cells by the increased level of melanin.

Exposure to UV radiation also is known to be an important risk factor in the development of NMSC. NMSC occurs most frequently on areas most exposed to sunlight, such as the head, neck, arms, and hands. In Australia, where immigrants of Celtic origin experience near year-round sun exposure, the highest rates of NMSC in the world are found.⁶ SCC appears to be more strongly related to sun exposure than BCC, because 20–30% of all BCCs are found on the relatively unexposed areas of the body, such as the trunk and eyelid. SCCs have been found to be more common with frequent or long-term sun exposure and southern geographic locations, where exposure to UV radiation is more intense.

Ultraviolet light and non-melanoma skin cancer

The association between sun exposure and skin cancer was first commented on over 100 years ago. UV radiation is

further discussed in Chapter 33.2. Numerous epidemiologic and experimental studies have presented overwhelming evidence that UV radiation is the primary risk factor for NMSC.⁷ This factor has important implications for the prevention of occupationally related skin cancer, because numerous occupations involve chronic, almost continuous exposure to sunlight.

The association between increasing age and the risk of NMSC is well known and is probably related to cumulative UV radiation dose. BCC has been found to be ten times more prevalent in elderly patients with severe actinic skin damage than in individuals of the same age without marked actinic damage. A history of sustaining multiple painful sunburns has been found to be associated with an increased risk of NMSCs and AKs. The carcinogenic effect of natural sunlight is possibly related primarily to ultraviolet B (UVB) in the 290–320 nm band.⁸ This is the component of the UV spectrum that produces normal sunburn.

There is also experimental evidence for UV causation of NMSC. Although keratinocytes are more resistant to the effects of UV radiation than Langerhans' cells, they have been found to have a shortened lifespan and to show evidence of cellular damage after UV exposure. Nude mice irradiated with UVB radiation inevitably develop SCCs, but wavelengths above this range do not induce malignant skin tumors in mice.

UV radiation in the 320–400 nm band, known as UVA, also has been implicated in photocarcinogenesis.⁹ UVA radiation can cause erythema of the skin but at dose levels 800–1000 times higher than the dose of UVB required. However, since UVA is much more prevalent in the solar spectrum than UVB, it may be responsible for as much as 15% of the erythema dose received at noon on a sunny day.

UV radiation in the 200–290 nm band, known as UVC, also is associated with skin carcinogenesis, but UVC is not causally related to skin cancer associated with sun exposure because it is completely absorbed by the stratospheric ozone layer. As the ozone layer is being depleted, rising incidences of NMSC have been observed. Industrial sources of UV, such as germicidal lamps and welding arcs, also emit UV below 290 nm. Workers exposed to UVC should be considered to have a potential carcinogenic exposure, and appropriate precautions to limit sun exposure should be taken.

The different topographic distribution of NMSC in men and women may be due to clothing styles and differences in occupational sunlight exposure. Skin cancers of all types occur more frequently on the ears of men and on the legs of women. These findings fit exposure patterns predicted from traditional hair and dress styles. The incidence rate for SCC in men is 3–4 times higher than in women, possibly related to greater outdoor occupational and recreational UV radiation exposure.

The relationship between UV radiation and SCC is more clear-cut than that for UV and BCC. In a study of Maryland fishermen, in whom exposure assessment was determined through a combination of a detailed occupational history with laboratory and field measurements, SCC prevalence

was strongly correlated with UV exposure but BCC prevalence was consistent with a dose saturation effect, with a plateau at higher exposures.¹⁰ About 33% of BCCs are found on relatively unexposed areas of the body. This suggests that different etiologic mechanisms may be operative in BCC and SCC.

The main bases on which UV radiation derived from sun exposure has been linked to the development of NMSC are as follows.

1. The preferential tendency for NMSC to occur on sun-exposed areas of the skin.
2. The increase in the incidence rate of NMSC as one examines populations closer to the equator, where there is greater exposure to UV radiation.
3. The higher incidence of NMSC in people with extensive outdoor exposures.
4. The predisposition of individuals with fair complexions, who sunburn easily, to develop NMSC.
5. The increased risk of NMSC in patients with a heritable disorder of defective repair of UV-induced DNA damage.

In recent years, increased solar irradiation as a consequence of stratospheric ozone depletion is thought to be partially responsible for the rising incidence rates of NMSC and has raised concern that the incidence of skin cancer will increase at even greater rates in the future.¹¹ A 50% drop in the ozone concentration overlying the Antarctic region has been observed. It has been estimated that every 1% decline in ozone concentration could result in a 2–6% increase in skin cancer. However, it is not likely that the sharp increase in skin cancer incidence observed in the past two decades is entirely due to ozone depletion. It is most likely that the increase is the result of changing behavioral patterns associated with increasing personal sun exposure.

Awareness of these behavioral patterns and the association with skin cancer has led to increasing use of sunscreens to protect against the harmful effect of solar UV radiation. The epidemiologic data suggest that sun protection will have the greatest impact if achieved as early as possible in life and that it will probably have an impact later in life, especially in those who had high childhood exposure to solar radiation. It is important that in implementing sun protection an increase in intermittency of exposure also be avoided.

The age at which exposure to the harmful effects of solar UV radiation occurs also may be an important factor in the pathogenesis of NMSC. In a study of solar keratotic lesions in Australians, it was found that British-born persons over the age of 40 who had migrated to Australia after age 20 had significantly fewer lesions than native-born Australians. This implies that a reduction in childhood and adolescent sun exposure may substantially reduce the incidence of solar keratoses and, by implication, SCC in adulthood.

Other physical agents in the environment associated with NMSC

Physical agents other than UV radiation have been associated with the development of NMSC, and include psoralen

combined with UV therapy (PUVA), Grenz ray treatment, and ionizing radiation (Table 30.9.1).

Whether or not long-term PUVA therapy is associated with the development of NMSC has been debated for several years.¹² The immunologic effects of PUVA include depletion of Langerhans' cells, cutaneous anergy, and tolerance to skin grafting in laboratory animals. Thus, PUVA therapy could conceivably lead to an increased risk of skin cancer. High-dose PUVA therapy appears to increase the risk of developing NMSC, especially for SCC. In patients treated with more than 260 individual PUVA sessions, Stern and Lange¹³ showed an 11-fold increase in squamous cell carcinomas compared with patients who had received fewer than 160 sessions. Of greater concern is the recent demonstration of an increase in malignant melanoma many years after the onset of PUVA treatments in patients who had received more than 250 treatments. Therefore, it seems prudent to limit exposure to PUVA to low doses if prolonged treatment is necessary and to provide medical surveillance for NMSC in patients who have received high doses in the past.

Grenz rays, also known as ultra soft x-rays or Bucky rays, have been used in the treatment of benign skin disease for more than 60 years. Grenz rays, given in usual therapeutic doses, appear to be associated with NMSC only rarely but may cause NMSC if given in high doses for prolonged periods.¹⁴ Work-related SCC on the finger has been described in a dermatologist who was notoriously careless about exposing his hand directly to the Grenz ray when he treated patients.

Treatment with prolonged administration of low-dose ionizing radiation is associated with subsequent NMSC, particularly BCC.¹⁵ Higher dose rate exposures appear to result in SCC, whereas lower dose exposures predominantly result in BCC. The latency period between first exposure to therapeutic ionizing radiation and the appearance of NMSC is presumed to be at least 20 years. In several studies, elevated risks in relation to therapeutic ionizing radiation were found to be confined to the site of radiation exposure and have ranged from an odds ratio of 3.30 to 5.7 for BCC to an odds ratio of 2.94 to 4.8 for SCC.

The first reported case of skin cancer due to x-ray exposure appeared in 1902. An x-ray technician who had exposed his hands directly to the x-ray beam for 4 years for demonstration purposes developed an invasive SCC of the dorsum of his hand, with regional lymph node metastases. The use of x-rays in the treatment of tinea capitis, facial acne, hypertrichosis, hemangioma, lupus vulgaris (cutaneous tuberculosis), toxic goiters, and eczema has been associated with the development of skin cancer. In a study of 2200 children receiving x-ray therapy for tinea capitis during the 1940s and 1950s, a relative risk of 6.1 was found for the development of NMSC compared with non-irradiated controls. In the 25% of the study population that had black skin, no cases of skin cancer occurred. Studies such as this suggest that UV exposure may interact with ionizing radiation exposure in the development of NMSC in susceptible individuals.

Chronic dermatitis following the application of ionizing radiation (e.g., chronic radiodermatitis) has been found to

be associated with NMSC, possibly as a result of chronic epithelial regeneration, as well as due to direct damage to the DNA of the epidermal keratinocyte. Skin type is a factor in one's propensity to develop NMSC following ionizing radiation exposure. The SCC risk following irradiation may be highest in persons with a sun-sensitive phenotype.

Ionizing radiation as a result of exposure to radioactive materials has also been associated with skin cancer. Skin cancers have been reported to develop in areas of chronic radiodermatitis occurring in radium workers who had been exposed to radium for 10 years or more. For instance, the incidence of BCCs in Czechoslovakian uranium miners exposed to radium was shown to have increased, most markedly in miners with more than 10 years of exposure. This increase has been attributed to external α -particle radiation to the basal layer of the epidermis. Radioactive gold jewelry also has been documented to cause NMSC. In the early 1980s, the state of New York conducted a voluntary screening program for radioactive jewelry and found 200 contaminated items out of 160,000 pieces of jewelry screened, indicating the risk of such exposure is small.

Repeated high doses of diagnostic x-ray exposures, such as in multiple fluoroscopic examinations to evaluate artificial pneumothorax therapy for tuberculosis in the 1940s and 1950s, have also been associated with the development of NMSC in the skin where the radiation was delivered. BCCs developing in sites of such radiation exposure may be more invasive than other types of BCC.

Injury and the development of NMSC

The description of a malignant skin cancer developing at a site of previous trauma was first reported in 1828. It has been found that SCCs associated with burn scars, draining sinuses, and radiodermatitis have much higher rates of metastasis than other forms of SCC, with distant spread occurring in 20–30% of all such lesions. In a review of 1774 BCCs requiring Moh's micrographic surgery, 7.3% of the cancer subjects reported a history of trauma at the site previously. The trauma-associated lesions were larger, required more Moh's surgery stages to excise, and were more deceptive clinically than other BCC lesions. NMSC has been found to occur in old unstable scars of tattoos, lupus vulgaris (cutaneous tuberculosis), chronic leg ulcers, hair transplant sites, varicella scars, vaccination scars, and colostomy sites.

Using a combination of criteria from various authors, the following useful list has been formulated by Stoll and Crissey¹⁶ as criteria to aid in the diagnosis of trauma-related skin cancer.

1. The skin must previously have been normal.
2. Adequate and authenticated trauma must have occurred, preferably confirmed and documented by medical personnel.
3. A positive diagnosis of a non-metastatic carcinoma must be made, and the tumor must be histologically consistent with the tissue of that site.
4. The carcinoma must originate from the exact point of injury.

5. A reasonable time interval (e.g., several years) between the trauma and the first appearance of the carcinoma must have elapsed.
6. There must be continuity of physical signs from the trauma event to the appearance of the carcinoma.

Chemical agents associated with the development of skin cancer

Percivall Pott first described the association of chemical exposure with the development of skin cancer in 1775, in his classic description of SCC of the scrotum associated with exposure to soot in chimney sweeps. Since then, a number of chemicals, compounds or industrial settings have been associated with an increased risk of skin cancer (Table 30.9.1). Arsenic, whether present in well water, medicinals, pesticides or industrial processes, is a well-documented cause of SCC and BCC, also discussed in Chapter 39.2. Substances containing polycyclic aromatic hydrocarbons (PAHs) such as coal tar pitch, mineral oil, and anthracene, also have been implicated in NMSC formation (see also Chapter 44). Other chemicals that have been suggested as potential skin carcinogens include PCBs, vinyl chloride, and other metals, but data are limited.^{17–19}

An association between the smoking of tobacco and SCC has been recently observed, with an estimated relative risk of 2.0 of developing SCC among smokers after adjustment for age, sex, and sun exposure.²⁰ No significant association was found between smoking and other forms of skin cancer. Proposed mechanisms include tobacco smoke acting as a skin carcinogen inducing specific mutations in the *P53* gene or due to the loss of immune surveillance since tobacco smoke has been shown to suppress immunologic functions, and immunosuppressed patients (described below) have an increased risk of squamous cell carcinoma.

Arsenic

The acute lethal effects of arsenic have been known since the Middle Ages. The carcinogenic effect of long-term exposure to arsenic was not described until 1809, when Lambe linked drinking arsenic-contaminated water with malignant disease. Paris described cancer of the scrotum in workers exposed to arsenical fumes from copper smelting in 1822. The first description of arsenic-induced skin cancer and its relationship to hyperkeratosis in patients exposed to medicinal arsenic was by Hutchinson in 1887. Arsenic is unique in that skin tumors may be produced by ingestion, injection or inhalation in humans, as compared with the necessity for skin contact in most other cutaneous carcinogens. Only inorganic arsenic has been associated with cancer.

Epidemiologic evidence has shown strong associations between arsenic and cancers of the lung, skin, liver, kidney, and urinary bladder in humans.^{21,22} However, until recently studies have been unable to show arsenic compounds as carcinogens in animal models, hindering mechanistic studies. While arsenic compounds are not mutagenic alone in standard bacterial and mammalian test systems, they have

been shown to increase the mutagenicity of other DNA-damaging agents, including UV radiation in animal models.²³ Arsenite (inorganic trivalent arsenic), the likely environmental carcinogen, is thought to act as an enhancing agent (co-carcinogen) with a genotoxic partner such as UV radiation by inhibiting DNA repair and disrupting *P53* function. A recent study found that SCCs occurring in mice given both UV radiation and arsenite were much larger and more invasive than in mice given UV radiation alone. No tumors appeared in mice given arsenite alone.²⁴

Arsenic may also cause the induction of gene amplification, the arrest of cells in mitosis, the replacement of phosphorus in the DNA chain, and the expression of heme oxygenase and *c-fos*. Other theories of carcinogenic modes include arsenic-induced chromosome abnormalities,²⁵ DNA damage due to oxidative stress from arsenic metabolites, and alterations in growth factors such as transforming growth factor- α (TNF- α), granulocyte macrophage-colony stimulating factor (GM-CSF), and interleukin-6, which then lead to cell proliferation and promotion of carcinogenesis.²⁶

The major clinical manifestations of chronic arsenic poisoning are hyperpigmentation, hyperkeratosis, and NMSC, regardless of the source of exposure. Hyperpigmentation is the most frequently observed clinical skin response to chronic arsenic toxicity. The lesions are dark brown, and usually are present at sites of normally increased pigmentation, such as the axilla, groin or areola. Arsenic-induced hyperkeratosis, known as arsenical keratoses, usually occur on the palms and soles, and are exhibited as small, multiple, non-tender, indurated elevations, usually 0.4–1 cm in diameter. The nodules may coalesce into plaques or form large verrucous-appearing growths. Skin tumors associated with arsenic exposure include SCC, BCC, and Bowen's disease. Arsenic-induced tumors usually are multiple and often occur at sites not directly exposed to UV. Arsenic-induced SCC and BCC do not differ histologically from SCC and BCC arising from other exposures, although they appear to be clinically more aggressive.²⁷

The use of inorganic arsenic in insecticides, herbicides, and fungicides has led to occupational, environmental, and dietary exposures. Although the commercial use and production of arsenic-containing substances have declined over the past few decades, it still remains an occupational hazard with the United States Bureau of Labor Statistics reporting 28 cases of occupational disease associated with arsenic from 1994 to 1995. In earlier decades, tobacco contained substantial amounts of arsenic, up to 40 mg/kg, as a result of the use of arsenical pesticides in agriculture. The inhalation of tobacco smoke from tobacco grown in the United States during the 1950s may have resulted in the intake of more than 100 micrograms of arsenic daily. Arsenic in well water also has been found to be associated with skin cancer. In a prevalence study of skin cancer in an area of Taiwan where arsenic-contaminated artesian wells had been in use for over 45 years, the authors found a positive dose-response relationship.²⁸ In the study population, the youngest skin cancer patient was age 24, the youngest with hyperpigmentation was age 3, and the youngest with hyperkeratosis was age 4. Examination of a nearby control

population did not reveal any melanosis, hyperkeratosis or skin cancer.

The association between arsenic exposure and skin cancer in a worker with arsenic exposure is considered strongly suspicious if the following criteria are met.

1. The simultaneous occurrence of arsenical hyperkeratosis and hyperpigmentation, which occurs at lower doses than arsenic-associated skin cancer.
2. The occurrence of multiple skin cancers, often in areas not exposed to the sun.
3. The development of such skin cancer at a relatively young age.

Polycyclic aromatic hydrocarbons (PAHs)

Workers are exposed to PAHs from inhalation as well as skin contact. PAHs are the major concern in exposures found in coal gasification, aluminum production, iron and steel foundries, coke production, and occupations involved with diesel engine exhaust, carbon black, and coal tar. Complex mixtures containing some PAHs have been implicated as causes of skin cancer²⁹ and compose a large group of chemical carcinogens found in the workplace. These chemical complex mixtures include coal tar pitch, mineral oil, anthracene, chimney soot, shale oil, creosote, asphalt, crude paraffin waxes, cotton-mule spinning oil, and others.

PAHs have also been associated with lung, skin, breast, and bladder cancer.³⁰ PAH-induced carcinogenesis involves a number of steps including: (1) the enzymatic activation of the PAH into metabolites; (2) the covalent binding of the PAH metabolites to DNA; and (3) the induction of mutations that serve to initiate the transformation process as a result of PAH-DNA adducts. PAH can covalently bind to DNA, RNA, and proteins, but it is the amount of covalent interaction between PAH and DNA that correlates with carcinogenicity.³¹

The relationship of PAHs and SCC of the scrotum is well known. The development of SCC of the scrotum has been related to the presence of numerous pilosebaceous follicles on the scrotal skin. It is theorized that the lipid-soluble carcinogenic chemicals concentrate in sebum. Despite long-established knowledge of this association, scrotal tumors continue to occur in exposed workers.

Exposure of the skin to coal tar and other PAH-containing products can cause erythema and an acute burning sensation at the site of contact. Exposure to sunlight intensifies the burning sensation because these agents induce phototoxic contact dermatitis. Long-term contact has been implicated in chronic skin changes, including irregular areas of atrophy, patchy hyperpigmentation and hypopigmentation, wart-like papillomas (known in certain trades as tar warts), BCCs, and keratoacanthoma. The inhalation of volatilized PAHs may be associated with the development of skin cancer, but the importance of this route is uncertain because skin contact also generally occurs. Despite the laboratory modeling of cutaneous carcinogenesis of coal tar, decades long use of this therapeutic agent alone and with ultraviolet light (Geokerman therapy) have not demonstrated a clear increase in the incidence of skin cancer in treated individuals.^{13,32}

Immunologic considerations in the development of NMSC

The interaction of the host's immune surveillance mechanism with tumor cells appears to be important in the development of NMSC. It is known that cell-mediated immune response declines with age, especially after age 50, leading to speculation that this decline may foster the development of skin cancer. Patients with primary immunodeficiency states have a much higher incidence of cutaneous malignancies than do normal individuals.^{33,34} The high prevalence of skin cancer in immunosuppressed organ transplant recipients also implies a role for the immune system. One study found that the risk of developing BCC in renal transplant patients was 3.4 times greater than that of the general population, whereas for SCC it was 36 times greater. Risks of 1.4 times and 18 times normal for BCC and SCC, respectively, in immunosuppressed subjects have also been reported.

Immunosuppression induced by oral glucocorticoids in the absence of organ transplantation has also been associated with an increased risk of NMSC, and SCC in particular.³⁵ In patients infected with HIV, the incidence of epithelial neoplasms is markedly increased especially in oral, cervical, and anorectal sites.³⁶ BCCs have been reported on unexposed sites in HIV-seropositive patients, as has metastatic BCC, probably as a consequence of immunocompromise.

Langerhans' cells present in the epidermis play pivotal roles in the immune surveillance of the skin, with important functions in contact hypersensitivity reactions and foreign antigen presentation. UV radiation has been shown to deplete the epidermis of this important cell, with resultant decreases in delayed hypersensitivity reactions to dinitrofluorobenzene, a contact-sensitizing agent. Evidence also exists that epidermal Langerhans' cells in patients with BCC are abnormal, including altered Langerhans' cell morphology and disruption of the usually uniform Langerhans' cell network.

UV radiation also has been shown to decrease the total number of circulating T cells, as well as decrease the T-helper/T-suppressor cell ratio, and increase the number of T-suppressor cells. These studies suggest that exposure to UV radiation may alter T cell function, hampering immune rejection of malignantly transformed keratinocytes.

Further support for the importance of the immune surveillance system in the control of NMSC comes from the effectiveness of immunomodulators such as interferon and imiquimod in the treatment of BCC. In a clinical trial of 194 patients with BCC, the use of α -2-interferon resulted in a complete regression of 89% of patients treated with interferon.³⁷ The mechanism by which IFN- α produces regression of BCC relates to a considerable increase in the number of CD4+ T cells infiltrating the dermis and surrounding the BCC. The CD4+ cytotoxic T cells are capable of inducing apoptosis in their target cells via CD95 receptor-CD95 ligand interaction. In IFN- α -treated patients BCC cells express not only CD95 ligand but also CD95 receptor. Upon intralesional IFN- α treatment BCCs commit suicide by concomitant expression of

both CD95 receptor and CD95 ligand.³⁸ More recently, the immune response modifier imiquimod has been demonstrated to induce cytokines including interferon- α and shown to be efficacious in the topical treatment of superficial BCC in clinical trials.³⁹

Other host factors that may relate to the development of NMSC

It is known that patients who lack skin pigment (albinos) develop skin cancer at an early age. In the rare skin disease xeroderma pigmentosum (XP) there is a hereditary defect in the ability to repair damage to DNA induced by UV exposure. Patients with XP develop AKs, SCCs, BCCs, and malignant melanomas (MMs) early in life and succumb from metastatic disease, often in their second or third decade. The risk of developing skin cancer in XP patients is 2000 times greater than the general population, and heterozygotes also are at greater risk.⁴⁰ Differences in the ability to repair UV-induced DNA damage have been associated with the development of BCC in women.

MALIGNANT MELANOMA (MM)

Non-malignant skin lesions

Dysplastic nevus syndrome

Large and irregular shaped nevi were first described in 1978 in a family with a high incidence of MM. Such lesions are now known to occur without a familial association while still carrying an increased risk for the development of MM.

Lentigo maligna

This lesion, also known as the melanotic freckle of Hutchinson, occurs on the exposed surfaces of the elderly and usually is found on the face. It is an in situ MM. It is indolent and slowly evolves over many years to become a large brown patch with uneven coloration. It is estimated that 30–50% of such lesions eventually metamorphose into invasive MM.

Clinical types of malignant melanoma

MM tumors are derived from the epidermal melanocyte. Its common morphologic variants are superficial spreading melanoma (SSM), lentigo maligna melanoma (LMM), nodular melanoma (NM), and acral or mucosal lentiginous melanoma. Although these histologic types do not correlate with survival as was suggested by early studies, the classification remains useful as a way to characterize the several morphologic variants of MM that may be seen clinically. These conditions are briefly discussed in turn.

SSM is the most common type of MM and comprises 70% of the cases in the United States. The lesions are usually 1–2 cm in diameter when discovered and classically involve the trunk and extremities, usually proximal to the ankles and wrist. The tumor usually has a radial growth phase of 1–7 years prior to initiating a vertical

growth pattern that results in the formation of nodules. The melanotic tumor cells appear uniformly malignant, with large nuclei and prominent nucleoli. The tumor cells are evident along the basal layer of the epidermis as well as being scattered through the upper epidermal strata. Clinically, one sees a patch of altered pigmentation with areas of recession of the pigment and areas of inflammation (Fig. 30.9.5). Regional node involvement or hepatic metastases may be evident if there is a nodule present due to vertical growth. In the absence of a nodular pattern of growth, there may be no extension of the tumor beyond the primary site.

NM represents approximately 15% of all cases of MM. It develops as an invasive nodule without lateral spread. The nodules may be dark gray or pink in color and usually arise more rapidly than other forms of melanoma. They may develop on any mucosal or cutaneous surface but usually are seen on the trunk. On examination, the patient has a black nodule, usually with an area of erythema around it. The history of the lesion may be as short as a few weeks and regional lymph node involvement or hepatic metastases are frequently evident.

LMM is the least common type of MM. Such tumors are seen in elderly patients with a history of sun exposure and occur almost exclusively on the face and neck. They arise out of persistent areas of hyperpigmentation known as lentigo maligna and appear as a brown patch with variegate pigmentation. Once these cells alter their growth pattern and invade the dermis, the lesion changes from an indolent lesion to one with the potential to metastasize.

Acral lentiginous melanoma and mucosal lentiginous melanoma occur more commonly in darker skinned patients. The acral variant usually occurs on the palms, soles, and subungual areas, with the mucosal surfaces being involved in mucosal lentiginous melanoma, as the name implies. The two subtypes are very similar histologically to LMM, although clinically acral and mucosal lentiginous melanomas tend to behave much more aggressively.

The prognosis in MM is highly dependent on the depth of penetration, which can be assessed by measuring the thickness of the lesion from the granular layer, or the ulcer

base, to the lowest extent of the tumor cells. The most recent American Joint Committee on Cancer⁴¹ guidelines classify melanoma into a TNM staging system whereby importance is placed on tumor thickness, the presence of histologic ulceration, the number of involved lymph nodes, and the presence of an elevated serum lactic dehydrogenase level.

Epidemiology of malignant melanoma

Similar to NMSC, the incidence of cutaneous MM has been rising rapidly.⁴² The American Cancer Society estimated that there would be 53,600 new cases of MM in the United States in 2002 with 7400 deaths. MM accounts for nearly 4% of skin neoplasms but represents close to 80% of skin cancer mortality. From 1973 to 1994, the incidence of MM rose 120%, faster than most other cancers in the United States. MM now accounts for between 1% and 2% of all cancer deaths in the United States. The current lifetime risk for Americans of experiencing melanoma is approximately 1 in 75. Unfortunately, cancer registries have not been as effective in the collection of data related to MM as for other cancers because often the lesions are excised in doctors' offices and may not be captured for incidence statistics. It is unclear to what extent improvement in the collection of such data may account for the observed changes in incidence.

Ultraviolet light exposure and malignant melanoma

There is an inverse relationship between latitude of residence and MM incidence, and individuals with light complexion, blue eyes, and blond or red hair appear to be at greater risk for MM, similar to NMSC.⁴³ However, the relationship of MM to sunlight exposure is more complex than that of NMSC.⁴⁴ With the exception of LMM, which is associated with cumulative sun exposure and appears primarily on the face and sun-exposed areas, long-term continuous exposure to sunlight does not appear to be a risk factor for MM. MM risk is more closely related to intermittent intense rather than total UV exposure.⁴⁵ MM is more common in professional workers of relatively high socioeconomic status than blue collar and outdoor workers,^{46–48} and in those with intermittent, intense UV exposure and sunburn in childhood. In fact, outdoor work has been found to be protective against the development of MM,⁴⁹ particularly in males who started work outside at a young age and continued for at least 10 years. The mechanism by which continuous sun exposure may be protective is unknown.

A number of studies support recreational and intermittent sunlight exposure as a risk factor for the development of MM. In Queensland, Australia, the occurrence of multiple sunburns has been used as a surrogate for acute high-dose UV radiation exposure, with an estimated relative risk of 2.4 for those categorized as having experienced six or more sunburns and a relative risk of 1.5 for those having had two to five sunburns in their lives. Another case-control study found that the MM incidence rate was

Figure 30.9.5: Superficial spreading malignant melanoma.

associated with frequent sunbathing between the ages of 15 and 24 and with exposure of the trunk while working outdoors.⁵⁰ Support for the intermittent exposure hypothesis also has come from studies of sunlamps and tanning booths. Increased risk for developing MM has been found to be associated with the use of artificial tanning devices. A case-control study found a 2.9-fold increase in MM risk in those who use UV lamps or sun beds; this risk increased as the duration of use increased.⁵¹

In addition to the manner in which one is exposed to UV radiation (e.g., intermittent or continuous), the age at which the UV exposure occurs is also an important factor. Among British immigrants to Australia, immigrants arriving before age 10 appear to have a risk of developing MM similar to that of native-born Australians. Immigrants arriving after the age of 15 were at one-quarter the risk. Other studies also have found an increased risk for MM with intense UV radiation exposure at an early age, with little risk occurring after the age of 30, and no risk associated with occupational exposure.⁵² These studies lend support to the idea of a critical time period of exposure being necessary for the development of MM. Possible explanations that have been advanced for the association of UV exposure in childhood and adolescence with the risk of MM are as follows.

1. Melanocytes may be more sensitive to the sun in childhood.
2. More severe blistering sunburns in the teenage years occur due to adolescent behavior patterns.
3. Passing through critical stages of a multistep pathway for carcinogenesis early in life increases the chance of later completing the remaining stages of carcinogenesis.

Host and genetic factors also play a role in the interaction of UV radiation exposure and the development of MM. After UV exposure subjects whose population of melanocytes is relatively small experience greater increases in the size of their melanocyte population in both exposed and unexposed skin when compared with subjects with larger pre-exposure melanocyte populations. Therefore, individuals with low melanocyte density (e.g., redheads) may constitute a high-risk group for development of MM due to the fact that their melanocyte must enter a higher mitotic rate following UV radiation exposure than more pigmented individuals.⁵³

Another host risk factor for MM is the propensity to freckle and develop nevi. It has been shown that the propensity to freckle is significantly higher in patients with MM than in controls. Increased numbers of melanocytic nevi have been associated with MM. The relative risk of developing MM has been found to be 30 in subjects with many nevi on the body. Increased risk of MM is seen in those with multiple, large or dysplastic nevi, a family history of MM, and dysplastic nevus syndrome.^{54,55}

Suspected and reported chemical causes of malignant melanoma

Although light is an important factor in the development of MM, MM cannot be accounted for totally by UV radiation exposure. In keeping with this concept, it is notable

that MM is ubiquitous in the vertebrate animal kingdom, from fish to higher forms of life in which UV radiation exposure often is limited due to the marked photoprotection offered by hair. The occurrence of acral lentiginous MM on the palms and soles of dark skinned individuals also argues against UV radiation as the sole causative factor.

Polychlorinated biphenyls (PCBs), which were previously used as insulating fluids in electrical transformers, capacitors, and switches, have been associated with melanoma. An epidemiologic study conducted among 138,905 men, mostly electrical power company workers, with long-term occupational exposure to polychlorinated biphenyls (PCBs) between 1950 and 1986 suggested that mortality from malignant melanoma increased with PCB exposure.⁵⁶ Rate ratios for melanoma relative to unexposed men ranged from 1.23 to 1.93 depending on the length of exposure. However, the preponderance of the epidemiologic studies suggests that PCB exposure and related congeners are only reliably associated with certain non-cancerous skin changes, acneiform eruptions, and eye irritation, and not with MM.⁵⁷⁻⁶⁰

Cutaneous MM has been associated with possible exposures in pulp and paper,⁶¹ airline,⁶² printing,⁶³ pharmaceutical,⁶⁴ telecommunications,⁶⁵ and petrochemical industries.⁶⁶ Although there is some limited experimental evidence to suspect chemical causes,⁶⁷ the human information is far too sparse to draw conclusions at this time. Consequently, the current theories on the pathogenesis of malignant melanoma have not been linked to chemical exposures except for psoralens in combination with UVA radiation (PUVA).⁶⁸

MYCOSIS FUNGOIDES

First described by Alibert in 1806, mycosis fungoides (MF) is now known to be a chronic T-cell lymphoma (CTCL) of the skin that may involve the blood, resulting in a mononuclear cell leukemia called Sezary syndrome. Incidence rates for CTCL vary considerably from 0.13 to 0.9 per 100,000 people per year. It is somewhat more common in men and tends to develop in the middle years of life. Although usually presenting as slowly growing flat lesions that slowly increase in number, it may start as an erythroderma or sudden fulminant disease with rapidly enlarging ulcerating tumors. It has been linked with an association with various industrial exposures⁶⁹ and multiple cases of MF have been reported in immune-suppressed patients with a history of organ transplantation or human immunodeficiency virus infection.⁷⁰ The role of long-standing topical antigen exposure with chronic allergic contact dermatitis and subsequent development of this malignant T-cell tumor is intriguing but remains an unlikely etiologic scenario.

PREVENTION OF OCCUPATIONAL SKIN CANCER

Personal protective equipment

Protective clothing is most useful as a barrier to UV radiation exposure. If this does not produce heat stress or interfere

with tasks at work, workers are more likely to comply. Hats with brims and sunglasses are also helpful. When clothing is not practical, topical sunscreen formulations can be used. It has been estimated that the use of sunscreens in childhood and adolescence could result in as much as a 78% reduction in the incidence of NMSC in adults.

Sunscreens should be used daily on individuals habitually exposed to the sun, by people with fair skin who freckle and sunburn easily, and by those who are hypersensitive to the sun. They fall into two broad categories of absorbing and reflecting agents. The absorbing agents contain chromophores that absorb photons of UV light and prevent its entry into the epidermis, thus preventing UV-induced injury. Early chemical sunscreen agents were frequently associated with allergic contact and photo-allergic contact sensitivity reactions and often discolored clothing. The common ingredients in current formulations are para-aminobenzoic acid (PABA) esters, cinnamates, and benzophenone and avobenzone. These products provide protection in the UVA and UVB spectrum and have the advantage of invisibility on the skin and thus they are cosmetically acceptable to most individuals.

Reflecting agents include substances like zinc oxide and titanium dioxide. Such agents provide excellent protection from UV, but are not invisible. Such products have enjoyed considerable use in high-altitude work. On the label of such products sold in the United States, a sun-protective factor (SPF) number is found. This number is the ratio between the time needed to produce a sunburn response in a normal person with the product divided by the time needed to do so without it. Greater photoprotection is provided at higher SPF numbers. A dry T-shirt alone only provides protection equal to a sunscreen with an SPF of 8. Once wet, its level of sun protection drops down to SPF 4.

Ionizing radiation can be effectively attenuated by the use of shielding devices such as gloves, aprons, and lead containers.

Protection from skin contamination with PAHs and other possible environmental causes of skin cancer can be accomplished by the use of appropriate gloves, gauntlets, uniforms, and aprons. Impervious materials should be used for these items since devices made of latex and vinyl may allow for the penetration of solvents. Frequent changes in the protective devices will give the best protection. Engineering alterations are preferred for situations where personal protection is necessary continuously.

Engineering controls

Enclosures can be constructed to limit exposure to UV radiation. Simple devices such as an awning over the work area of a fishing boat can significantly reduce UV radiation exposure. This equally applies to ionizing radiation sources.

In an experimental study of skin tumor induction in mice, lubricating oils that had been treated with a new form of severe hydro treatment to remove PAHs, did not induce skin tumors. Control groups of mice treated with unrefined crude oil and benzo[a]pyrene developed a significant number of skin tumors. Analysis of the hydro-treated

lubricating oil found a substantial decrease in the PAH concentration.⁷¹ This shows that new severe hydro-treated lubricating oils have been converted from carcinogenic to less carcinogenic materials.

Medical surveillance

The surveillance program for workers with exposure that could lead to the development of skin cancer should involve a cutaneous examination. The procedure must be carried out in a well-lit room by staff experienced in such examinations. Early diagnosis in the case of MM may be life saving.⁷² In the case of SCC, Bowen's disease, and actinic cheilitis, early intervention may significantly alter the outcome and prevent death of the worker. In the case of AKs, BCCs, and SCCs developing on sun-exposed skin, early intervention should reduce scarring and disfigurement. While surveillance programs are important in monitoring the efficacy of hygiene practices, regular annual integumentary examinations for individuals with exposure to UV light through occupation or recreation is advisable.

The implementation of preplacement and periodic examinations leads to the consideration that certain workers may be at greater risk of developing skin cancer. Some of these risk factors are evident on cutaneous examination. For instance, workers with fair skin, blue eyes, and red or blonde hair who freckle are more susceptible. Should such a worker choose to enter a job where there are higher levels of exposure to UV radiation and/or photo-sensitizers, he or she should be advised of the risk and careful skin self-examination and use of protective practices for work and recreational activities. It is likely that in the future, biomarkers of an increase in susceptibility to skin cancer may be available. Recent work suggests that women with BCC have a reduced ability to repair altered DNA in their peripheral white blood cells. These markers may offer additional ways to target workers who may be at increased risk and ensure that all steps are being taken to prevent the development of skin cancer, but should not be used to exclude workers from jobs with exposure to skin carcinogens.

Chapter 33

Radiation

33.1 Ionizing Radiation

H Gregg Claycamp, Niel Wald

EXPOSURE SETTINGS

Ionizing radiation is composed of electromagnetic energy or high-energy subatomic particles that have sufficient energy to break atomic bonds in absorbing materials, including biologic tissues. The high-energy electromagnetic radiation includes x-rays and gamma rays, while the particulate radiations include electrons, protons, neutrons, alpha particles or other subatomic particles. Everyone is exposed to ionizing radiation from natural sources, with additional exposure from technology-enhanced or artificial sources. The principal natural sources of ionizing radiation are: (1) cosmic rays, which originate in outer space, (2) terrestrial radiations, which emanate from radium, thorium, uranium, and other radioactive elements in the earth's crust, and (3) internal radiations, which are emitted by potassium-40, carbon-14, and other radioactive isotopes ('radionuclides') normally contained within living tissues. The principal artificially derived sources of radiation exposures include x-ray machines, particle accelerators, nuclear reactor or accelerator produced radionuclides and numerous lesser sources.

The average dose received annually worldwide from natural sources of ionizing radiation amounts to about 80% of the total average annual dose (Table 33.1.1). Typically more than one-half of the naturally derived radiation dose is from indoor radon (primarily ^{222}Rn) and its radioactive progeny occurring in the home. Medically derived radiation exposures, amounting to about 20% of the average annual dose, fall primarily on the elderly and the ill. Occupational exposures from ionizing radiation contribute little to the worldwide population average annual dose (Table 33.1.1); however, to occupationally exposed individuals, the average annual dose on a worldwide basis approaches 1 mSv per year. Other groups in the population who receive greater than average doses are those who reside at high elevation (e.g., Denver, Colorado), where cosmic rays may be twice as intense, or those residing in areas where the earth's content of uranium and/or radium is comparatively high. Cigarette smokers can also receive up to 200 mSv per year to the lung from the polonium-210 that is present naturally in tobacco products. Finally, sources of small doses to the population include natural radioactive minerals in building materials, phosphate fertilizers and crushed rock, radiation-emitting components of television sets, smoke detectors, and other consumer products.

Ionizing radiation is a hazard that can be encountered in many different occupations (Table 33.1.2). Workers in both radiation and non-radiation occupations that use

radiation-emitting devices or materials have widely variable exposures depending on their work assignments and working conditions (Fig. 33.1.1). The average yearly dose equivalent of whole-body radiation received occupationally by monitored workers in the United States who do not work at nuclear reactors is less than 1 mSv (Table 33.1.3) – similar to the dose received from natural background irradiation. Most workers in Table 33.1.3 receive doses that are less than or near the lower detection limits of personnel dosimeters, and relatively few workers (<1%) reach the maximum permissible dose limit of 50 mSv in any given year. It is also important to note that the average annual doses to radiation workers have declined steadily over several decades, primarily as a result of effective radiation protection programs.

Exposure to ionizing radiation in the ambient and occupational environments differs not only in amount, but oftentimes by the type of ionizing radiation. Much ambient and medical exposure is from external sources of ionizing radiation in the form of x-rays or gamma rays. These radiations are from the very high frequency end of the electromagnetic energy spectrum, beginning near ultraviolet light energies (about 0.0001 joule) to several joules of energy per gamma ray. X- and gamma rays are highly penetrating forms of ionizing radiation that can easily impart energy to any part of the body not effectively shielded from them. Typically, lead or other high-density materials are used to shield workers from high-intensity sources of x- or gamma rays. Radionuclides in the environment or the work place might emit gamma rays but might also give off radioactive particles such as alpha particles, beta particles or, rarely, neutrons. These particles have different properties from x-rays and gamma rays in terms of their ability to penetrate tissue and with respect to the biologically effective dose (discussed below). For example, high-energy beta particles can readily penetrate millimeters of soft tissues in the body whereas alpha particles are poorly penetrating and can be effectively blocked by the dead layers of the epidermis. Thus, alpha-emitting radionuclides can cause hazardous exposures only when they are deposited internally.

Each radioactive element or radionuclide has its own unique pattern of radioactive decay with a characteristic half-life (the time over which one-half of a given compound's radiation will be released) and decay scheme – the types and energy of the emitted ionizing radiation. What is most relevant medically is that the types of radiation released for each radionuclide are known and, therefore, the theoretical total absorbed dose can be modeled

Source	Average annual effective dose equivalent (mSv)	Percent of total
<i>Natural</i>		
Cosmic radiation and cosmogenic radionuclides	0.31	11
Terrestrial external	0.46	16
Terrestrial internal (excluding radon)	0.23	8
Internal radon-222 and its decay products	1.28	44
Total natural	2.28	79
<i>Medical radiation</i>		
Diagnostic medical radiation	0.3	10
Therapeutic medical radiation	0.3	10
<i>Industrial</i>		
Radionuclides in medical, educational and industrial applications	<0.001	0.0003
Nuclear fuel cycle	0.03	0.0103
Occupational	0.001†	0.0003
Total artificial	0.632	21
<i>Total</i>	2.91	

* Compiled from data in UNSCEAR 1993.¹⁹
† The occupational figure is averaged over the entire population. Occupational doses approach 1 mSv per year on a worldwide basis.

Table 33.1.1 Average annual dose equivalent from various sources of ionizing radiation*

Aircraft pilots and crews	Petroleum refinery workers
Cathode ray tube makers	Physicians
Dental assistants	Pipeline oil flow testers
Electron microscope makers	Pipeline welders
Electron microscopists	Radiographers
Electrostatic eliminator operators	Plasma torch operators
Fire alarm makers	Radar tube makers
Gas mantle makers	Radiologists
High-voltage vacuum tube makers	Radium laboratory workers
High-voltage vacuum tube users	Television tube makers
Industrial fluoroscope operators	Thickness gauge operators
Industrial radiographers	Thorium-aluminum alloy workers
Inspectors using, and workers located near, sealed gamma ray sources	Thorium-magnesium alloy workers
Klystron tube operators	Thorium ore producers
Luminous dial painters	Underground metal miners
Nuclear submarine workers	Uranium mill workers
Nuclear reactor workers and operators	X-ray aides
Oil well loggers	X-ray diffraction operators
Ore assayers	X-ray technicians
	X-ray tube makers

Table 33.1.2 Workers who may be exposed to ionizing radiation*

for a given exposure scenario. This is particularly true for external exposures from x-rays, gamma rays, and some particles; however, the absorbed dose from radionuclides deposited internally depends on the chemical properties of the element and/or the chemical to which the radionuclide is bound. The target organ(s), retention and elimination for radionuclide will be completely governed by the chemical – not radiological – properties of the radionu-

Types of work	Numbers of exposed workers annually	Average dose equivalent per year (mSv)
Nuclear fuel production	13,870	0.42
All defense activities	115,000	0.6
Nuclear reactors	186,000	2.18
Industrial uses (monitored workers)	274,000	0.55
Medical applications	734,000	0.42

* Data from UNSCEAR 1993.¹⁹

Table 33.1.3 Estimated numbers of monitored US workers exposed to ionizing radiation, with their estimated annual doses*

clide. Thus, radioactive isotopes of iodine will be taken up in the thyroid; heavy metals like radium or radioactive strontium will be stored in bones; and radioactive sodium will follow stable sodium through tissues. The characteristics of some common radionuclides to which humans are exposed are summarized in Table 33.1.4.

DOSE ASSESSMENT

The international unit of absorbed dose from ionizing radiation is the *gray* (Gy), which equals 1 joule of absorbed energy per kilogram of absorbing medium, e.g., tissue. Formerly, ‘radiation absorbed dose’ or the *rad* was used for this measure (and still is by the US Nuclear Regulatory Commission): the conversion is 1 Gy = 100 rad. Different types of ionizing radiation elicit different amounts of tissue injury for a given amount of dose. The relative biologic effectiveness (RBE) is a term that designates the ratio of doses from standard gamma or x-rays to that of a test radiation for a given level of effect, under a given biologic endpoint. RBE varies for different biologic endpoints (e.g., lethality, mutation, erythema, etc) and as a function of dose, making the measure impractical for use in health protection programs. Thus, a physical quantity representing the rate of energy transfer per unit path length of tissue – linear energy transfer or ‘LET’ – is used as a surrogate measure of the RBE (radiation weighting factors for various radiation types provided in Table 33.1.5).

The LET of the radiation is used to weight the radiation dose by the relative biologic effectiveness, creating a unit of *dose equivalent*. For many years, the unit ‘radiation equivalent man’ or *rem* was used to indicate the dose equivalent. More recently, the sievert (Sv) was adopted internationally as the official unit of dose equivalent. Since the radiation weighting factor is dimensionless, the base units of Sv remain in joules per kilogram (1 Sv = 1 J/kg). The conversion between Sv and rem also remains as 1 Sv = 100 rem. A Sv of equivalent dose is defined as the dose in Gy multiplied by the LET weighting, or Q-factor, for the type of radiation (Table 33.1.5). Thus, 1 Gy of alpha particles delivers an effective dose of 20 Sv to exposed tissue because the LET for alpha particles is 20-fold that for x-rays. For low-LET radiation, such as gamma rays or beta particles, the absorbed dose in Gy equals the biologically effective dose in Sv.

Figure 33.1.1: Numbers of monitored radiation workers and average annual effective dose in the US radiation industry. Adapted from UNSCEAR.¹⁴

Radionuclide	Half-life	Typical source of exposure	Emission(s)	Target organ
Tritium (^3H)	12.3 yr	Biomedical research, nuclear weapons, power plants	Beta	Body water
Strontium (^{90}Sr)	27 yr	Nuclear fallout	Beta	Bone
Technetium (^{99}Tc)	6 hr	Medical diagnosis	Beta, gamma	Not stored
Iodine (^{131}I)	8 day	Medical diagnosis and therapy	Beta, gamma	Thyroid
Cesium (^{137}Cs)	30 yr	Radiation sources	Gamma	Bone
Radon (^{222}Rn)	3.8 day	Indoor environment; mines	Alpha	Lung
Uranium (^{238}U)	4.5 billion yr	Weapons production	Alpha, beta	Lung, Kidney
Plutonium (^{239}Pu)	20,000 yr	Weapons production, reactors	Alpha	Lung

Table 33.1.4 Characteristics of commonly encountered radionuclides

Ionizing radiation may also be measured in other ways important for health effects assessment. The former unit representing the *quantity* of radioactive material is the curie (Ci), which was originally defined as the number of radioactive transitions ('radioactive decays') per second in 1 gram of pure radium-226. This quantity is 3.7×10^{10} transitions per second. The new SI unit of radioactivity is the becquerel (Bq), which is defined simply as 1 transition per second. Thus, $1 \text{ Ci} = 3.7 \times 10^{10} \text{ Bq}$. Users of radioisotopes or radionuclides purchase them by the curie or becquerel; or, in the case of *radiolabeled* chemicals used as tracers in biomedical research, the typical units are Ci or Bq per

millimole or per gram of the labeled chemical. In the atmosphere or in drinking water, the concentration of radionuclide is typically expressed in picocuries (pCi) per liter or becquerels (Bq) per cubic meter.

A special case for units of air-borne radioactivity is encountered in uranium and certain other types of mining environments. The direct assessment of air-borne radon radioactivity is complicated by the fact that the products of the radioactive transition of radon are also radioactive. In order to account for the complex equilibrium among these air-borne radionuclides, a unit of measure was defined based on the total amount of energy emitted by

Table 33.1.6 Tissue weighting factors for radiation protection*

the mixture of radionuclides. This unit is the working level (WL), or 1.3×10^5 MeV per liter of air. When radon and its progeny radionuclides are in equilibrium, the WL is equivalent to about 100 pCi/L. The working level month (WLM) is a measure of the cumulative occupational exposure defined as an exposure of 1 WL in the atmosphere for 170 hours – a ‘working month’.

The various tissues and organs of the body may receive different radiation doses, depending on the circumstances of exposure. The risk of injury to a specific tissue depends on the dose to that tissue. It is therefore important to know the distribution of the radiation dose. The *effective dose* is the sum of the dose equivalents to the individual organs of the body, weighted by factors that represent the relative risk that injury in these tissues contributes to detriment for the entire individual (Table 33.1.6). The weighting factor is derived from the risk of cancer in the specific tissue, the probability of death from cancer in that tissue, the relative loss of life expectancy and the age-weighted risks of cancer in specific tissues.¹ In the case of the gonads, the detriment includes the risks to offspring (i.e., genetic effects) from radiation doses in the exposed individual. The apportionment of risk by the tissue-specific factors enables a risk

weighting of a radiation dose in cases in which the external exposure is non-uniform. According to this system of risk-weighted dosimetry, a dose selectively delivered to the lung ultimately involves 12 times more detriment (risk) than does a radiation dose delivered to the thyroid, for example (Table 33.1.6).

Evaluation of the radiation dose

Radiation doses to individuals can be evaluated using instruments to measure the radiation emitted by sources and/or by calculations estimating the intensity of radiation exposure and the resulting dose. Dose estimates in radiation protection programs provide valuable assurance that occupational risks are understood and managed appropriately. In radiation oncology, knowledge of doses to both the tumor and to normal tissue is essential for effective radiation therapy. Dosimetry in diagnostic radiology and nuclear medicine is necessary for quality assurance in imaging and to ensure that an unnecessary radiation dose to the patient is avoided. Finally, an evaluation of radiation doses in accidents provides a basis for prognosis, treatment, and patient management.

In protection programs, personnel monitoring with film badges, thermoluminescent dosimeters or digital pocket dosimeters is frequently used to assess exposures from external sources. Regular monitoring of radiation-exposed workers is usually required if it is possible that the individual might receive one-tenth of an annual occupational dose limit during normal workplace procedures. Personnel monitoring is typically supplemental to measurements of radiation sources using instruments such as ionization chambers. If the results from personnel monitoring or direct reading instruments are not available, mathematical modeling of the radiation fields may be used to provide an estimate of dose. The duration of the exposure, the relative positions of the source with respect to the exposed individual, and the presence of any shielding materials are important factors in completing the calculation. In radiation accidents, accurate descriptions of these variables are invaluable steps toward providing reliable dose estimates.

It is important to distinguish between situations in which an individual is exposed only to the radiation from an external source and those in which the individual is exposed to radioactive materials as the result of a release of such material into the environment, resulting in deposition on or in the body. An evaluation of the dose resulting from external exposure requires knowledge of the intensity of the radiation and the damage that the various types of radiation can cause. In general, particles can penetrate tissue far less readily than x-rays or gamma rays so they can cause effects only on tissues near which they are deposited or stored in the body. For this reason, they are termed internal emitters. The different types of radiation also differ by their relative ability to impart energy or injury to tissue (e.g., Table 33.1.5).

In accident cases in which the patient was exposed to external sources of gamma rays, x-rays, beta particles or alpha particles, patient management does not present

radiation safety problems because the patient is not made radioactive by these exposures. However, in accidents in which radioactive materials are deposited on or in the body, or are generated within the body by external exposures from neutron sources, radiation exposure to the patient continues as long as these materials are present. Special handling may be needed because the material may be transferred to others or contaminate the environment. An evaluation of surface contamination may be made using a portable Geiger counter or scintillation probe that could detect the radiation from this material on skin or other surfaces. Alternatively, a wipe test may be made by wiping the surface with paper or cotton and analyzing the sample with a suitable detector.

An evaluation of the dose caused by internal exposure is based on calculations using knowledge of the type of material present, its quantity, its distribution in the body, and the change in quantity and distribution as a function of time. These factors may be determined directly using radiation detectors placed external to the body; by sampling body fluids, tissues or excreta and analyzing these in suitable bioassay instruments; or by dose modeling. The physical and biochemical characteristics of the material, use of dosimetry, or other radiation detectors determine the appropriate method. A whole-body counter is a shielded scintillation detector system used to evaluate the quantity of radioactive material in the body when radiation from that material can be detected outside the body. The gamma camera is employed in nuclear medicine to determine the distribution of radiopharmaceuticals administered for diagnostic purposes. These instruments may be applied to the evaluation of accidents in appropriate cases. Bioassay techniques require the careful preparation of samples and analysis with specialized laboratory instruments such as the well or liquid scintillation counter. The evaluation of radiation dose is a specialized task that may be performed by health or medical physicists, addressing both radiation dose and associated risks.

MANAGEMENT AND PREVENTION

The prevention of radiation injury is the primary goal of radiation protection programs. To this end, all unnecessary exposures to radiation should be minimized and permissible occupational exposure must be kept as low as reasonably achievable (ALARA). The operating limits on the doses of radiation that may be delivered to members of the public and to radiation workers are not expected to prevent all mutagenic, carcinogenic and teratogenic effects (because thresholds for these effects *may* not exist) but they should keep the risks of these effects within acceptable bounds. The minimization of unnecessary radiation exposures requires careful design of the workplace, equipment, and work procedures; thorough training and supervision of workers; and implementation of an appropriate radiation protection program, including systematic oversight and monitoring by health physicists. The radiation protection

program also should include plans for coping with radiation accidents, including a delineation of the lines of authority for managing such accidents, a knowledge of the local medical facilities that are capable of evaluating and treating radiation accident victims, and arrangements for handling and transporting radioactive victims.

CLINICAL EFFECTS

Types and subcellular mechanisms of radiation injury

Ionizing radiation, in contrast to non-ionizing radiation, is capable of depositing enough localized energy in living cells to disrupt the atoms and molecules on which it impinges, producing ions and free radicals in the process, thus giving rise to the biochemical changes that may lead to injury. The distance between successive atomic collisions along the path of an impinging radiation depends on the energy, mass and electrostatic charge of the radiation. In the case of the alpha particle, the collisions typically occur so close together that the particle gives up all of its energy while traversing only a few cells. Thus, if emitted externally, alpha particles pose little risk of injury, even to the skin. In the case of x-rays or gamma rays, on the other hand, the collisions typically occur so far apart from one another that the radiation may penetrate through the entire body.

The molecular changes produced by a given dose of radiation and, in turn, the probability of cellular injury depend on the microscopic distribution of the energy that is deposited in the cell. In general, the relative biologic effectiveness of radiation increases with the ion density – or LET (linear energy transfer) – of the radiation. Hence, a given amount of energy deposited in the cell by alpha particles is more likely to cause injury than the same amount of energy deposited by x-rays. Because of the differences in potency, doses of different types of radiation are customarily normalized by LET-dependent weighing factors (Table 33.1.5) when they are evaluated for purposes of risk assessment or radiation protection.

Although a large enough dose of radiation, in principle, can alter any molecular constituent of the cell, DNA is the most critical biologic target because of the limited redundancy of the genetic information it contains, i.e., damage to a single gene, if unrepaired, may kill or profoundly alter the affected cell. A dose of radiation large enough to kill the average dividing cell (approximately 2 Sv) causes hundreds of lesions in its DNA. Most such lesions are repairable, however, with the result that the ultimate fate of a given lesion depends on the outcome of DNA repair processes as well as on the initial lesion itself. An irreparable lesion in DNA is more likely to be produced by densely ionizing radiation (e.g., a proton or an alpha particle) than by sparsely ionizing radiation (e.g., an x-ray or a gamma ray). Unrepaired or misrepaired damage to DNA, manifested in the form of mutations, has been well documented in many types of cells. At a given genetic locus, the frequency of mutations characteristically increases linearly with radiation dose approximating 10^{-5} to 10^{-6} per Sv.

Radiation-induced damage may also involve chromosome breakage, thereby giving rise to changes in chromosomal structure and number. The combined frequency of translocations, dicentrics, rings, and other chromosomal aberrations increases linearly with the dose in the range below 1 Sv, approximating 0.1 per cell per Sv in human lymphocytes irradiated *in vitro*. The frequency of such aberrations has also been observed to increase with the dose in the lymphocytes of atomic bomb survivors, radiation workers and persons residing in areas of elevated natural background radiation. The dose–response relationship for such changes has been characterized well enough so that the aberration frequency can serve as a useful early biologic dosimeter in radiation accident victims.

Damage to genes, chromosomes and other vital organelles may be lethal to the affected cells, especially dividing cells, which are particularly radiosensitive as a class. The survival of dividing cells, measured in terms of proliferative capacity, tends to decrease exponentially with increasing dose: 1–2 Gy generally suffice to reduce the surviving fraction by about 50%. Although the killing of individual cells is a stochastic process, too few cells are killed by a dose below 0.5 Gy to cause clinically detectable changes in most tissues and organs, except those of the embryo. Thus, there are substantial thresholds for the acute effects of radiation, which vary from organ to organ as noted subsequently.

Acute radiation injury

Tissues in which the cells proliferate rapidly are generally the first to exhibit injury. Mitotic inhibition and cytologic abnormalities may be detectable immediately after intensive irradiation in such tissues, in contrast to fibrosis, other degenerative changes and neoplasia, which may not appear until months, years, or decades later. Because of homeostatic mechanisms, including the repair of DNA damage and compensatory proliferation of surviving stem cells, tissues generally suffer less injury from a given dose if the radiation is accumulated gradually over a period of days or weeks than if it is absorbed in a single brief exposure. The injury from a given dose is also generally less severe if only a fraction of a tissue is exposed than if all the cells in the tissue are exposed. A brief summary of the effects of radiation on key organs and on the whole body follows but more detailed information is available in specialized texts, such as the publication by Mettler and Upton.²

Skin

Erythema may occur within minutes or hours after exposure, depending on the radiation dose, energy, and the size of the area irradiated. The threshold for erythema in a 10 cm² field varies from 6 to 8 Sv of gamma rays or x-rays delivered in a brief exposure, to more than 30 Sv delivered in daily exposures over a period of weeks. After rapid exposure to a dose of 6 Sv or more, the erythema typically appears within hours, lasts a few hours, and is then followed 2–4 weeks later by one or more waves of deeper and more prolonged erythema and epilation. A

dose as large as 10–20 Sv delivered acutely may cause transepithelial injury with moist desquamation and possibly necrosis of the skin within 2–4 weeks.

Bone marrow and lymphoid tissue

A dose of 2–3 Sv delivered rapidly to the whole body will kill enough mature lymphocytes as well as their precursors to produce severe lymphopenia, reaching a minimum within 48 hours. There will also be enough precursor hemopoietic cell damage to cause severe depression of the granulocyte and platelet counts within 3–5 weeks. A dose above 3–5 Sv without medical treatment is likely to result in fatal infection and/or hemorrhage during that vulnerable period (Table 33.1.7), with almost immediate aplasia of lymphoid tissues, lymphopenia and depression of the immune response.

Gastrointestinal tract

Stem cells of the intestinal mucosa are killed in sufficient numbers by an acute dose of 10 Sv to produce ulceration of the overlying epithelium. If a large enough area of the mucosa is affected, the injury may result in a fatal, dysentery-like syndrome within 1–2 weeks (Table 33.1.7).

Gonads

Acute exposure of both testes to a dose as low as 0.15 Sv will kill enough spermatogonia to depress the sperm count for months, beginning about 6 weeks after exposure. A dose of more than 2 Sv will cause more prolonged and possibly permanent sterility. Acute exposure of both ovaries to a dose of 1.5–2.0 Sv will, similarly, cause temporary sterility, and a dose of 2.0–3.0 Sv can cause permanent sterility, depending on the age of the woman at the time of exposure.

Lens of the eye

Irradiation of the lens can cause the formation of lenticular opacities within a matter of months. The threshold for a vision-impairing cataract is estimated to vary from 2–3 Sv absorbed by the lens in a single brief exposure to 5.5–14 Sv absorbed over a period of months.

Respiratory tract

The respiratory tract can withstand considerable localized radiation injury, such as may result from intensive irradiation of a small part of the lung. When all or most of both lungs are heavily irradiated, however, a fatal pneumonitis can result within 1–6 months. The lethal dose for 50% of a theoretical population for this reaction is about 8–10 Gy for gamma rays delivered in a single brief exposure. Those who survive the acute inflammatory phase of the reaction may succumb later to pulmonary fibrosis or cor pulmonale. The pathogenesis of the lesion involves a complex series of reactions apparently resulting from damage to alveolar cells and pulmonary vasculature.

This pulmonary pattern has been recognized in patients treated with radiation therapy, as well as occupational exposures, including firemen who dealt with the Chernobyl reactor fire and radiation workers involved in more recent industrial accidents in Israel and Japan in

Acute dose equiv (Sv)	Incidence (%)	Latency hours	Syndrome or organ involved	Characteristic symptoms	Critical period after exposure	Therapy	Prognosis	Lethality (%)	If injury is fatal	
									Death within	Cause of death
1–2	0–50	>3	Bone marrow	Mild leukopenia and thrombopenia	2–6 weeks	Symptomatic	Excellent	0–10	Months	Infections and/or hemorrhage
2–5	50–90	1–2	Bone marrow syndrome	Thrombopenia, leukopenia, hemorrhage, infections, epilation	2–6 weeks	Transfusions of leukocytes and platelets, supportive care (isolation, antibiotics, fluids), cytokines, stem cell transplantation	Uncertain depending on success of therapy	0–90	Weeks	Infections and/or hemorrhage
5–10	100	0.5–1	Bone marrow syndrome	Thrombopenia, leukopenia, hemorrhage, infections, epilation	2–6 weeks	Cytokines, stem cell transplantation, transfusions of leukocytes and platelets. Supportive care (isolation, antibiotics, fluids)	Uncertain depending on success of therapy	0–90	Weeks	Infections and/or hemorrhage
10–15	100	0.5	Intestinal syndrome	Diarrhea, fever, electrolytic imbalance	3–14 days	Palliative	Very poor	90–100	2 weeks	Enterocolitis, shock
>50	100	<1	Neurologic syndrome	Cramps, fever, ataxia, lethargy, impaired vision, coma	1–48 hours	Symptomatic	Hopeless	100	1–4 hours	Cerebral edema

Table 33.1.7 Features of the acute radiation syndrome

whom the hematologic damage was effectively treated. It includes respiratory failure associated with interstitial edema and pneumonitis. This has appeared within 1–3 months after radiation therapy of 8–9 Gy to the chest and within 3–30 days in seven Chernobyl-injured workers.

Total body radiation injury

Intensive irradiation of the whole body or a major part of it may cause sufficient simultaneous damage to several key organ systems, such as the hematopoietic system, the gastrointestinal tract, nervous and cardiovascular systems, to produce the collection of signs and symptoms known as the acute radiation syndrome. This syndrome is characterized by a succession of manifestations that can be grouped temporally into a prodromal stage, a latent period, a stage of manifest illness, and, finally, for survivors, recovery. The duration and severity of the associated phenomena are strongly related to the magnitude of the evoking exposure. With increasing dose, the syndrome may be dominated clinically by the consequences of malfunctioning of a particular system; hence, the acute radiation syndrome has been subdivided into the hematologic, gastrointestinal, neurovascular and pulmonary forms. The overall pattern of the acute radiation syndrome is summarized in Table 33.1.7.

Regardless of which form of the syndrome ultimately dominates the clinical course, the early or prodromal symptoms characteristically include anorexia, nausea, and vomiting (and diarrhea at higher dose levels), occurring within a few hours after irradiation. These are primarily transient neurogenic phenomena, which are then followed by a symptom-free interval of dose-related duration, until the onset of manifest illness (Table 33.1.7). The ensuing clinical phenomena fall into three or four general patterns.

The hematologic form, reflecting bone marrow suppression, with deficit in the production of hematologic cell lines, is triggered by about 1 Gy or more. This form is characterized by infections, particularly including oropharyngitis, mucositis, enteritis, pneumonitis, and septicemia between the third to fifth postexposure week. Infections include opportunistic bacteria, viruses and fungi. Also prominent are the external and internal hemorrhagic manifestations associated with thrombocytopenia, including petechiae, purpura, epistaxis, hematemesis, melena, hematuria and internal bleeding.

Somewhat higher levels of exposure of about 10 Gy or more can lead to gastrointestinal sequelae related to the insufficiency of cell production necessary to maintain the integrity of the gastroenteric mucosal lining. Beginning by the end of the first postexposure week, signs of malnutrition, dehydration, electrolyte disturbances, and gastrointestinal infection and bleeding become increasingly prominent.

Still higher levels of radiation exposure, exceeding about 20 Gy, can elicit a neurovascular response after a short latent period including ataxia, somnolence, coma alternating with hyperexcitability, and convulsions accompanied by hypotension, hypothermia, and death within hours to 1 or 2 days.

Clinical evaluation strategy

The signs and symptoms of radiation injury are non-specific; the clinical evaluation of an irradiated person requires integration and synthesis of pertinent information from the individual's exposure record, medical history, physical examination and laboratory data. In managing a radiation accident victim, even if the patient was heavily irradiated or contaminated, an evaluation of burns, smoke inhalation, mechanical trauma or other forms of injury should be performed. Contaminated clothing should be removed promptly, isolated in a plastic bag, and labeled to denote radioactivity; the victim should be isolated; and the contaminated area sealed off as soon as possible. The management of the radiation injuries themselves (Table 33.1.7) will vary depending on their severity and the particular organs that are affected.

Because the nature and severity of any injury that may result from exposure to radiation depend on the size and anatomic distribution of the dose, assessment of the dose is a useful adjunct to the clinical evaluation of an exposed person. Present maximum permissible exposure limits for radiation workers are sufficiently restrictive to prevent detectable impairment of organ function under normal conditions of occupational exposure. However, if a sizable proportion of the entire body is more heavily irradiated, a rapid assessment of the extent of anticipated injury will greatly facilitate subsequent clinical management.

Physical dosimetry can be helpful, but processing of dosimeters and careful reconstruction of the exposure events usually requires significant time. Fortunately, there are a number of biologic dosimeters that can help to provide early information about the extent of injury for which to prepare. Much can be learned by a careful history, physical examination and sequential complete blood counts, including differential analysis, platelet and reticulocyte counts. If feasible, peripheral blood cytogenetic examinations should be performed. The early prognostic information to be gained by clinical observations and blood counts alone is summarized in Table 33.1.9. A listing of useful early procedures, with the time of appearance of some key findings, and the minimum exposure that evokes them, is provided in Table 33.1.8. This simplified approach can be helpful when assessing large groups of people, as well as with individual patients.

Procedure	Finding	Approximate time of onset	Minimum exposure required
History	Nausea, vomiting	Within 48 hours	1.5 Gy
Physical examination	Erythema	Within 48 hours to days	3.0 Gy
Blood count and differential	Hair loss	Within 2 weeks	3.0 Gy
Chromosomal analysis	Lymphocytes < 1000/mm ³	Within 24–48 hours	1.0 Gy
	Dicentrics, rings, and/or fragments	Within hours	0.10 Gy

Table 33.1.8 Radiation injury evaluation procedures and their results in relation to time and magnitude of radiation exposure

<i>Evaluation procedures</i>	
1. Observe and record time of onset of clinical signs and symptoms	
2. Perform daily blood count	
<i>Findings</i>	<i>Potential outcome</i>
Nausea, vomiting, diarrhea within minutes. Ataxia, disorientation, shock, coma in minutes to hours	Neurovascular syndrome
Nausea and/or vomiting and some blood count derangement in 2 days	Minor hematologic syndrome
Marked leukocyte and lymphocyte count derangement in 3 days	Major hematologic syndrome
Diarrhea within 4 days and marked platelet derangement within 6 to 9 days	Gastrointestinal syndrome

Table 33.1.9 Preliminary evaluation of acute radiation injury following overexposure

Treatment considerations

The management of acute radiation injury has evolved on an empirical basis largely from experience with populations exposed to atomic weapons and radiation therapy, as well as accidental exposure to a variety of occupational sources. Such treatment can be divided into supportive and intensive care, reviewed in a consensus symposium in mid-1989, the proceedings of which have been published.³ Supportive care includes provision of a pathogen-free environment; early administration of antibiotics for prophylactic treatment of the upper respiratory and the gastrointestinal tracts; utilization of intravenous nutrients, fluids and blood components; and active therapy of any overt infections that develop.

A more intensive form of therapy that has been used in the treatment of the hematologic form of acute radiation injury has been bone marrow or stem cell transplantation from umbilical cord blood, peripheral blood, and fetal tissue. This therapy was originally developed in the 1960s with support from the US Atomic Energy Commission to improve understanding and treatment of radiation injury, but quickly entered broader clinical use to treat leukemias, other neoplastic disorders and some genetic disorders. Various protocols for stem cell administration have now been employed in 30,000–40,000 patients worldwide, and this population is currently increasing by 10–20% per year.^{4,5} In this form of antileukemic therapy, a conditioning regimen of total body irradiation of about 10–12 Gy in one brief exposure or 15 Gy divided over 3–7 days is generally given, preceded by preconditioning with antineoplastic therapy, and followed by transfusion of bone marrow or stem cells.

In a literature review of relevant case series published from 1981 to 1987, with sufficient pertinent data over a 60-day follow-up period, seriously ill patients had a postirradiation 60-day survival rate of 85–90%. Bone marrow transplantation was first used to treat radiation injury 3–4 weeks after accidental radiation overexposure following a reactor accident in Vinca, Yugoslavia, in 1958 without clear evidence of a positive effect on outcome.^{6,7} The first successful such use of bone marrow transplantation followed the Pittsburgh accelerator accident in 1965 in which one of the three industrial accelerator workers involved had a mean

whole-body exposure of about 6 Gy and much higher extremity doses that eventually led to quadruple amputations. In a transplantation from an identical twin, hematologic recovery began about 10 days after the transplantation, which was performed on the ninth postexposure day.⁸

Thirteen of the approximately 200 patients with acute radiation syndrome treated in Moscow and Kiev after the Chernobyl reactor accident received bone marrow transplants, and six were given fetal liver cells. Two of the former and none of the latter survived. Both survivors rejected the transplant by 36 days postexposure, although transient engraftment may have aided survival. It must be emphasized that all these patients had whole-body exposures above 6 Gy, with thermal and radiation burns exceeding 50% of the skin surface, as well as other trauma complicating recovery.

The poor results of hematopoietic stem cell transplantation at Chernobyl must be weighed against those obtained in poor-risk medical patients undergoing radiation therapy and in industrial accidents. The method probably warrants consideration in radiation accident patients with life-threatening exposures in the range of 8–12 Gy or higher, with an individual risk–benefit judgment required a case-by-case basis.

The clinical use of hematopoietic growth factors is another recent therapeutic development that may obviate the problems of finding appropriate bone marrow donors and ensuring that the overall benefits of transplantation outweigh risks. The identification of various hematologic growth factors began in the 1960s, with recombinant gene technology leading to availability of myeloid (G-CSF, interleukin-3, PIXY321), myeloid/macrophage (GM-CSF), myeloid/lymphoid (SCF), macrophage/monocyte (M-CSF), lymphoid (interleukin-2), erythroid (erythropoietin or EPO) and megakaryocytic (MGDF/TPO) growth factors. In general, these factors enhance the survival, proliferation and differentiation of the committed progenitor cells of the various cell lines.

The potential value of these factors for radiation accident patients with hematologic injury is apparent, despite uncertainties associated with any new therapy. The first scientific report of the use of granulocyte-macrophage colony-stimulating factor was in eight patients exposed to cesium-137 contamination in a 1987 incident in Goiania, of whom four survived.⁹

The same factor was used to treat three patients in an industrial sterilization unit accident in San Salvador in 1989. All recovered from the hematologic effects, although one died 8.5 months later from radiation pneumonitis and other complications.¹⁰ A third accident involved a radiation worker in Israel in 1990, who received a bone marrow transplant and interleukin-3 following massive exposure that proved fatal within 36 days.¹¹ Other accident patients, including a worker at an irradiation facility in Belarus in 1991¹² and two workers in Tokaimura, Japan, 1999, survived the hematologic impairment period only to succumb later to the respiratory injury. Successful management of pulmonary injury remains an unmet challenge in treating acute whole-body high-dose radiation overexposure.

The gastrointestinal form of acute radiation syndrome has not been treated successfully in either victims of Chernobyl or earlier accidents. It should be noted, however, that many patients with hematologic diseases who undergo stem cell transplants have survived after exposures to 10–15 Gy, an exposure level that would be expected to produce some gastrointestinal damage without such aggressive therapy. Similar results in animal studies suggest that additional use of leukocyte growth factors may enhance the survival of accident victims exposed to such levels of ionizing radiation. The neurovascular and, as noted above, the pulmonary manifestations of high-dose total-body radiation exposure remain therapeutic challenges.

Local injury

External radiation sources can produce localized tissue injury. Such injuries constitute the most frequent form of occupational overexposure, usually involving the hands. Correct diagnosis depends on an accurate history and observation of transient waves of erythema after exposures of about 3–6 Sv. These may be followed by bullae formation in the ‘wet’ form of radiodermatitis associated with exposures of about 10–20 Sv, occurring within 1–3 weeks depending on dose. Treatment is supportive, but tissue grafting may become necessary for healing. Over the longer term, a reactive obliterative endarteritis may compromise regional blood supply, necessitating amputation of the necrotic tissue.

Radionuclide contamination

Accidental radionuclide contamination may involve the external surfaces of the body and internal deposition by inhalation, ingestion, or through traumatic injuries. Following (or during) any necessary emergency treatment of life-threatening injuries, prompt action including decontamination, is desirable to avoid incorporation of surface activity, to enhance decorporation of any actual intake, and to minimize psychological sequelae. A clinical challenge is the large number of variables that must be considered in dealing with such exposures, including the physicochemical and metabolic characteristics of the radioactive compound involved, routes of entry, and sites of deposition. NCRP Report number 65 is a practical monograph providing guidance in the management of these

clinical problems.¹³ Isolation measures and use of personal protective equipment by healthcare providers and emergency responders may be required.

External surface contamination can be treated by applying the least irritating agents first, such as soap and water. Insufficient results may require increasingly strong measures, such as abrasive soap, detergents, oxidizing agents, complexing agents, or chelating agents. Cleansing efforts should be terminated when all significant radioactivity or unbound activity has been removed, or when there is evidence of hyperemia or abrasion of the skin that might enhance transcutaneous movement of radioactivity.

For radionuclide inhalation, naso-oropharyngeal irrigation is indicated. After inhaled material is deposited in the lungs, there is no simple effective agent to use. For a major deposition of a highly hazardous, long-lived isotope, bronchopulmonary lavage has been used, but this requires general anesthesia and management by an experienced pulmonologist.

In cases of radionuclide ingestion, which may be associated with inhalation, naso-oropharyngeal lavage is also indicated. Unless performed immediately, emesis or gastric lavage are not likely to be useful. Purgatives will accelerate the transit time of material through the gastrointestinal tract, reducing the mucosal contact time and absorption.

For contaminated lacerations, thorough irrigation and surrounding skin decontamination are necessary steps before any effort at closure. The use and extent of surgical debridement and possibly of excision of contamination, must be individualized based on clinical judgment. After these initial measures have been taken, evaluation of the amount of residual internal radioactivity, its medical significance, and the rate of spontaneous decorporation will determine the need for further treatment. This assessment may involve bioassays of excreta and whole-body radioactivity measurements. If necessary, there exist several approaches to decorporation, including dilution, blocking, mobilization and chelation. Appropriate agents for various important radionuclides are provided in Table 33.1.10.

Combined injury

Importantly, the existence of one type of radiation injury does not preclude the concurrent presence of another, nor does radiation injury prevent the simultaneous occurrence

Method	Isotope	Agent
Dilution	^3H	Water
Blocking	^{32}P	Phosphorus (Neutra-Phos)
	^{137}Cs	Ferric ferrocyanide (Prussian blue)
	^{131}I , $^{99\text{m}}\text{Tc}$	KI (Lugol's solution)
	^{89}Sr , ^{85}Sr	Aluminum phosphate (Phosphogel)
		Aluminum hydroxide (Amphojel)
Mobilization Chelation	^{86}Rb	Sodium alginate (Gaviscon)

of other trauma. This can result in combined injury, the severity of which may exceed those of the individual component parts. This has been seen in catastrophic situations, such as the atomic bombings of Hiroshima and Nagasaki, Japan, and the explosion and fire at the Chernobyl nuclear power station near Kiev, Ukraine. There are significant differences in clinical management, such as the timing of surgical intervention and the choice of pharmaceuticals under these circumstances. The combined effects of low-dose, chronic intermittent radiation exposure and exposure to other agents is an area receiving increasing recent attention, as they are more representative of the majority of the workers exposed to radiation. A discussion of these issues is included by Mettler and Upton,² and in more detail in the United Nations 2000 report.¹⁷

Psychologic stress

Common to most accident incidents, regardless of the extent of actual radiation injury and/or radionuclide contamination, is anxiety and fear in the people who perceive themselves involved. Historic incidents, such as the Hiroshima and Nagasaki atomic bombings, the nuclear weapons tests at Bikini and Nevada, and accidents at Three Mile Island and Chernobyl, and all their repercussions have received extensive media coverage. It is therefore necessary to anticipate concern on the part of patients, relatives, and those who perceive themselves as possibly affected. Helpful measures include prompt dissemination of honest factual information and provision of evidence that the situation is understood, and that a practical plan for clinical management is in place and can be implemented as needed. Appropriate prior education of individuals potentially encountering radiation is important in preventing panic.¹⁹

Mass radiation terrorism or accident casualties

There are three broad areas to consider in preparing to address the potential problems associated with terrorist activities involving radiation exposure on a large scale. One requisite is an understanding of the potential radiation sources such as radiation dispersal devices (RDD) and the consequent health effects, including the psychosocial ones, and their care. Another is knowledge concerning incident command and control procedures at federal, state and local levels, as well as the crucial aspects of communication and information flow to the public. These include cleanup recommendations and guidance on dose limitations for the impacted public as well as for the responders. A third requisite is familiarity with emergency planning, response resources and personnel training for radiation events.

For those for whom radiation has only been familiar as a research subject or tool in industry, or as a clinical or experimental therapeutic modality, the reality is that the likelihood of being called upon to assist in the event of an accidental or deliberate radiation incident is increasing. The National Council on Radiation Protection and Measurement (NCRP) has published NCRP Report number 65, a patient-oriented monograph on the *Management of Persons Accidentally Contaminated with Radionuclides*¹³ and NCRP report number 138, *Management of Terrorist Events*

Involving Radioactive Material,¹⁴ which cover the basic public health information with which to anticipate, prepare for, recognize and deal with a deliberate public assault involving radionuclides. The information and resource listings in these reports make it useful for every 'responder' and medical organization to have reference copies at each site where such information might be needed on an emergency basis. Other guides are also available.^{15,16}

Chronic effects

Effects on cancer incidence

Radiation workers were among the first to demonstrate the carcinogenic effects of irradiation. Historic examples include: (1) carcinomas of the skin in pioneer radiologists and x-ray workers, (2) leukemias in early radiologists, (3) osteogenic sarcomas and carcinomas of the cranial sinuses in early radium watch dial painters, and (4) lung cancers in pitchblende and other underground hard-rock miners. Although the risks of such cancers in radiation workers are drastically reduced as a result of modern radiation protection standards, the extent to which radiation workers might be at risk for cancer remains a concern. Radiation thus continues to be among the most thoroughly investigated of occupational carcinogens.

The neoplasms induced by irradiation characteristically take years or decades to develop, and they are indistinguishable from neoplasms induced by other environmental, occupational or lifestyle causes. Moreover, the induction of radiation-related cancers has been detectable only after relatively large radiation doses (>0.5 Gy) and has varied with the type of neoplasm as well as age and gender of the exposed individual. The dose-incidence data for most neoplasms are consistent with a multistage, linear non-threshold relationship. Overall, the extent to which the risk of cancer might be increased by low-level radiation exposures cannot be estimated except by extrapolation from dose-response relationships based on highly exposed populations, extrapolating to low radiation doses.

Among various dose-incidence models for estimating the risks of low-level radiation [R(d)], the one that has been judged to fit the currently available data best is a multiplicative model of the form:

$$R(d) = R_0 [1 + F(d)g(b)]$$

where R_0 denotes the age-specific background risk of death from a specific type of cancer, d is the radiation dose, $F(d)$ is a function of dose that is linear for cancers other than leukemia and linear-quadratic for leukemia (i.e., $f(d) = a_1d$ or $f(d) = a_2d + a_3d^2$), and $g(b)$ is a risk function dependent on other parameters, such as gender, age at exposure, and time after exposure.

Epidemiologic data from atomic bomb survivors and other irradiated populations have been used to estimate lifetime incidence and mortality risks for various cancers (Fig. 33.1.2).¹⁷ The risk projections derived from these data provide a range of estimates for the lifetime risk from cancer

Figure 33.1.2: Excess relative risk of mortality (and 90% CI) from specific solid cancers in atomic bomb survivors. An excess relative risk = 1 is a 100% increase in risk or a doubling of the background mortality for the tumor type. The data shown are standardized for females exposed at age 30 years. The dashed line is the excess risk for all cancers combined. Data from UNSCEAR.¹⁴

mortality (Table 33.1.11). The result of radiation risk analysis summarized in Table 33.1.11 demonstrates that the risk of exposure-induced death (REID) from solid cancers, after exposure to an acute whole-body dose of 1 Sv, is about 6.5–9.9% (combined male and female population). The range of estimates here is generated by the type of risk projection model and whether the risk is calculated as a multiple of the normal cancer risk (relative risk, or RR) or an absolute increase above the normal cancer risk (absolute risk or AR). The corresponding REID for leukemia is about 1.19% after a dose of 1 Sv. The estimates of REID after acute doses of 0.1 Sv – twice the annual occupational dose limit in the US – are 0.7–1.1% for solid cancers and 0.06% for leukemia (Table 33.1.11).

Much of the difference between the upper and lower estimates in the estimated ranges results from uncertainty regarding longer latencies of 40 years or greater following irradiation. Although the risk of leukemia in irradiated populations has been observed to reach a peak and then decrease within 25 years following exposure, latencies for other cancer types may remain elevated. To determine the extent to which the risk of cancer in persons irradiated during childhood may be elevated relative to the general population will require further follow-up of atomic bomb survivors and other exposed populations.

In addition to the uncertainty about the length of time that cancer risk remains elevated following irradiation, other sources of uncertainty that complicate assessment of the risks of low-level irradiation include: (1) uncertainty about the shape of the relevant dose–incidence relationship, (2) uncertainty about the extent to which the carcinogenic effects of a given dose may be affected by variations in the distribution of the radiation time and space, (3) uncertainty about the degree to which the risk of a given cancer may vary with age at irradiation, sex, smoking habits, diet and other factors, and (4) uncertainty about the accuracy of the dose measurements, diagnoses, and other data on which the estimates are based. Because of these uncertainties, the existing risk estimates must be interpreted with caution.

Projection model	Risk model	Male	Female	Both
<i>Solid cancer mortality (dose of 1 Sv)</i>				
Age at exposure	RR*	8.5	16.4	12.5
	AR	8.5	11.5	9.9
Attained age	RR	6.2	12.4	9.3
	AR	5.4	7.6	6.5
<i>Leukemia mortality (dose of 1 Sv)</i>				
Age- and time-varying	AR	1.13	1.25	1.19
<i>Solid cancer mortality (dose of 0.1 Sv)</i>				
Age at exposure	RR	0.9	1.9	1.4
	AR	0.9	1.3	1.1
Attained age	RR	0.7	1.4	1.0
	AR	0.6	0.8	0.7
<i>Leukemia mortality (dose of 0.1 Sv)</i>				
Age- and time-varying	AR	0.06	0.06	0.06

* RR: risk relative to unexposed cancer risk; AR: absolute risk
Data from UNSCEAR 2000.¹⁴

Table 33.1.11 Estimates of lifetime risk of exposure-induced death (REID, in percent) following an acute whole-body exposure to a population of all ages

Caution must also be exercised in extrapolating from the estimates tabulated Table 33.1.11 to predict the risk of cancer following the accumulation of a given dose over a period of weeks, months, or years. For instance, the carcinogenic effects of low-LET radiation in laboratory animals are reduced by a factor of 2–10 if the exposure is sufficiently prolonged to allow recovery through homeostatic processes.¹⁸ Because comparable human data on the comparative carcinogenicity of protracted low-LET irradiation are lacking, it is not possible to specify the extent to which the projections tabulated (Table 33.1.11) may overestimate the doses accumulated over longer periods; however, it is conceivable that they may overestimate risk by a factor of two or greater.

Epidemiologic studies of underground uranium, iron, zinc, lead, and fluorspar miners, who were exposed to ele-

vated concentrations of radon, have convincingly demonstrated excess lung cancer from exposures to the high LET radiations emitted from radon (^{222}Rn) and its radioactive progeny.¹⁹ The observation that indoor radon contributes more than 50% of the annual effective dose equivalent received by the population from all radiation sources, together with the dose–risk relationships derived from the miner studies, indicate that indoor radon exposures may account for up to 10% of all lung cancers. Indoor radon may thus represent the most significant risk factor for lung cancers in the non-smoking population. The National Research Council's Committee on the Health Effects of Exposure to Radon (BEIR VI) recently estimated the attributable risk for lung cancer death from domestic exposure to radon (using 1985–89 mortality rates) to be as great as 27% in never-smokers, and 14% in ever-smokers. Using the BEIR VI risk models, the absolute number of radon-related lung cancer deaths in the US in 1995 would be 15,400 or 21,800, depending on the risk model used for estimation. Among these deaths, an estimated 2100 or 2900 would have occurred among never-smokers.

While the risk of lung cancer from domestic radon exposures cannot be directly validated from existing residential studies, the exposure–response relationships are consistent with occupational miner data, when the latter are restricted to exposures under 50 WLM. However, a large-scale study of county-based lung cancer mortality and average indoor radon concentration resulted in an exposure–response relationship that differs markedly from the BEIR VI exposure–risk models.²⁰ Given current epidemiologic methodologies, it is unlikely that differences among risk assessment models can be resolved. Some of the uncertainties that affect the estimates of low-dose lung cancer risks from indoor radon include those listed in Table 33.1.12. While significant uncertainties regarding dose–response relationship remain, most risk assessments of lung cancer in residential settings have generally supported the issuance of guidelines limiting residential radon exposure.

The average dose of radiation received by members of the United States population from natural sources other than radon approximates 1 mSv (100 mrem) per year, which is estimated to account for less than 3% of all

cancers in the population. Epidemiologic studies to determine the extent to which the rates of cancer may actually vary with natural background radiation have been inconclusive. In certain studies, the rates of cancer have been found to vary inversely with natural background radiation levels, a relationship interpreted by some observers as evidence of beneficial (or hormetic) effect of low-level irradiation;²¹ however, the relationship has not persisted after controlling for the effects of altitude and other confounding variables. Although the risk associated with low levels exposure to natural background radiation is uncertain, the studies to date generally support the risk estimates tabulated in Table 33.1.11.

In reference to occupationally exposed populations, a significant excess of leukemia has been found in only one of 17 recent studies of radiation workers, without a significantly positive dose–response relationship in nine studies assessing radiation dose. These findings suggest that the average risk of leukemia in today's radiation workers is no larger than predicted from extrapolation models discussed above. Notably, risk for multiple myeloma has been observed to be elevated in several occupationally exposed cohorts, including workers at the Hanford nuclear facility (Washington State); the disease has not increased in frequency in the majority of cohorts investigated.

Increased cancer rates have been reported in some cohorts of radiation workers. The mortality rate from lung cancer, for example, was reported to increase with cumulative occupational exposure in workers at Oak Ridge National Laboratory. However, the increase was not significant in non-monthly workers, nor were there any deaths from lung cancer in male monthly workers whose accumulated doses exceeded 40 mSv. In the group as a whole, moreover, the lung cancer mortality rate was less than two-thirds of that would have been expected from national rates. Hence, the findings must be interpreted with caution. Excesses of other forms of cancer also have been reported occasionally in various occupationally exposed cohorts; however, because of methodologic problems and other sources of uncertainty that arise in studies involving low-level exposures, the findings are of equivocal public health significance.

In the vicinity of Sellafield, Dounreay, and other nuclear installations in the United Kingdom, the occurrence of clusters of childhood leukemia has suggested the possibility of radiation release; however, the releases are estimated to have increased total radiation dose by less than 2% above background. In contrast, large-scale studies of cancer in populations having very high natural radiation backgrounds (i.e., several times usual background) have not revealed significant increases in cancers. Also noteworthy is the fact that mortality rates for childhood leukemia in United States counties containing nuclear installations have revealed no significant excess.

The aftermath of Chernobyl

Although there have been significant health consequences of the Chernobyl reactor accident in 1986, uncertainties regarding chronic cancer risk remain, due to problems in

- | |

Uncertainties in parameter estimates in the underground miner data b. Uncertainties in application of the lung cancer exposure–response model and in its application to residential exposure to the general US population. 2. Uncertainty arising from difference in radon progeny dosimetry in mines and in homes. 3. Uncertainty arising from estimating the exposure distributions for the US population exposure distribution model. 4. Uncertainty in the demographic data used to calculate lifetime risk. |
|---|

Table 33.1.12 General sources of uncertainty in estimates of lifetime risk of lung cancer mortality resulting from exposure to radon in homes

Figure 33.1.3: Thyroid cancer incidence among populations exposed to the Chernobyl accident. The data are for thyroid cancer diagnosed in children under 15 years old at the time of diagnosis. Adapted from UNSCEAR.¹⁴

assessing individual doses, cancer reporting methods, baseline disease rates, and short latency since the accident. In spite of these limitations, it is apparent that an increase in thyroid cancer exists in children exposed to radioactive iodine (principally ^{131}I) released during the accident¹⁷ (Fig. 33.1.3). The observations of thyroid cancer are consistent with the fact that the thyroid in children is known to be one of the most radiosensitive tissues in the body.²¹

While leukemia is usually considered to be a sentinel disease in irradiated populations, and can occur with a latency period of less than 2–3 years, no increased risk of leukemia related to radiation exposure has been validated among residents living near Chernobyl or among clean-up workers. Some reports attempted to attribute findings of leukemia in these groups to radiation exposures from the accident; however, these were flawed by use of national health registries using different reporting methods. A finding of no increased leukemia risk was reported in a 1997 case-control design.²³

Solid tumors other than thyroid cancers have not yet been reported in populations exposed from the Chernobyl accident; however, the longer latencies required for solid tumors has not allowed an accurate assessment of risk to date.

Effects on the growth and development of the embryo

During critical stages of organogenesis, exposure to as little as 0.25 Sv has been observed to cause malformations in many animal models. In humans, a dose-dependent increase in the prevalence of mental retardation and decreases in intelligence quotient scores and scholastic performance were observed among atomic bomb survivors of Hiroshima and Nagasaki who were between the eighth and fifteenth weeks of prenatal development at the time of exposure.

Heritable abnormalities

Heritable effects of radiation have yet to be demonstrated conclusively in human germ cells, despite a search for such

effects among the children of the atomic bomb survivors. On the basis of the data from mouse models, the dose required to double the frequency of heritable mutations in germ cells is estimated to exceed 1 Sv. It is inferred that less than 1% of all genetically determined diseases is attributable to natural background irradiation.

33.2 Non-Ionizing Radiation

Christopher J Martin, Alan M Ducatman

INTRODUCTION

Non-ionizing radiation is a general term for the various frequencies of the electromagnetic spectrum that lack the energy to ionize the molecules in living cells. The continuum of non-ionizing radiation is conventionally subdivided into bands expressed as frequency for radiofrequency radiation and wavelength for optical radiations (ultraviolet, visible, infrared and lasers, Figure 33.2.1). Table 33.2.1 gives the frequency ranges and acronyms associated with radiofrequency bands. Part of the ultraviolet (UV) spectrum overlaps into the domain of ionizing radiation, but will be discussed here for comprehensiveness. Radiant heat is technically part of the non-ionizing spectrum, but is dealt with separately in Chapter 34.

Non-ionizing radiation is not a new concept – the adverse effects of infrared (IR) radiation on the eye were first recognized in 1786. However, concerns about the potential hazards of lower frequencies of non-ionizing radiation have led to intense study in recent years. The ubiquitous nature of these exposures means that research efforts, differences in interpretation of epidemiological data, policy initiatives, and societal concerns regarding non-ionizing radiation are assured for the next decade. Society also faces a major disease epidemic and vast economic cost related to UV radiation effects.

In addition to a review of the known and suspected health effects associated with each band of non-ionizing radiation, three specific sources will be discussed: cellular telephones, video display terminals (VDTs), and lasers. Table 33.2.2 summarizes the known or suspected health effects associated with each form of non-ionizing radiation discussed in this section.

SUB-EXTREMELY LOW FREQUENCY (SELF) AND EXTREMELY LOW FREQUENCY (ELF) Exposures

The generation, transport, and use of electricity are associated invariably with ELF and SELF fields. However, it is technically confusing to refer to long-wavelength SELF and ELF fields as radiation. When the wavelength is very long, exposed subjects will be enveloped within one wavelength of the source. The physical characteristics of such confined fields dictate that the relative energy effects will be trivial compared with radiation of shorter wavelengths. For alternating current (AC) what the exposed subject experiences is an induction field, in which charges from the nearby electromagnetic source induce currents and charges on and within the exposed body. In contrast, direct current (DC) induces little secondary current in the body and only if the body moves within the field. Remembering this technical

difference will help the reader understand the confusion between the very low imparted energies and the real, possibly important, physiologic responses of cells to induction fields.

Electric and magnetic field components are necessarily generated together – so-called electromagnetic fields (EMF). The strength of the magnetic field increases with the flow of electric current, while both fields decrease rapidly with distance from the source. However, while electric fields are easily shielded or distorted by intervening objects, magnetic fields are not. Because of this phenomenon, accurate measurement of exposure to electric fields is, for practical purposes, almost impossible. Accordingly, the magnetic field has been implicated in relation to health outcomes. The logic of this is clear, yet there is no reason to rule out the electric field as causing health effects.

Magnetic fields are measured in units of milliGauss (mG) in the United States or microTesla (μ T) in most other countries, with 1 μ T equal to 10 mG. There are both natural and anthropogenic sources of EMF. The earth's magnetic field ranges from a low of about 250 mG (25 μ T) at the equator to a high of 650 mG (65 μ T) at either pole. Since the earth's EMF consists of DC only, far less secondary current is induced in comparison with anthropogenic (AC) sources.

A prominent source of exposure in and outside of the workplace is the power line. Types of power lines include powerful transmission lines (69 to 765 kV), distribution primaries (5 to 35 kV), and distribution secondaries (110 to 220 V). Residential magnetic field exposures from household electrical wiring typically vary between 0.6 and 2.5 mG (0.06 to 0.25 μ T).¹ Magnetic fields are also generated by the use of any electrically powered device, including home appliances (Table 33.2.3). When in close proximity, these sources may provide greater exposures than that of the largest nearby power lines.

Health effects

Health physicists have been complacent historically in regard to low frequencies of non-ionizing radiation. This type of energy is orders of magnitude less than natural background ionizing radiation, and naturally occurring electromagnetic fields (such as the earth's static magnetic field) are several orders of magnitude more intense than those induced by power lines.

However, in 1979, considerable concern arose following the publication of a now famous case-control study of childhood cancer by Wertheimer and Leeper.² These investigators reported statistically significant excesses of leukemia, brain cancer and total cancer associated with residential EMF exposure. A surrogate measure of exposure ('wire codes', a summary index of wire type, configuration and distance from the residence) was substituted for field exposure measurements. Many subsequent studies using this or more refined exposure metrics have now revisited the question of electromagnetic field exposures and childhood

cancer. None has duplicated the original strongly positive results of the original study. A nested case-control study combining data from five occupational cohorts in three countries estimated a relative risk of 1.12 (95% confidence interval 0.98–1.28) for brain cancer, and 1.09 (95% confidence interval 0.98–1.21) for leukemia for each year of exposure of 100 mG (10 μT).³

Studies of workers with high field exposures have not been fully consistent, but do generate viable additional hypotheses for liver, breast, kidney, pituitary gland, and melanoma as cancer outcomes potentially associated with EMF exposures.

The International Agency for Research on Cancer (IARC) reviewed the data on the carcinogenicity of ELF radiation.⁴ This review noted that the most consistent finding from pooled analyses was an approximately two-fold increase in childhood leukemia from residential power line exposure where magnetic field strengths exceeded 4 mG (0.4 μT). While this finding was felt not to be due to chance, it may have been affected by selection bias. No consistent evidence was found between ELF radiation and other childhood tumors or adult cancers at any site. Overall, ELF radiation was classified by IARC as ‘possibly carcinogenic to humans’ (Group 2B), based on the childhood leukemia association.

EMF exposure has also been associated with increased risk for a variety of non-cancer outcomes including neurodegenerative and psychiatric diseases. Studies have reported an elevation for amyotrophic lateral sclerosis most consistently,⁵ although Alzheimer’s disease, Parkinson’s disease, and depression have also been implicated.⁶ Elevations in cardio-

Name	Frequency or wavelength	Potential sources	Known or (suspected) health concerns
Extremely low	30–300 Hz	Power lines Video display terminals Mobile phones Electric appliances Natural sources	(leukemia, brain, breast cancer) (neurodegenerative disease) (cardiovascular disease) (depression) (adverse reproductive outcomes)
Radiofrequency/Microwave	3 kHz–300 GHz	Telecommunication equipment Cellular phones Radar RF heaters/sealers Medical equipment Radio Television	Thermal damage Cataracts (hypertension) (hypogonadism) (non-thermal effects – headache, malaise) (testicular cancer)
Infrared	760 nm–1 mm	Hot objects (molten glass, metals)	Eye damage – cataracts, choroidal damage and retinal burns Burns
Visible	400–760 nm	Sun and artificial light	Eye strain Injuries
Ultraviolet	100–400 nm	Sun Welding Lasers UV lamps (tanning, laboratory, germicidal)	Seasonal affective disorder Skin Acute: Sun burn Phototoxicity Photosensitivity Chronic: Cancer Solar elastosis Solar lentigines Telangiectasia

vascular mortality⁶ and adverse reproductive outcomes (birth defects⁸ and miscarriages⁹) have also been observed.

In summary, a number of studies using increasingly sophisticated exposure metrics have now accumulated, indicating either no association or the possibility of a

modest association between EMF and brain cancer or leukemia. More recent endpoints of other cancer types, non-neoplastic disease, and adverse reproductive outcomes are less well studied. The inability to assign exposure status accurately has been a pervasive problem in the epidemiology of EMF. A further constraint is the rarity of most of the outcomes under study, which has limited the ability of even large studies to achieve sufficient sample size. Some have argued that little is to be gained through further studies on brain cancer and leukemia; what is now required is a breakthrough on the biologic understanding of the effects of EMF which can inform future epidemiological investigations.¹⁰ In view of the expanding list of potential outcomes, the relevance of any new line of research to policy making or public concern should be borne in mind.¹¹

Recommendations and prevention

As noted, the strength of EMF falls off sharply with distance from source, and electrical (but not magnetic) fields are

easily shielded. Although electrical devices must usually be turned on to generate magnetic fields, electrical fields are maintained unless units are also unplugged.

A general strategy of 'prudent avoidance' has been advocated as a measure to deal with the possible hazard of ELF radiation. This refers to simple, minimally disruptive, low-cost measures to reduce exposures even in the absence of clear evidence of risk. Examples of prudent avoidance include routing high-powered lines away from schools, unplugging electric blankets before going to bed, and standing away from electrical appliances during operation. Several countries have adopted prudent avoidance as a regulatory policy for EMF.

However, given the complex, ubiquitous nature of EMF exposures, the utility of such policies is unknown and perhaps unknowable. More detailed guidance on limiting exposures has been provided by the International Commission on Non-Ionizing Radiation Protection (ICNIRP).¹²

VIDEO DISPLAY TERMINALS (VDTs)

VDTs are potentially associated with relatively high electromagnetic field exposure levels, therefore many of the hazards discussed previously apply to this source. A specific concern regarding a possible reproductive hazard from VDT exposure arose when clusters of adverse reproductive outcomes were reported in frequent users in the 1970s and 1980s. However, several extensive studies subsequently failed to find an association, leading NIOSH to conclude in 1998 that VDTs do not represent a reproductive risk.¹³

An additional concern, most prominent in Nordic countries, is skin rashes (so called 'screen dermatitis') and other symptoms ('sensitivity to electricity') in VDT users. Double blind studies, in which such individuals are unaware of when the electromagnetic field has been turned on or off, have failed to consistently reproduce such symptoms.¹⁴

Visual fatigue is common among computer users, especially when poor screen resolution and room lighting decrease the legibility of the electronically displayed information. There is little doubt of the existence of focusing or accommodation fatigue following prolonged computer use.

The ergonomic aspects of VDT work are important, but they are unrelated to electromagnetic fields and are discussed elsewhere (Chapter 15).

RADIOFREQUENCY (RF) RADIATION, INCLUDING MICROWAVES

Exposure measurements

These bands are generally defined to include the frequencies from about 3 kilohertz to 300 gigahertz, corresponding to wavelengths of 1 mm to 3 km in air. The intensity of RF fields includes both an electric and magnetic component. At distances of several wavelengths from the source (the

so-called 'far field'), the two are related and intensity is described by the power density in units of milliwatts per square centimeter (mW/cm^2). Near field measurements must include separate electric and magnetic field measurements in units of volts per meter (V/m) and amperes per meter (A/m) respectively.

The amount of energy absorbed from RF radiation also varies with the frequency of the source and the dimensions of the exposed body. Because of this, an additional quantity, the specific absorption rate (SAR) in units of watts per kilogram (W/kg) has been used more recently.

A variety of telecommunications devices operate within these frequencies (Fig. 33.2.1 and Table 33.2.1). Much of the concern about RF radiation has focused on microwave exposures produced by radar, telecommunication devices, diathermy machines and microwave ovens. One extensively studied source of RF radiation is cellular phones, which is dealt with in a separate section.

Health effects

A major difference between RF and ELF exposures is that RF exposures, especially RF exposures in the microwave band, may have thermal effects. Unlike other forms of heat stress, the degree, rate, and distribution of heating are less predictable. It is well recognized that heating of deep tissue by RF radiation can occur without skin heating, thereby creating a risk of serious thermal damage without the normal warning signs.

Case reports of overexposure to microwave radiation are limited and usually involve military radar sources. Outcomes have included erythema and a heating sensation acutely followed by hypertension and psychiatric symptoms lasting several months, the latter attributed by some authors to post-traumatic stress disorder.¹⁵ Hypogonadism in a man has also been described.¹⁶ Although the belief and warning literature remain widespread, current microwave ovens no longer pose a risk of interference with cardiac pacemakers.

Microwave-induced cataracts have been produced in experimental animals and reported, rarely, in humans. The experimental cataractogenesis is of two types. Rapid and complete lens opacification occurs after overwhelming exposures, while low-intensity microwaves may cause small, apparently reversible lenticular opacities after a latent period of several weeks. The posterior subcapsular cortex of the lens is most commonly involved when the transmitting source is not applied directly to the eye. While human studies are extremely limited, the present consensus is that very high intensity (greater than $1.5 \text{ kW}/\text{m}^2$) exposures are required to produce detectable eye damage.

A case series of six men exposed to high levels of RF radiation in the very high frequency (VHF) range of 100 MHz through work on transmission mast antennas describes a variety of non-specific, multisystemic symptoms (headache, diarrhea, malaise) without objective abnormalities.¹⁷

Additional non-thermal effects of RF radiation have been demonstrated in animal studies and include behav-

ioral alterations, changes in immune cells, and adverse reproductive outcomes.

In response to specific concerns about a link between testicular cancer and traffic radar devices used by police, the US National Institute for Occupational Safety and Health (NIOSH) published a review of this literature in 1995.¹⁸ This report indicated that present day exposures appeared to be low in this setting, and that no assessment could be made regarding the chronic, non-thermal effects from this source in view of the extremely limited number of scientific studies since the mid-1980s. A recent cohort study of 40,581 Korean War veterans with potentially high exposure to radar found no evidence of increases for brain cancer, testicular cancer, or overall mortality.¹⁹

Prevention and recommendations

Shielding, warning signs and personal protective devices should be used for any source of high-intensity RF exposure that can cause acute thermal effects. Electrical injury associated with powerful RF sources should be considered in all engineering designs. Specific recommendations for the safe use of traffic radar devices have been provided by NIOSH.

Exposure limits have varied widely, due to disagreement on the need to protect against non-thermal effects. An OSHA standard of 10 mW/cm² is designed to protect against thermal effects only, while the American Conference of Governmental Industrial Hygienists (ACGIH) recommendation based on a whole body SAR < 0.4 W/kg is more stringent.

CELLULAR TELEPHONES

Use of cellular telephones has increased dramatically in the US and worldwide in the last decade. At the beginning of 2001, there were an estimated 108 million phone subscribers in the US alone, with about 46,000 new subscriptions per day. Cell phone use is higher in other parts of the world, such as Scandinavia. The cell phone used at the beginning and through the last decade was analogue. Voice messages are transmitted by varying either the amplitude or frequency of the radiowave. A progressive shift to digital cell phones is underway today. Digital messages are transmitted as rapidly pulsed digits. Thus, the technology studied to date is not identical to the technology that will be used by increasing numbers of people in the future.

Exposure

Cellular telephones and cell phone base stations transmit and receive RF signals in the microwave range, between 800 and 2000 MHz, with specific emphasis on 824–894 MHz for the phone unit. As noted in the section on RF and microwaves, this wavelength is capable of causing cellular heating by inducing electrical currents and by increasing molecular movement. Cell phone power outputs are typically so small (around 0.25 W) that the small changes in tissue heat that they might induce are much less than

occurs with normal bodily functions. In contrast to the subtle hypotheses concerning induced heating fields or currents and possible chronic CNS outcomes, acute hazards of cell phones are easy to visualize. Operators of moving vehicles are deprived of the use of one hand while keying or holding a cell phone and may experience 'exposure distraction', especially while keying and talking.

Health hazards

Three well-performed studies have now evaluated the relationship between cell phone use and cancer, with an emphasis on brain cancer, salivary gland cancer, and leukemia. One of these studies, using a nationwide retrospective cohort based on subscriber data linked to a national cancer registry, is quite large.²⁰ These investigations do not support the hypothesis of an association between cell phone use and cancer outcomes. These findings are reassuring, and indicate that the average user of the analog technology will not experience significantly increased cancer risk during a relatively short latency period. Longer term studies are in progress; these should address issues of peak exposures, longer latencies and, over time, new technologies. Anecdotal reports of headaches are common in cell phone users. No adequate epidemiologic data address this question.

In contrast to the initial reassuring news about cell phones and cancer, cell phone use during motor vehicle operation should be assumed to create hazards for drivers, passengers, and those nearby. Preliminary data show a marked increase in accident rates among cell phone users. 'Hands-free' phones were not protective. Driving left of center and striking fixed objects are among excess outcomes in preliminary data. It is possible that this hazard will also improve with better technology (hands-free phones with voice-activated dialing). Additional well-funded studies of chronic health hazards are underway, but the data concerning the outcome of merely talking are not encouraging, and have already come under regulatory scrutiny in areas.

Cell phones do interfere with cardiopulmonary monitoring devices and other equipment in the hospital setting. Mayo Clinic researchers deemed the interference important enough to potentially interfere with the interpretation of data or cause the equipment to malfunction in 7.4% of 526 tests.²¹ Digital and analogue phones produced different kinds of interference. Most alarming was interference with mechanical operations of a ventilator. They conclude that malfunctions and interference are less likely if the phone is kept at least 60 inches from sensitive equipment. Banning the use of cell phones in patients' rooms or procedure areas is suggested to be an adequate precaution.²⁰

Prevention and recommendations

While waiting for the definitive follow-up of already reassuring data about cell phones and cancer, those concerned with exposure can minimize it by: not using cell phones or minimizing use; obtaining a cell phone with relatively

lower power or that directs RF away from the user. Some manufacturers provide these RF data. Consultants for the World Health Organization have cited the precautionary principle in recommending prudent minimization of cell phone use, and have emphasized minimization of use by children. These recommendations are not based on data, but on gaps in data relating to plausible latency, study follow-up time, and evolving technology.

In contrast, acute hazards from cell phone use next to patient care equipment and in moving vehicles are assumed to be real, a reality supported by disconcerting preliminary data. Cell phone use, including 'dialing' operations and even hands-free communication, should be regulated until studies document that safer technologies address both attention and control. Designed studies of distracted attention with present technology and epidemiologic evaluation of health outcomes (accidents, injuries) will be appropriate, and logically more important than the studies concerning hypothesized chronic hazards.

INFRARED (IR) RADIATION

Exposures

All objects with temperature above absolute zero emit IR radiation. IR-A extends from 760 nm to 1.4 μm and borders on visible light. IR-B extends from 1.4 to 3.0 μm . IR-C has the longest wavelength and is furthest from visible light (3.0 μm to 1 mm). IR-A is also referred to as 'near IR' and IR-C as 'far IR'. IR-A is sometimes perceptible to the eye as a dull, red glow. IR-B and IR-C are invisible. Sources of significant IR include the sun, furnaces, molten glass, welding arcs, IR heaters and dryers. A variety of lasers also emit IR; lasers are discussed in a separate section.

Health effects

Biologic systems exposed to IR experience a corresponding rise in the temperature of the absorbing tissue. IR is absorbed by tissue water and, therefore, is non-penetrating; energy transfer is directly to the outer surfaces. Normal skin has good warning properties (pain) for thermal injury caused by IR (see Chapter 34). Unfortunately, the eyelid and eye do not have adequate thermal warning properties.

Critical to an understanding of the effects of IR radiation is an appreciation that with decreasing wavelength, the bands become more energetic but also less penetrating. Therefore, the physiologic effects of IR-C are confined to heating of superficial tissues. However, excessive ocular exposure to IR-A may lead to damage to the lens (cataracts), choroid and retina. IR-B can damage the cornea, conjunctiva and aqueous humor. The focusing ability of the eye may concentrate IR-A energy onto a localized point on the retinal pigment epithelium, leading to burns. Retinal burns may vary in severity from discrete peripheral lesions, which do not affect the visual field, to local or even global hemorrhage, leading to blindness.

Historically, chronic IR-A exposure was associated with posterior cortex cataract formation, as in glass and furnace

workers or others who handle molten materials at temperatures greater than 1500 degrees C. When prevalent, this condition appeared to require intense, unprotected exposure for several years. With mechanization of glass manufacture and use of protective goggles, this condition has become rare.

Recommendations and prevention

Permissible exposures to IR-C relate to heating and vary with ambient temperature. There are no legal exposure limits for IR-A or IR-B (except in the case of laser use). The ACGIH provides a recommended threshold limit value intended to be protective for near-infrared effects on the eye, which varies depending upon the spectral characteristics and position of the worker.

Protective eyewear for workers with significant IR exposures should include appropriate infrared filters.

VISIBLE LIGHT

Exposure

The human eye detects light in the narrow band between 760 nm (red end) and 400 nm (violet end), with peak sensitivity at 555 nm. Light perception is partly a photochemical process. Light is measured in units of footcandles or SI units of lux, with 1 lux = 0.093 footcandles. Consideration should also be given to the quality of visible light, including the amount of glare, contrast, brightness and color.

Health effects

Inadequate amounts or poor quality of lighting have obvious effects of reduced worker performance and increased injury rates. Lighting has also been found to contribute to complaints which may initially be ascribed to air quality in the indoor environment. Although animal studies have shown that chronic exposure to excessively bright light may lead to premature degeneration of the cones responsible for color vision, there is no evidence that normal amounts of visible light exhaust human photochemical processes or produce chronic eye damage. Excessive luminance in the visual field (glare) may overcome the adaptive abilities of the pupil and retina. Glare reduces visual perception and causes visual fatigue. Severe glare can cause reversible iritis and blepharospasm.

Many individuals use bright artificial light therapeutically for the prevention of depression in seasonal affective disorder (SAD). Possible mechanisms include effects of light upon melatonin, serotonin, and cortisol regulation. Numerous clinically designed but obviously non-blinded studies have addressed this belief. Most show a positive outcome for light intensities up to 10,000 lux (workplace light is typically 200–400 lux), without adverse effects.²²

An interesting controversy relating indoor lighting to human health is the question of full-spectrum light, which, by including wavelengths in the ultraviolet (UV) range, more closely replicates the spectrum of natural

daylight. Advocates of full-spectrum light believe that the absence of the full-spectrum emissions from traditional indoor fluorescent lighting represents a source of physical and psychologic harm. They point out that full-spectrum light is natural and used in the treatment of seasonal affective disorder. Their suggestion is that UV frequencies should also be emitted from fluorescent lighting, but the preventive value of this recommendation is uncertain.

A role for excessive exposure to light at night, possibly acting in conjunction with electromagnetic fields, in the development of breast cancer has also been proposed (see section on SELF and ELF).

Recommendations and prevention

The most important consideration for this spectrum is to ensure that an appropriate amount and suitable quality of lighting is present in the workplace. For activities such as reading and writing, a work surface should have a minimum of 215 lux (20 footcandles) of appropriate quality light. The investigation of buildings with concerns about air quality should also include an assessment of indoor lighting. A useful summary with references on lighting is provided by the Environmental Protection Agency.²³

In the absence of data, occupational physicians should not make full-spectrum light a workplace recommendation.

ULTRAVIOLET (UV) RADIATION

Exposures

Ultraviolet (UV) radiation extends in a narrow band between 400 to 100 nm. The UV band is subdivided into UV-A (400–315 nm), UV-B (315–280 nm), and UV-C (280–100 nm). As with all forms of radiant energy, with decreasing wavelength, the bands become more energetic but less penetrating. Therefore, UV-A is the least energetic but penetrates deepest into skin. UV-C is the most energetic and potentially damaging but is unable to penetrate the superficial layers of non-viable epidermis. UV-B is intermediate between the two.

The most important source of UV radiation is the sun. Although UV-C is the most energetic band and capable of greatest tissue damage, it lacks the ability to penetrate the earth's stratosphere. Therefore, the UV bands of environmental concern are UV-A and UV-B. All three bands may be produced by artificial sources of UV radiation, which are listed in Table 33.2.4.

Health effects

The harmful effects of UV light are caused largely by UV-B, although UV-A is a more common exposure and has been more recently recognized to have important health effects. UV-C is so readily absorbed by air and superficial skin cells that, in the rare event of exposure, it is unlikely to cause even residual erythema. Because of generally poor penetration properties, UV radiation effects are confined to the

Ultraviolet lamps
germicidal (air, water sterilization)
tanning beds
curing of resins (dental bonds, circuit boards), coatings, and inks
medical (PUVA)
photochemical processes (agricultural chemical, pharmaceutical production)
graphic arts
laboratory (spectrophotometers)

welding
furnaces
UV lasers

Table 33.2.4 Artificial sources of UV radiation

skin and eyes and, depending on the degree of exposure, may be either acute or chronic in nature.

The main cause of both sunburn (solar erythema) and melanogenesis is UV-B. Sunburn usually appears 1–6 hours following exposure and fades after 3 days. Severe sunburn may cause blistering and destruction of the skin surface, with a risk of secondary infection. Human skin is partially protected from this hazard by melanin pigment production and thickening of the stratum corneum through keratinization in response to sunlight. Dark-skinned people are better protected than are light-skinned people. Although there is some immediate darkening of the skin in normally tanned individuals, the tanning process consists primarily of melanogenesis, which begins shortly after exposure and becomes visible within about 3 days.

UV-A is a less potent cause of sunburn. However, solar UV-A penetrates to the earth's surface to a greater extent than UV-B and effects from the two are additive. UV-A is also the cause of phototoxic and photosensitivity reactions (discussed in Chapter 29.2) and contributes to skin cancer and photoaging.

Sun exposure causes a constellation of chronic morphologic changes in the skin (see also Chapter 29.2). These consist of increased keratinization (solar keratosis), changes in underlying connective tissue (solar elastosis), vascular changes (telangiectasia), and pigment alterations (solar lentigines). Outdoor activities, ranging from agricultural work to outdoor construction, are associated with these changes. Similar to acute sun damage, dark-skinned individuals are relatively protected from these chronic outcomes.

The most important UV outcome is skin cancer (see also Chapter 30.10). Recent increases in all three major types of skin cancer have been linked to UV radiation exposure, most clearly to UV-B but with limited evidence implicating UV-A as well. Basal cell carcinoma is more strongly associated with peak exposure episodes (sunburn) while squamous cell carcinoma is very strongly associated with cumulative exposure. The relationship of melanoma to sun exposure is complex and involves a combination of both acute and cumulative exposure, with the strongest single exposure factor being a history of sunburn. Recent epidemiological data indicate that melanoma mortality is now declining in some parts of the world, concordant with preventive efforts in these regions.²⁴ A completely

preventable cause of adverse effects stems from the use of UV tanning devices for cosmetic purposes. Corneal and retinal injuries, first- and second-degree skin burns and increased risk of melanoma have all been reported from this source.

The acute effects on the eye from UV radiation include photokeratoconjunctivitis (see also Chapter 20.1). Since human eyesight perceives UV poorly, acute damage may occur before the individual is aware of exposure. Keratitis and conjunctivitis are dramatic, but they are usually self-limited and heal within several days. Potential sources of this exposure include electric arc welding ('welder's flash'), germicidal UV lamps, and intense environmental sun exposure in colder climates ('snow blindness') or on water. Chronic ocular outcomes of UV exposure are a major concern. Exposures in the middle of the UV-B spectrum induce cataract formation most effectively, with a clear dose-response relationship.²⁵ Cortical cataracts are most prevalent in geographic areas where solar radiation is high and in outdoor workers.²⁶ In contrast, the incidence of nuclear cataracts appears to be unaffected by UV exposure.

Pinguecula and pterygium are localized areas of benign conjunctival thickening associated with prolonged UV exposure. Pingueculae are found adjacent to the limbus, more frequently on the nasal side. When the lesion crosses onto the cornea it is called a pterygium. Although both may be a cosmetic concern, symptoms only arise when a pterygium obstructs vision or causes astigmatism. Spheroidal degeneration (also known as climatic droplet keratopathy) is a form of corneal degeneration characterized by the presence of fine yellowish drops underneath the conjunctival or corneal epithelium which is usually asymptomatic. In addition to geographic associations with areas of increased UV exposure, spheroidal degeneration, pingueculae and pterygia have all been reported at higher frequency among outdoor workers²⁷ and in welders.²⁸

Concern has also arisen about a possible relationship between long-term exposure to ultraviolet radiation and heightened risk of age-related macular degeneration, but limited studies to date have presented conflicting results.

Prevention and recommendations

Efforts should be made to reduce both UV-A and UV-B exposure. Recreational exposures that may lead to repetitive cycles of sun burning should be particularly avoided. Light-skinned, blue-eyed, freckled individuals are at greatest risk. Increased appreciation for outdoor recreation, increased residence time in sunbelt areas, and loss of ozone in the earth's atmosphere are likely to accentuate the risk and need for preventive interventions.

Exposure to natural UV radiation can be reduced by avoiding the midday sun (10am to 2pm). The National Weather Service and the Environmental Protection Agency have developed a daily UV Index for many US cities which estimates the risk of overexposure ranging from 0 (minimal) to 10+ (very high). Residents are advised to take special care when the index is 5 or higher.

Skin exposure can be reduced by wearing a wide-brimmed hat and long-sleeve clothing. Sunscreens represent the least desirable level of protection. In addition to compliance concerns, the protective effect of sunscreens for longer wavelengths of UV-A and chronic photodamage is unclear.²⁹

Ocular exposure can be reduced through protective eyewear which blocks both UV-A and B. Although many companies now offer 'UV absorbing' contact lenses, there are limited studies that indicate reduced efficacy relative to comparable approved sunglasses – the latter should still be worn.³⁰ Arc welders' photokeratoconjunctivitis can be prevented with appropriate face shields.

LASERS Exposures

A laser (Light Amplification by Stimulated Emission of Radiation) is a device emitting intense monochromatic radiation, continuously or in pulses. The wavelength of lasers overlaps that of the IR, visible and UV spectra. The hazard arises from the high intensity of the laser beam. IR lasers include the neodymium:yttrium, aluminum garnet and carbon dioxide lasers. Visible light lasers include dye, helium-neon, and krypton lasers. UV lasers include excimer lasers. These excited dimers of argon-fluoride or xenon-chloride are used for tissue excision purposes. Laser classification according to the recently revised American National Standards Institute (ANSI) and associated hazards are described in Table 33.2.5.³¹

Health effects

The most consistent hazard of lasers is related to non-beam effects such as electrocution or ignition of surrounding flammable materials by these powerful devices. There is also a significant acute hazard to the eye, skin, and deeper tissues from exposure to the beam depending on the wavelength, intensity, and duration of exposure of the laser.

Class of laser	Potential danger
I	Essentially harmless
II	Essentially harmless (do not stare at the laser)
*IIIa and IIIb	Hazardous Direct viewing is very dangerous Specular reflections are also dangerous Skin exposure is harmful
*IV	Extremely hazardous Direct viewing must not occur Specular reflections extremely dangerous Diffuse reflections extremely dangerous Skin exposure extremely hazardous Fire hazard
Note: When class III and IV lasers are fully embedded into an enclosed system that has full safety interlocks, the system may be classified as a class I system. * Protection is required.	

Table 33.2.5 ANSI laser classification

Laser injury is determined primarily by beam power (Table 33.2.5). The eye is the organ most vulnerable to acute damage, partly because the cornea and lens focus visible and near IR laser energy to small areas on the retina. At the point of focus, radiant exposure can be increased by more than five orders of magnitude. Both direct and reflected beams may cause eye damage. Pupil size, focusing ability, and myopia or aphakia may also influence the amount of retinal damage. Direct laser injury may cause partial or complete loss of small or large visual fields, depending on the extent and position of damage in the retina.

A great deal of concern has arisen recently over the increasingly widespread use of laser pointers, which may be deliberately directed to the eyes in an effort to distract or 'dazzle' the victim. Although permanent retinal damage has rarely been reported from laser pointers (most of which are class II or IIIa), this requires uninterrupted eye contact in excess of 10 seconds, making inadvertent injuries unlikely.³²

Until recently, the indirect hazards of medical laser use have been less recognized. Laser surgery or any other tissue use of class IV lasers will inevitably generate smoke. In addition to being malodorous, there is evidence that this plume contains viable infectious agents (both viruses³³ and bacteria³⁴) toxic gases (benzene, hydrogen cyanide, and formaldehyde),³⁵ and is mutagenic.³⁶ Medical use of UV lasers has also been calculated to increase UV exposure by the equivalent of 1 day of sunbathing.³⁷

Prevention and recommendations

Detailed information on the safe operation of lasers can be found in ANSI Z136.1, 2000 Guidelines for the Safe Use of Lasers. Several important points of relevance to the occupational health provider are discussed below.

Ideally, lasers should be enclosed during use. Unfortunately, this is often impossible in research uses. Laser-using facilities must also be carefully designed to prevent reflections. They should be well lit so that the pupils are not dilated.

The eyes and skin are best kept out of the beam by interlock devices, which turn off the laser electronically or provide physical barriers between the operators or bystanders and the beam during operations. Not all research or medical laser activities are amenable to interlock protection. Laser surgery is a prime example. In such circumstances, personal protective devices are then used. Eye shielding must be selected in accordance with the wavelength of the laser used and should include side shielding. Absorptive filters are generally preferred over reflective types because absorptive filters are reliable regardless of the incident angle of the beam. A problem with optical density markings on laser-protective eye wear has been uncertainty with the reliability of the manufacturers' markings concerning transmittance. Independent checks are not truly achievable with available equipment so it is important to identify reliable suppliers.

Another problem with eye protection is that complete protection from visible beams blinds the user, interfering

with safety and efforts at beam alignment. In our experience, this tempts scientists to remove their eye protection to align the beam. For this reason, we recommend eye shields that are largely, but not absolutely, protective for open visible beam alignment operations. Under these circumstances, scientists will be afforded the eye protection necessary while their ability to view hazards and align the beam is adequately maintained. Laser users ought to assume that any ruby or neodymium laser capable of causing material surface ablations is also above the safe limits for viewing diffuse reflections. Laser retinal injuries continue to occur, despite the well-known safety precautions.

Specialty applications may present particular hazards. The optical hazards of beam splitters and the wavelength consequences of doubling crystals are understood by users but are not translated into safety practice. Installation and repair of fiber-optic communication systems is potentially hazardous; visualization of tightly packed energized cables or optically aided visualization of individual fibers may cause injury. Laser-equipped weapons present potentially uncontrolled hazards, which may be encountered in warfare, training simulations, or war games. Laser welding applications are often open-beam configurations with class IV lasers. There is usually significant diffuse reflection within 2 m of the target, whose direction becomes difficult to predict because of the use of process-shielding gases. Barriers, eye wear, and gloves are mandated for open laser welding.

Skin protection is also important for the operation of non-interlocked class IV lasers. The American Medical Association Council on Scientific Affairs makes specific recommendations for skin protection against carbon dioxide laser burns in surgical fields, using wet towels and sponges.³⁸ Carbon dioxide–nitrogen lasers emit invisible UV energy, so burns may potentially be severe before the hazard is appreciated. Barrier protection is required. Recommendations to control smoke from medical lasers have been described by NIOSH.³⁵

Occupational physicians are asked frequently about medical surveillance for users of class IIIb and IV lasers. There are clear, acute hazards associated with laser use, but the existence of a chronic hazard amenable to medical surveillance is uncertain. Epidemiologic studies addressing chronic effects of laser exposure are not currently available, and new lasers and uses for lasers are introduced continually; so the absence of future chronic hazards should not be assumed. In particular, efforts should be made to reduce UV scattering in laboratories, to protect skin and eyes, and to follow workers who may receive substantial UV exposures.

For established programs experiencing no difficulties, it makes sense to obtain preplacement evaluations, evaluations at the time of suspected laser incidents, and termination evaluations. Evaluations include ocular history, visual acuity, macular function (Amsler grid or similar pattern), contrast sensitivity (Arden sine wave or similar pattern), and fundoscopic evaluation with careful documentation of abnormalities.

Acknowledgment

The authors would like to thank Dr Gilles Thériault of McGill University for his review of a draft of this chapter.

Chapter 34

Thermal Stressors

Oyebode A Taiwo, Mark R Cullen

Thermal stress on workers represents perhaps the oldest recognized occupational hazard. Thermal stresses, and their consequent health effects, are created by exposure to extreme ambient temperatures, high humidity, physical activity, and the use of specialized clothing and gear. Although these problems have been alleviated to a large extent in developed countries by modern climate control, problems related to thermal stress remain widespread among industrial workers everywhere. Indeed, new problems in thermal stress have been created by advancing technologies, even as old ones have disappeared. Although reliable data on the incidence and prevalence of the major sequelae are not available from most parts of the world, compensation files and hospital admissions records document that disorders related to heat and cold exposure continue to be reported.

Thermal stresses are also important outside the workplace, particularly in vulnerable populations, such as infants and elderly and homeless persons. So great is the problem in these groups that it is generally viewed as beyond the scope of environmental medicine and will not be addressed in this text. Similarly, thermal burns, which are extremely important in both occupational and non-occupational settings, have been extensively reviewed in existing surgical texts and are also beyond the scope of this book. Accordingly, this chapter will focus on exposures to heat and cold in the occupational setting, the major clinical problems that these stresses create, and current strategies for their prevention and treatment.

HEAT STRESS

Exposure settings

Occupational heat stress or heat load is the combination of external factors of heat on the worker. This includes environmental conditions (temperature, humidity, heat index), work demands (nature of job, duration), and clothing requirements. The resulting heat strain is the immediate physiologic response of the body to heat stress. This includes an increase in body temperature, heart rate, and sweating.¹

The potential for a work environment to produce heat stress sufficient to interfere with function depends on three largely independent factors:

- the amount of heat generated by the worker over time;
- the external heat load; and
- the capacity for effective heat removal.

The amount of heat generated by the worker is related to the intensity and type of work performed. For example, heavy physical work generates a larger amount of heat than medium, light or sedentary work. The external heat load is a function of the ambient temperature plus the radiant temperature. The latter occurs from sources such as heating elements, fires, or sunlight and provides an additional load. The capacity for heat removal can be determined by environmental evaluation. Low humidity and high air movement against the skin strongly favor heat removal. Clothing covering the skin, especially if it is impermeable to water, will impede heat removal. Protective clothing has become increasingly important in some occupations, such as hazardous waste removal, to block exposures to chemicals, or biotechnology work, to protect work products.^{2,3}

The assessment of potential heat stress requires simultaneous knowledge of six factors:

- ambient temperature;
- radiant temperature;
- relative humidity;
- air velocity;
- physical activity level; and
- clothing cover and permeability.

Air temperature, radiant temperature, humidity, and air velocity can be measured by separate devices or collectively measured with a single device, i.e., the wet bulb globe thermometer. Various indices, including the corrected effective temperature and the wet bulb globe thermometer index, calculate the thermal stress on workers better than temperature alone.⁴ However, given the quantitative importance of the work intensity itself as the major source of heat stress, excess reliance on these environmental measures may be misleading. Therefore it is essential to evaluate all sources of heat gain as well as the potential for heat loss to assess adequately the overall risk for incurring heat-related disorders.⁵

A four-stage strategy for evaluation and prevention of risk due to work in thermal environments has been proposed.⁶ In the first stage, a screening tool is used to detect the majority of the risk factors related to safety, health, and well-being of the employees and workplace. The conclusion would be to determine if there is a need for further investigation. The second stage consists of close observation of the climatic and working conditions over the entire year to identify particular circumstances, specific tasks, and unusual working conditions where problems might exist and to determine solutions to eliminate the problems. The third stage, analysis, usually conducted by occupational hygienists, is carried out where a heat-stress

problem remains after stage 2; therefore it will deal with specific conditions and usually involves measurement. The objective is to find technical solutions and, where exposure is unavoidable, to define organizational solutions and short-term protection measures. At the end of this stage, most of the conditions should be under control. If an unacceptable risk of heat stress remains, further assistance of an expert will be required for studying these unusual circumstances, using specific investigational techniques such as plane radiant thermometry, clothing permeation, or oxygen consumption measures. Not all four stages need be performed; the procedure stops when adequate solutions have been implemented.

Physiology

Body temperature represents a balance between heat production and heat loss. The maintenance of body function requires that the temperature of vital internal organs be at or near 37°C. Body heat is primarily produced by continuous metabolic activity. A resting adult produces about 75 kcal of heat per hour as a byproduct of the basal metabolism. Physical activity adds heat to the body at a greater rate than does a hot environment. Work activities can range from 80 to 700 kcal/hour (Table 34.1). Heat is also gained from the environment, either through radiation from the sun, the heated ground, reflected radiation from the sky or radiant sources such as furnaces.

Heat loss occurs through four mechanisms: conduction, convection, radiation, and evaporation. Conduction is the heat exchange between two surfaces in direct contact. It is generally the least important mechanism of heat loss since behavioral thermoregulation generally intervenes. Convection is the heat transferred from a surface to a gas or fluid, usually air or water molecules circulating in the body. As the air in the immediate contact of the skin is warmed, heated molecules move away and cooler ones replace them and, in turn, are warmed up and the process continues. Radiation is the transfer of heat between the body and its surroundings by electromagnetic waves. The magnitude of heat loss or gain by radiation depends on the temperature difference between the skin and the surrounding environment, and the body surface area. Evaporation

is the conversion of a liquid to the gaseous phase. Evaporation of water takes place from the lungs and skin.

The body will attempt to unload the excess heat gained, to maintain a normal body temperature. The body's primary defense against overheating is sweating. Each liter of sweat that completely evaporates from the skin removes 600 kcal from the body. Although a healthy adult can produce up to 1.5 liters of sweat per hour, the ability of this sweat to carry heat from the body depends on its ability to be evaporated. Thus, sweat loss by dripping, absorption onto clothing, and climactic conditions (such as high humidity and slow air movement) impedes heat loss. Only small amounts of heat are lost by radiation or by direct convective transfer to air.

Heat is distributed throughout the body by convection in the blood stream. Thermal sensors in the brain respond to the increased blood temperature and relay signals to a central integrative area in the hypothalamus, which, in turn, directs thermoregulatory effectors to conserve or unload the excess heat gained. Heat loss responses induce increased rates of blood flow to the skin and sweating. These responses promote an increase in the rate of heat transfer from the body core to the environment. The increased heat transfer from the core to the skin occurs as a result of increased convection in the elevated skin blood flow, and the increased transfer from the skin to the environment is achieved partly by the increased radiation and convection and, primarily, by the evaporation of sweat. When the rate of heat dissipation becomes equal to the rate of heat production, the body temperature becomes stable.

The absolute rise in body temperature in any heat gain condition is a function of the speed of the heat dissipation response. A relatively fast response will result in less heat being stored in the body and, thus, in a smaller rise in deep-body temperature on reaching a steady state. A rise in body core temperature of more than 2°C to 2.5°C will be accompanied by side effects that reduce both performance and the ability to prolong activity. These effects are primarily the result of a progressive redistribution of blood flow and, hence, of blood volume toward the skin. A reduction in central circulating blood volume acts to reduce the filling pressure of the heart. If compensatory reflexes are not activated, the ability of the heart to maintain an adequate blood flow will diminish, resulting in a fall in arterial blood pressure and blood flow to the brain. As blood flow to the brain is reduced, the effect will be a feeling of light-headedness or dizziness, disorientation, and, eventually, a loss of consciousness. The physiologic compensatory responses to a fall in the heart's filling pressure include an increased heart rate and constriction of non-essential vascular beds, including those of the skin. The latter reflex serves to shift blood to the body's core, thereby helping maintain central blood volume and, thus, flow to the brain and contracting muscles. A relatively fast thermoregulatory mechanism, resulting in relatively lower body heat storage, provides a greater margin of safety and time before compensatory responses need to be invoked.⁷

With the occurrence of heat stress and a subsequent loss of body water by sweating, substantial changes may occur

Activity	Rate (kcal/hr)
Bicycling	360–600
Climbing stairs	360–720
Construction tasks	300–600
Domestic work	75–300
Driving	120–180
Heavy labor/factory work	210–400
Light assembly/inspection	90–160
Machine operator/manual trade	120–240
Office work (sitting)	75–120
Resting (sitting or lying)	60–90
Standing (inactive)	90–120
Swimming	300–880
Walking on a flat surface (3–5 km/hr)	300–400

Table 34.1 Rate of heat generation for common occupational activities

in the composition of body fluid. Sodium and potassium are both lost in sweat, at concentrations that rise as sweating is prolonged. The decline in renal blood flow accompanying heat stress stimulates the renin–aldosterone axis to conserve sodium, but this may exacerbate potassium losses. Antidiuretic hormone release is stimulated because of the decrease in central blood volume. The plasma osmolality increases because of excess water loss and inadequate sodium delivery to the distal nephrons accompanying the reduced renal blood flow.

Although these changes are physiologically stressful, adverse health effects will occur only if the heat stress exceeds the individual's heat tolerance capacity. In otherwise healthy individuals, factors predisposing the worker to hyperthermia include salt and/or water depletion, fever, infection, and obesity.⁸ Workers with underlying diseases, even if controlled clinically and not routinely disabling, may be at particularly high risk. Common risk factors include cardiovascular disease, alcoholism, diabetes mellitus, and hyperthyroidism.^{9–11} In addition to these factors, any disorder of sweat production, including miliaria or a prior episode of heat stroke, cystic fibrosis, scleroderma, healed burns, or dermatitis may be a serious problem (Table 34.2).¹² Among the more prevalent risk factors in the workforce is the use of therapeutic or recreational drugs. Agents that have proven or suspected effects are listed in Table 34.3, but any agent that may interfere with

autonomic function, vascular tone, motor activity, or cardiovascular responses should be considered likely to lower the threshold at which thermoregulation fails and the core temperature begins to rise.^{13,14}

After the body's core temperature starts to rise, pathologic responses ensue. Acutely, hyperthermia may contribute to the development of hepatic necrosis and pancreatitis. Fibrinolysis and activation of platelet activity may lead to disseminated intravascular coagulation (DIC). Skeletal and myocardial muscle is disrupted, leading to rhabdomyolysis and myocardial necrosis. Renal function, already compromised by low renal blood flow, may be more severely disrupted by the outpouring of myoglobin and uric acid from this cascade. Ultimately, the central nervous system is affected by the heat, DIC, and metabolic disturbances.^{15,16}

Heat acclimatization

Many of the physiologic alterations induced by heat stress are attenuated by the process of heat acclimatization. To become heat acclimated, an individual must undergo gradually increased exposures to both heat stress and exercise stress. Furthermore, these must occur on a regular basis over a period of about 2 weeks to be maximized. Although some changes may occur from heat stress alone without physical activity, such as during very hot times of the year, only regular and repeated exposures to heat and activity induce acclimatization sufficient to alter heat tolerance substantially.^{17,18} Heat acclimatization is characterized by the following.

1. *Enhanced cardiovascular fitness.* This includes increased maximal oxygen uptake in the muscles, increased plasma volume, increased cardiac stroke volume and contractility, and reduced heart rate for a given cardiac output.¹⁹
2. *Altered sweat.* The sweating onset for a given thermal load occurs sooner, and the maximum sweating rate is increased. Furthermore, the sodium concentration of sweat is markedly decreased, thereby acting to conserve the body's sodium store.^{20,21}
3. *Enhanced renal function.* The glomerular filtration rate may increase up to 20% over baseline, largely as a result of cardiovascular changes.^{19,21}

The net effect of these changes is such that acclimated workers have a markedly enhanced tolerance for heat stress. This fact forms the basis for an administrative control over heat-related disturbances; the gradual introduction of new or non-acclimated workers to jobs with high thermal stress.

Classification of disorders resulting from thermal stress

ACUTE DISORDERS OF SYSTEMIC HEAT STRESS

Heat syncope
Heat edema
Heat tetany

Normal persons	Predisposing diseases
Salt and/or water depletion	Cardiovascular disease
Infection	Diabetes mellitus
Fever	Malnutrition
Lack of acclimatization	Acute or chronic alcoholism
Obesity	Electrolyte disturbances
Drugs (Table 34.3)	Hyperthyroidism
Advanced age	Impaired sweat production
	Miliaria
	Sweat gland injury after prior heat stroke
	Cystic fibrosis
	Scleroderma
	Healed thermal burns

Modified from Knochel JP. Heat stroke and related heat stress disorders. *Dis Mon* 1989; 35:301-77.

Table 34.2 Risks predisposing to exhaustion and heat stroke

Alpha and beta (sympathetic) blocking agents
Anticholinergics
Antidepressants
Antihistamines
Calcium channel blockers
Cocaine
Diuretics
Dopaminergics
Ethanol
Lithium
Neuroleptics
Sympathomimetics

Table 34.3 Drugs that may enhance risk for heat stress-induced disorders

Heat cramps
 Heat exhaustion
 Predominant water depletion
 Predominant salt depletion
 Exertional heat stroke

SUBACUTE EFFECTS OF HEAT STRESS

Infertility
 Teratogenesis

SKIN DISORDERS CAUSED BY HEAT STRESS (see Chapter 29.2)

Erythema ab igne
 Miliaria

MAJOR DISORDERS CAUSED BY HEAT STRESS

Although the major heat-related disorders can be separated from each other on clinical grounds, there is considerable overlap; therefore, they should be considered as a series of syndromes along a single spectrum.

Heat syncope

Clinical pattern

Heat syncope is a relatively benign disorder that occurs primarily in the unacclimated worker as a result of vasodilatation and diminished venous return during the early adaptation to heat stress. It is indistinguishable clinically from syncope caused by postural hypotension of any cause. There may be postural symptoms preceding an actual syncopal event. Workers with low blood volumes related to diuretic use or those receiving pharmacologic agents that impede autonomic function are at highest risk.^{22,23}

Evaluation

Individuals who experience postural dizziness or frank syncope after unaccustomed exertion in the heat are readily diagnosed; sinus tachycardia and mild postural hypotension should be evident, along with sweating. The body temperature is generally normal, unless a febrile illness has predisposed the patient to this event. Cardiac and central nervous system causes of syncope can generally be excluded by the history and physical examination. Vasovagal episodes are distinguished because of their presentation with bradycardia rather than tachycardia.

Treatment

The most important steps in management are placing the patient in a recumbent position to maximize blood flow to the brain and administering salt and water. This rarely requires an intravenous line because the patients are usually stable and able to drink sitting up long enough to replenish lost fluids and electrolytes. Further testing or prolonged observation is generally unnecessary.

Course and prognosis

Patients generally recover quickly and completely after fluid administration. There are no further steps necessary other than recognition that heat stress is excessive, at least for the particular affected person, and must be modified before a return to work, generally on a subsequent day.

Heat edema

Clinical pattern

Heat edema represents a second clinical response to the physiologic adaptation of unacclimated workers to heat stress. Generally within 1 to 2 days after first exposure, new-onset dependent edema may occur (or an increase in pre-existing peripheral edema). This is probably caused by relative oliguria and hyperaldosteronism, although other hormonal factors such as insulin and growth factor may be involved.²³

Evaluation

This diagnosis should be made by the history and physical examination with attention to excluding coincident cardiovascular events. Further diagnostic testing is not indicated unless the edema persists for more than a few days.

Treatment

Because body fluid expansion is part of the acclimatization process, steps to interfere with this, such as diuretics or salt restriction, are strongly contraindicated. Patients with predisposing risks for edema or complications, such as congestive heart failure, should be excluded from further exposures to heat stress; others may carry on.

Course and prognosis

The disorder is self-limiting and will disappear as the glomerular filtration rate and cardiac output rise during the acclimatization process. There are no sequelae or evidence that individuals who experience this problem are at particular risk for other heat-related health problems.

Heat tetany

Clinical pattern

Heat tetany is a third benign disorder, generally occurring in the unacclimated individual early after heat stress. The cause is central hyperventilation, leading to systemic alkalemia. Symptoms such as perioral paresthesia and signs of frank tetany generally resolve when the patient is removed to a cooler area, usually before medical attention can be obtained.²³

Evaluation

The diagnosis should be considered based on the history. In an individual without underlying health problems, the major differential diagnosis is with hyperventilation syndrome or panic disorder. Although the manifestations

and laboratory findings of hypocarbia and high partial pressure of oxygen are identical, heat tetany should be distinguished from these other causes because of the stigma associated with them, the different treatment modalities, the likelihood of recurrence, and the proper assignment of cause. Rarely, determination of serum calcium and arterial blood gases may be necessary to exclude more serious disorders.

Treatment

Removal from the heat stress is all that is required. In general, affected workers should have their heat loads modified to prevent recurrences prior to full acclimatization.

Course and prognosis

This disorder is completely benign and has no implication other than that mentioned in regard to a modification of the heat load.

Heat cramps

Clinical pattern

Heat cramps are characterized by brief, intermittent, and often excruciating cramping pain in the muscles that have been subjected to excessive work. The most common muscle groups affected are the muscles of the extremities. The cramps typically occur late in a workday or after the muscles have cooled, e.g., in the shower. In severe cases, there may be muscle necrosis with leakage of creatinine and muscle enzymes, although frank myoglobinuria with renal involvement has not been described in this setting. The basis for heat cramps is hyponatremia. Acclimated workers are at far greater risk because of the adaptation that allows them to sweat far greater volumes than in the control state.²⁴ Although adaptation to heat reduces the concentration of sodium in the sweat, the marked increase in sweat volume results in far greater total sodium losses than would otherwise be possible. The replacement of water losses without replacement of salt losses creates the condition in which heat cramps occur.^{22,23}

Diagnosis

Similar to other heat-related disturbances, the pattern of the illness in the typical setting is usually diagnostic. The body temperature is usually normal and the individual sweats normally or there is excessive sweating. Heat cramps must be distinguished from the more common cramps that occur during strenuous work. Common cramps generally last longer but will resolve completely with rest and massage; they are unrelated to systemic fluid and electrolyte imbalances. A determination of serum electrolyte levels will distinguish the two conditions. It is also important to distinguish simple heat cramps from the more life-threatening syndrome of heat exhaustion (see later), in which cramps may also occur. As a matter of definition, if cramps occur together with constitutional symptoms (such as fatigue, weakness, headache, gastrointestinal

upset, or mental status changes), the diagnosis of heat exhaustion is appropriate.

Treatment

The key to treatment is the correction of hyponatremia by the administration of fluids containing adequate concentrations of sodium. This can almost always be done orally in cases of simple heat cramps. Rest alone is not sufficient because the condition often occurs in the resting state after a work shift. If continued heat stress is present, as in very hot climates, the control of heat cramps is easier if the patient is removed to a cooler area where sweating will slow or stop.

Course and prognosis

Heat cramps, although benign in and of themselves, are a premonitory sign of decompensation caused by heat stress. Unlike syncope, tetany, and edema, the condition is not self-limited and will resolve only after sodium losses are replaced. More importantly, continued work under conditions of heat stress without replacement may lead to heat exhaustion, with a possibility of heat stroke supervening unexpectedly at any time.

Heat exhaustion: predominant salt-depletion type

Clinical pattern

When water replacement of sweat is adequate but salt replacement is not, heat exhaustion of the salt-depletion type, with or without cramps, may occur. Unlike simple heat cramps, this syndrome typically occurs during periods of heat stress and is more common in unacclimatized individuals, although all workers are at risk.²³ The predominant symptoms are nausea, vomiting, dizziness, weakness, and anxiety; alterations of mental status are often seen, although they are not profound early. Thirst is generally minimal or absent because plasma volume and intracellular volume are generally well preserved at the expense of the interstitial spaces, which lack oncotic forces. Clinically, the patients appear clammy and pale. Normal skin elasticity may be lost as a result of depletion of the interstitial fluid. The body temperature is normal or may be low unless heat stroke supervenes. The urine volume may also be normal. In the unacclimated worker, cardiovascular strain may be evidenced by hypotension and tachycardia. Similar to heat cramps, hyponatremia is uniformly present in this condition.

Diagnosis

As in other heat-related disorders, the history and signs described should be sufficient to make the correct diagnosis. The presence of cramps suggests hyponatremia. The biggest differential consideration is coincident viral syndrome, which this disorder might mimic. A demonstration of low serum sodium levels and response to salt replacement should serve to differentiate these two.

Treatment

Because this disorder typically begins during conditions of heat stress, removal to a cool place is essential to slow the ongoing salt losses. The specific treatment is replacement of sodium, usually with additional water because the total body water may also be somewhat low. Fluids of normal tonicity should be administered orally or intravenously until the symptoms have cleared, the pulse has normalized, and the urine flow is high and contains adequate (i.e., > 10 mEq/l) sodium. In the rare individual whose serum sodium has fallen to very low levels (i.e., < 120 mEq/l), replacement should be paced to avoid a too rapid correction with its inherent risk of central pontine myelinolysis.^{25,26} An important consideration is avoidance of aspirin use or any non-steroidal anti-inflammatory drugs for this disorder, because of anecdotal reports of paradoxical hyperthermic responses to these agents in this setting.

Course and prognosis

Treated individuals should recover completely. Obviously, patients would not be returned to heat stress until total correction has occurred and the conditions that led to this extremely serious outcome have been investigated and corrected.

Heat exhaustion: predominant water-depletion type

Clinical pattern

This severe disorder of heat stress is heralded by changes in mental status, starting as anxiety and weakness, but frequently advancing to confusion, agitation, and delirium. Patients usually complain of thirst but may be incoherent. Signs include evidence of dehydration, oliguria, and hyperthermia; hyperventilation and tetany also may occur.

The underlying disturbance is failure to replace water losses related to sweating, with subsequent volume loss and hypernatremia. Because thirst itself is not impaired until late in the course of the illness, the setting of heat exhaustion of this type is typically one in which access to water is restricted, as in construction, farming, military work, and mining.²³ However, thirst is the least sensitive of the body's sensory systems and should not be relied on to signal the body water deficit adequately, especially in older workers.

Diagnosis

Although recognition of this disturbance is crucial and often life saving, it should present few problems diagnostically unless the history of heat stress is unavailable because of the patient's mental status. In the setting of delirium or coma without a history, the diagnosis should be evident from the signs of total body volume depletion and hyperthermia, combined with hypernatremia. Ruling out coincident sepsis may be difficult if the history is not available; stress leukocytosis and hypocapnia do not distinguish between the two. Similarly, in a diabetic subject, serum glucose levels may rise rapidly and raise consideration

of non-ketotic hyperosmolar coma. In either case, neither consideration of infection and search for a source nor concern about underlying metabolic disturbance should distract the clinician from the recognition that the manifestations of heat exhaustion of this type may occur from heat stress alone.

Treatment

Unlike all the preceding disorders, heat exhaustion of the water-depletion type is a medical emergency because heat stroke, with cardiovascular collapse and rapid rise of body core temperature, may supervene at any moment. Therefore, victims should be emergently transported to a hospital rather than attempting oral fluid replacement on site.

The mainstay of treatment is the administration of water, with or without sodium. If hypotension is evident, half-normal or even normal saline should be given. After the blood pressure is stable, hypotonic solutions, such as 5% dextrose in water, should be given, with the goal to correct the serum sodium level at a rate of 1 to 2 mEq/l/hour. There is a serious risk of cerebral edema from a too rapid correction.

Course and prognosis

Although full recovery is the rule, improvement in mental status may be delayed for several days, well after the fluid and electrolyte disturbances have been corrected. Needless to say, the worker's return to heat stress after the hospital discharge must be done cautiously and only after full appreciation of the circumstances that led to the event.

Heat stroke

Clinical pattern

The hallmark of heat stroke is the ultimate failure of heat-dissipating mechanisms to compensate for heat stress, with a rapid rise in the core body temperature to more than 40°C and often much higher. Profound dysfunction of central nervous system activities occurs, with depression of the level of consciousness, often preceded by delirious or even psychotic behavior. Circulatory collapse with hypotension is frequent. The signs on the physical examination may be variable, depending on the setting and severity of the episode. In exertional heat stroke, unlike the classic picture of this disease in the elderly patient, sweating and other compensatory mechanisms may still be active when the patient is first seen, so skin may or may not be hot and dry.²⁷ Despite peripheral evidence of volume depletion, pulmonary edema may be present as a result of myocardial involvement. Focal neurologic signs may be present because of direct central nervous system involvement or secondary to seizures, which typically occur during the early cooling phase, although often before the patient arrives at the hospital. The laboratory findings are striking. Muscle enzymes are invariably elevated, with often spectacular creatine phosphokinase (CPK) levels. The serum potassium concentration is usually low, but it

Feature	Classic	Exertional
Age group	Very young, very old	Working age
Health status	Chronic illness common	Usually healthy
History of recent febrile illness	Unusual	Common
Drug use	Autonomic antagonists, diuretics, neuroleptics	Amphetamines, cocaine
Sweating	Usually absent	Often present
Respiratory alkalosis	Dominant	Mild
Lactic acidosis	Absent or mild	Often marked
Acute renal failure	<5% of patients	30% of patients
Rhabdomyolysis	Seldom severe	Severe
Hyperuricemia	Modest	Severe
Creatine phosphokinase/aldolase	Mildly elevated	Markedly elevated
Hypocalcemia	Uncommon	Common
Disseminated intravascular coagulation	Mild	Marked
Hypoglycemia	Uncommon	Common

Modified from Knochel JP. Heat stroke and related heat stress disorders. *Dis Mon* 1989; 35:301-77.

Table 34.4 Comparison of classic and exertional heat stroke

may be elevated if muscle and other cell necroses are advanced and renal failure has begun. Serum uric acid and phosphate levels are often elevated because of tissue damage, and hepatic enzyme concentrations are also frequently elevated. Generally, the serum creatinine level is high because of muscle cell lysis and renal failure. At the same time, evidence of DIC is usually evident, with thrombocytopenia and abnormal clotting parameters. Blood gas measurements may demonstrate respiratory alkalosis, but lactic acidosis is usually the dominant acid-base disorder. If the liver is extensively involved, serum glucose levels may be low. The urine, if there is any, typically shows myoglobin and pigmented casts.^{15,28} The differences between heat stroke seen in the occupational setting and the classic disease of infants and elderly persons are summarized in Table 34.4.

Diagnosis

The only diagnostic issues are early recognition and appropriate and expectant classification of the involved organ systems. Before total decompensation, patients still sweating may not appear hyperthermic. Therefore, when heat stroke is considered, the rectal temperature must be obtained immediately. After hyperthermia is demonstrated, two important drug-related conditions with differing mechanisms and treatments must be ruled out. The first is malignant hyperthermia, which results from administration of anesthetic agents in susceptible subjects.²⁹ This can usually be excluded because of the setting and the presence in that disorder of profound muscle rigidity. The malignant neuroleptic syndrome, caused by haloperidol, phenothiazines, and lithium, also is characterized by profound muscle rigidity and striking extrapyramidal movement abnormalities.³⁰ An important differentiating characteristic of each of these drug-induced conditions is the continued rise in core temperature until treated; core temperature begins to fall in heat stroke after the patient is removed from the thermal stress.

Treatment

The management of this life-threatening disorder should be undertaken by a team experienced in intensive care

medicine. Because of the complexities of the neurologic, cardiovascular, renal, metabolic, and hematologic disturbances, the details of such care are beyond the scope of this text. The basic steps in early intervention are summarized here.

1. As with any other life-threatening condition, airway support, effective ventilation, and circulatory support must be ensured. After intravenous access has been established, baseline studies should be obtained. The next most crucial step is rapid body cooling. This is most easily accomplished by spraying the naked patient with cool mist while using fans to enhance airflow over the body. This method reduces temperature by 0.06°C to 0.16°C per minute. The common practice of placing icepacks on the body surface is not effective and may be counterproductive because icepacks can increase peripheral vasoconstriction and may induce shivering.³¹ Lavaging the stomach with iced saline solution has also been found to be no more effective than the evaporation procedure.³² Rapid cooling should be continued until the core temperature is below 39°C. The control of seizures, which often occur during cooling, may be accomplished with diazepam. Shivering, which also generates heat, can be controlled by the use of phenothiazines.
2. Cardiovascular adequacy must be maintained. Although the intravascular volume may initially be low, fluids should be given cautiously because of the intense vasoconstriction that will occur with cooling. The possibility of pulmonary edema from a volume overload must be considered, given the likelihood of myocardial damage from the heat stroke. Monitoring of central pressures, with a Swan-Ganz catheter, can assist with this aspect of management.
3. Acid-base and electrolyte disturbances must be corrected. If the serum potassium level is depressed, careful repletion is essential. Renal output and function must be carefully watched to avoid rapid hyperkalemia. Disturbances in plasma tonicity should be corrected by the choice of fluid administered. If the blood glucose level is low, high dextrose-containing

solutions must be given that are consistent with the demands of serum osmolarity correction.

4. Renal function must be optimized. Because of the invariable insult to the nephrons from myoglobinemia, extreme hyperuricemia, hypokalemia, dehydration, and impaired cardiac output, acute renal failure is likely. The most important step is maximizing the renal blood flow by maintaining the cardiac output and blood volume and by cooling, which will reshunt the blood back to the visceral organs. Beyond these measures, ensuring the patient's survival and minimizing the sequelae will depend on attention to the specific organ complications of the disease. Treatment of DIC, renal failure, myocardial infarction, hepatic insufficiency, and neurologic manifestations is no different in this setting than in catastrophic illnesses of other origins, such as overwhelming sepsis.

Course and prognosis

The course of the acute illness will depend on the extent of involvement of the vital organs and their response to treatment. Many patients will require prolonged stays in intensive care units. Despite this, with ideal care, as many as 95% of all patients will survive the episode, although they may be left with residual damage to one or more of the involved organs. Among those who recover fully, it is important to recognize that the sweat glands are often affected by an episode of heat stroke and may not recover normal function for many weeks, if ever. For this reason, patients who recover from heat stroke should be excluded from heat exposure for at least 4 weeks. Subsequent return should be carefully monitored to determine whether the patient's tolerance for heat has been diminished permanently. Needless to say, the circumstances of exposure must be rectified.

Reproductive effects of heat stress

There is a growing body of literature reporting that routine heat stress is associated with decrements in sperm production. A quantitative study of populations examined during cool seasons and again in the summer has shown drops in the baseline sperm counts of 20% or more during warmer weather.³³ That this has an impact on actual reproductive success is suggested by the seasonal differences in birth rates in temperate climates, with the lowest rates occurring in the spring and the highest in the fall.³⁴ This effect appears to be of sufficient magnitude to merit consideration in the workup of male infertility. Similarly, confounding by heat exposure must be taken into account in studies of the reproductive impact of other environmental agents (see Chapter 27.2). There is also growing speculation that thermal stress to the developing fetus may be teratogenic in humans. Experimental data in animals suggest a significant potential for retardation of central nervous system development after even brief periods of intense heat exposure early in gestation. It has been hypothesized, but not proved, that working women in the first and early second

trimester may be at risk. These data have not been confirmed in well-controlled human studies.^{35,36}

PREVENTION OF HEAT STRESS DISORDERS

The prevention of disorders resulting from heat stress involves a combination of environmental and administrative controls. The use of personal protective equipment has no direct protective role for this hazard but is discussed because of its importance as a contributory risk factor that can be modified.

Environmental control

When possible, direct control of temperature, humidity, air velocity, and radiant sources should be used where strenuous, heat-generating activities will occur. In some settings, this can be effectively combined with other engineering tools, e.g., the delivery of large quantities of fresh air to underground miners cools the air and replaces stale air. When temperature itself cannot be controlled, the potential value of manipulating the other variables should not be underestimated, e.g., the use of rapid air circulation and dehumidification or shielding of sources, such as furnaces, in metals refining or processing operations.

Personal protective equipment

It has been already noted that devices used to control other hazards may promote heat stress. Uniforms and protective clothing may be maladaptive in this regard.² Conversely, there are few devices to enhance heat removal. The goal, therefore, is to minimize the impact of clothing and gear. When possible, direct exposure of the skin surface to the ambient environment will enhance sweat evaporation and heat removal. The only negative consideration is exposure of the skin to radiant sources such as the sun. When the skin must be covered, the goal is to maximize the air movement through the clothing (pumping action) to support evaporation of further sweat. Impermeable garments, although advantageous for workers exposed to chemical or biologic hazards, block evaporation completely. Newer materials are now being marketed that effectively support breathing of the clothing while preventing permeation of liquids from the outside in.³⁷ Whether these will prove effective compromises between competing hazards remains to be determined in field studies.

Administrative controls

Given that climatic controls are often unfeasible, especially for outside work, administrative controls must form a preventive program. There are four mainstays: acclimatization, work scheduling, fluid and salt supplementation, and surveillance.

As noted above, the human body undergoes quantitatively large adaptations to heat stress over a period of

about 2 weeks with regular exposure. Taking due precautions, workers exposed to uncontrolled heat stress must go through acclimatization, a graded program for 2 weeks before work as usual may commence safely. During this time, the loads must be sufficient to cause some cardiovascular stress, e.g., tachycardia, but not severe enough to induce even the minor disorders described above. Symptoms such as syncope or tetany should flag the need to slow the process and evaluate the adequacy of other administrative controls. Workers who are absent from work for more than 1 week, either on vacation or as a result of illness, need to be reacclimatized before resuming regular work. This is particularly true in the case of illness, which itself may predispose to heat exhaustion or stroke.

Work scheduling is a time-honored way to minimize the risk from heat-induced illness. Depending on the nature of the load, providing rest intervals sufficient to allow removal of any burden that has resulted in the elevation of temperature and to allow an opportunity to replace the salt and water losses is an invaluable control technique. Most cases of major heat disorder have occurred during stresses in which rest was not incorporated into the work schedule.

Replacement of salt and water losses is crucial. Workers must have access to water at all times. Where losses will exceed more than 1 to 2 liters during a work shift, salt must also be provided, either in tablet form or in salt-containing beverages/electrolyte drinks. However, to prevent heat exhaustion and hypernatremia, it is imperative that salt supplements never be given in the absence of free access to salt-free drinking water. Electrolyte drinks are more effective because they are formulated to optimize the provision of energy, water, and essential electrolytes, particularly sodium, and are more palatable than salt tablets.^{38,39}

Finally, an active surveillance program of heat-exposed workers is vital. All must be examined before the onset of acclimatization to evaluate their underlying risks for heat-related illness. The decision to allow a worker to proceed should be based on a careful evaluation of data. Table 34.2 lists the conditions that may predispose the worker to the life-threatening effects of heat stress. Although the choice is generally straightforward for individuals with serious conditions, such as cardiovascular disease or complications of diabetes, it is more difficult for the young hypertensive worker receiving medication or the moderately obese worker. In such cases, it may be advisable to proceed under close medical scrutiny or elect a job change; sometimes, a simple change in medical management may lower the risk, such as elimination of diuretics. Pregnant women should probably not participate in jobs that require acclimatization. Non-pregnant women, in general, appear to have a lower risk for developing hyperthermia than do their male counterparts.³⁴

Beyond initial screening and modification of medical or work regimens as indicated, continued surveillance is highly advisable. Periodic questionnaires and examinations may provide further clues that existing controls are

inadequate or that particular individuals may be more sensitive than average to thermal stresses.

COLD STRESS

Exposure settings

Because the normal physiologic state at comfortable ambient temperatures involves positive heat production with its obligatory removal, only excessive, uncompensated heat losses contribute to cold stress. The most prevalent mechanism is by excess convective transfer of heat from the skin into the air or water. Radiative losses are smaller, and losses caused by evaporation of sweat cease to be a problem because cold itself inhibits sweating. Work activities themselves are protective because they generate heat; sedentary activities favor a net heat loss.

Two aspects of cold stress must be considered: systemic and local. Systemic cold stress occurs when heat loss exceeds heat production (as during outdoor activities in cold climates), refrigeration work (as in food processing), and body immersion (as in diving). Although these exposures have been associated with potentially important clinical sequelae, there is not, in general, much potential for uncontrolled progression to frank hypothermia in workers.

Local exposures to cold, usually involving the extremities, are far more common. These occur frequently in outdoor workers who cannot perform their tasks wearing gloves, such as in the maritime industries, in military activities, and in any setting of systemic cold exposure in which an extremity is unprotected. Because the local effects may be somewhat delayed, prolonged exposures are commonplace. It is important to recognize that local exposures need not be to freezing or subfreezing temperatures to be deleterious to local tissues; prolonged exposure at temperatures as high as 10°C may induce acute and chronic effects.

Physiology

The responses to cold stress can also be divided into systemic and local. When the total heat loss from the body begins to exceed the heat production, cardiovascular, neuroendocrine, and metabolic adaptations occur. The most striking of these is enhanced sympathetic and adrenergic discharge, with a marked increase in skin vascular resistance and a relative shunting of blood centrally. This simultaneously reduces heat losses from the body and protects the internal organs from cooling. The net effect on systemic vascular resistance and cardiac output is variable in the healthy individual. However, in the individual with pre-existing vascular lability, such as essential hypertension, there is evidence of exaggerated pressor responses. Similarly, adrenergic stimulation is believed to enhance platelet aggregation, at least in those with an underlying predisposition. Cold exposure is often accompanied by enhanced spontaneous muscle activity to generate additional heat (shivering). Interestingly, although people chronically exposed to cold appear to be better adapted in

that they may comfortably wear fewer clothes and shiver less to a given stimulus, there is not a well-delineated cold adaptation comparable to the acclimatization induced by heat.⁴⁰

The local responses to cold are more complex and clinically important. With the decrease in local temperature, peripheral vascular resistance increases as a result of local and systemic factors. This occurs spasmodically, with cyclic decreases in the skin temperature interspersed with transient increases. Accompanying this response, there is endothelial leakage and stasis of the blood flow, leading to local tissue injury. With severe or prolonged temperature decreases, vascular necrosis and thrombosis occur. Exposures to temperatures below freezing also have a direct effect on non-vascular tissues. Ice crystals form, leading to high intracellular osmolality. This causes direct mechanical trauma on the cells, especially axons and melanocytes, leading to depigmentation and axonopathies that persist long after the soft tissue and skin changes have healed.^{41–43}

MAJOR DISORDERS ASSOCIATED WITH COLD STRESS

Hypothermia

Clinical pattern

Hypothermia is defined as core body temperature less than 35°C. Primary hypothermia occurs when normal heat conservation mechanisms cannot overcome low environmental temperature. Secondary hypothermia occurs when heat conservation mechanisms are disturbed by underlying disease. Such states may interfere with hypothalamic temperature regulation, shivering, redistribution of blood, and ability to leave the environment. Hypothermia is most likely to occur in infants (whose large body surface area predisposes them to rapid heat loss) and the elderly (who may have impaired ability to sense decreasing tempera-

ture, to limit heat loss by peripheral vasoconstriction, or to shiver). Drugs that alter the sensorium (e.g., alcohol) or other drugs that act on the central nervous system (e.g., barbiturates, phenothiazines) may inhibit the body's response to cold and thus increase susceptibility to cold. Risk of hypothermia is increased by hypothyroidism, hypopituitarism, hypoadrenalism, diabetes, sepsis, and head injury.⁴⁴ Decreased core temperature establishes the diagnosis and severity of hypothermia and determines appropriate treatment.

In mild hypothermia, defined as core temperature ranging from 32°C to 35°C, patients are pale, cool, and have maximally vasoconstricted blood flow to the skin. Patients may shiver uncontrollably, and have varying degrees of mental status change. These patients have tachycardia, tachypnea, and cold diuresis induced by increased cardiac output and, as a result, increased renal perfusion.

In moderate hypothermia, core temperature ranges from 28°C to 32°C. Symptoms are more severe, and may include impaired mental status, muscle rigidity with absent reflexes, and dilated pupils. The shivering reflex is lost, and the blood pressure, heart rate, and respiratory rate decrease. Cardiac arrhythmia is common, and electrocardiography may show the pathognomonic J-point elevation or Osborne wave.⁴⁵ At this point, with no ability to generate heat, the patient cools to the ambient temperature and dies if warming is not accomplished.

Severe hypothermia (core temperature less than 28°C) causes the patient to appear dead. Blood pressure is not recordable, respiratory rate is extremely slow, the patient is in a coma, pupils are dilated and fixed, and reflexes are absent. Atrial arrhythmia may be present, and ventricular fibrillation may easily be induced, even by moving the patient slightly. This type of arrhythmia resists pharmacologic or electrical cardioversion without core rewarming; however, magnesium sulfate, quinidine, or bretylium tosylate may be helpful in these cases.^{46,47}

Treatment

The goal of initial treatment for hypothermia is prevention of further heat loss. Basic life support should be initiated, ensuring adequate airway and circulation. Cardiopulmonary resuscitation is indicated in patients who have a non-perfusing cardiac arrhythmia. Severe peripheral vasoconstriction in hypothermic patients typically makes pulses difficult to palpate, therefore pulse should be examined for a full minute to help avoid inappropriate chest compression. Oxygen and intravenous fluids should be warmed before being given to a hypothermic patient.⁴⁸ Passive rewarming, such as moving the patient to a warm shelter, removing wet clothes, and application of a dry blanket, should be attempted initially in all hypothermic patients and may suffice for mildly hypothermic patients who are otherwise healthy. Active external rewarming techniques can supplement passive rewarming and include application of exogenous heat sources (heating blankets, heating lamps, hot packs). More invasive techniques for core rewarming may include peritoneal dialysis or hemodialysis.^{49–51}

Essential hypertension

There has been experimental evidence that the risk for and progression of essential hypertension correlates with vascular reactivity to cold, usually measured by the cold pressor test, in which arterial blood pressure is measured before and after a systemic cold stimulus.⁵² Moreover, among people with essential hypertension, slightly elevated blood pressure has been observed during winter months.^{53,54}

The question is raised, therefore, whether actual exposure to chronic cold stress may either cause elevated blood pressure or enhance progression in hypertensive patients to more serious levels of blood pressure elevation. At present, it is premature to extend this speculation into clinical decision making, other than to consider a modification of the work environment for those with hypertension.

Thromboembolic disease

Two important lines of evidence raise concern that cold exposure may enhance the risk for thromboembolic disease, particularly coronary artery disease and cerebrovascular accident. First, it has been well established that the risk for these disorders in different regions of the world follows a temperature gradient that other risk factors cannot explain alone. Second, cold exposure has been shown to enhance acutely the levels of factors that induce platelet aggregation, such as thromboglobulin and platelet factor IV, probably as a consequence of adrenergic stimulation.⁵⁵ Although these two independent observations are insufficient to identify causality between cold exposure and the risk for major diseases, they suggest that further exploration of these associations is warranted. It may be prudent to exclude subjects with active vascular disease, e.g., poorly controlled angina or congestive heart failure, from chronic cold exposure.

Menstrual disorders

Anecdotal evidence suggests that dysmenorrhea is more prevalent in cold climates and during colder seasons. To date, no other menstrual or other reproductive system effects have been ascribed to cold exposure.

PREVENTION OF DISORDERS CAUSED BY COLD STRESS

In general, climatic control is impossible in situations in which cold stresses occur, e.g., out of doors or in refrigeration work where cold is essential. The keys to control, therefore, are a modification of work to minimize the exposure opportunity, education to recognize early symptoms of local injury, and the use of protective equipment. Medical surveillance plays a minimal role, i.e., it is limited to the examination of workers who undertake cold exposure occupations to identify those few who might be at special risk. Continued monitoring for the ill effects of cold, other than for the purpose of scientific enquiry, is probably not warranted.

Dedication

Ethan Nadel, who co-authored this chapter in the first edition, died before the preparation of this revision, which still bears his stamp.

Chapter 35

Noise

Derek E Dunn, Peter M Rabinowitz

Noise is one of the most prevalent workplace hazards. Hearing loss caused by noise is also one of the oldest known occupational diseases. Ramazzini identified noise-induced hearing loss in the 1700s at a time when the noise was almost exclusively from the hammers of carpenters, blacksmiths, or other smiths. The general mechanization of industry, farming, and transportation not only has increased the occupational range that exposes workers to noise but also, for the first time, has introduced significant exposures to uninterrupted or continuous noise.

While most research into the adverse effects of noise has focused on damage to the auditory system (see also Chapter 20.2), some studies have also examined the non-auditory effects of noise on the cardiovascular and other organ systems. Noise in settings other than the workplace, such as homes near an airport, is also a rising environmental concern. Because these exposures, however, are not usually as intense as those in the occupational setting, this chapter will primarily focus on the hazardous effects of excessive noise exposure in the workplace.

OCCUPATIONAL NOISE EXPOSURE SETTINGS

Today, the majority of workers exposed to noise levels potentially damaging to their hearing are employed in manufacturing. The Occupational Safety and Health Administration (OSHA) estimates that in the United States alone, more than 8 million manufacturing workers are occupationally exposed to noise greater than 80 dBA (decibels measured using a sound level meter's 'A' weighted scale). These workers do not include the more than 3 million employed in agriculture, mining, construction, transportation, or the Federal government. The number of workers in the American manufacturing sector who have hearing loss from occupational noise is estimated to be more than 1 million; one half of these workers have moderate to severe hearing impairment. One worker in four exposed to 90 dBA of noise during a working lifetime will have hearing loss attributable to occupational noise exposure. Surveys of machinery noise indicate that more than 50% emit noise levels between 90 and 100 decibels (dB), and approximately 50% of the industrial work environments have noise levels between 85 and 95 dB. Fewer than 6% of the machines surveyed by the National Institute for Occupational Safety and Health (NIOSH) produce noise levels below 85 dB.

Despite the prominence of noise in manufacturing, significant numbers of people in other occupations (e.g.,

construction, agriculture, mining, transportation, and the armed forces) are also exposed to hazardous noise. Data reveal that 50% of construction workers and 57% of carpenters employed for over 20 years have hearing impairment at age 50. By age 50, 90% of coal miners have a hearing loss. Table 35.1 lists some of the occupations for which hazardous noise exists. Table 35.2 lists the average and range of noise levels for selected industries. Table 35.3 identifies some of the common noisy tools.

NON-OCCUPATIONAL EXPOSURES

Outside the workplace, individuals may be exposed to a wide range of noise sources capable of causing damage. Approximately 60 million Americans own firearms¹ and many use them without adequate hearing protection. Other non-occupational sources of noise include chain saws, power tools, amplified music, and recreational vehicles, such as snowmobiles. While community noise sources, such as airport and traffic noise, may not be of sufficient intensity to damage hearing, those noises may increase the risk of non-auditory effects, e.g., sleep disturbances, cardiovascular changes, and psychological changes.

SOUND AND NOISE

Basic properties of sound

The mammalian auditory system is sensitive to sound pressure waves, which are rapid fluctuations in the ambient air pressure. Something must create a disturbance in the ambient air pressure to generate the sound pressure waves. The source of the disturbance is usually a vibrating object or a sudden expansion of gases, such as occurs in an explosion. The basic traits of the sound pressure waves that allow us to distinguish one sound from another are amplitude (loudness), frequency (pitch), and temporal pattern. Amplitude and frequency may vary independently of one another. For example, a pure tone has one frequency (i.e., the number of times per second that the changes in the ambient air pressure occur), but may vary in intensity or loudness.

Definition of noise

Noise (sometimes referred to as unwanted sound) is composed of many pure tone frequencies that interact

Industry group	Employment levels (thousands)	Percent exposed
Fishing and forestry	82	6.1
Mining	82	13.0
Construction	2535	7.9
Manufacture (total)	15,241	23.0

Based on data from NIOSH. National Occupational Hazard Survey. Washington, DC: Department of Health, Education, and Welfare, Public Health Service, Center for Disease Control, National Institute for Occupational Safety and Health, DHEW (NIOSH) Publications No. 74-127, May 1974, pp. 177-213; and DHEW (NIOSH) Publications No. 78-114, July 1977.

Table 35.1 Numbers and percentages of workers in the United States exposed to noise levels 85 dBA or greater by industry group and by industry within the manufacturing group

Industry	Average noise level (dB)*	Range of noise (dB)
Food	87	72-95
Textiles	88	82-104
Apparel	78	77-82
Lumber	85	73-105
Paper, printing, publishing	89	70-102
Chemical	95	73-106
Leather	92	73-115
Stone, clay, glass	90	68-112
Metals	95	73-115
Fabricated metal	89	68-108
Machinery	88	80-113
Aircraft	87	78-94

*Note: These levels are for the general work area; noise levels near the machines were higher. Maximum noise levels at the sound source exceeded 110 dB for lumber and chemicals. Source noise levels exceeded 120 dB for metals, machinery, and aircraft.

Table 35.2 Work area noise levels for industry

with one another to yield a sound with a complex mixture of loudness and pitch. A noise with a given frequency composition that is more or less constant in intensity is

Tools	Minimum and peak octave band noise levels (75-9600 Hz)
Riveting/chipping	75-125
Saws	70-100
Planers	70-109
Steam and air tools	70-105
Tumblers	77-95
Grinders	70-105
Welding	68-103
Lathes	65-100
Drills/milling	73-95
Furnaces	70-100
Mixers	55-98

Table 35.3 Range of sound pressure for typical tools

referred to as continuous or steady-state noise. If the same noise has significant drops in intensity or ceases, it is classified as interrupted noise. Impact or impulse noise is characterized by a sudden rise in its intensity, followed by a quick decay in intensity. The relative hazard to hearing from exposure to continuous, interrupted, impact, or impulse noise depends on the combination of the intensity, duration, and frequency making up the noise.

The human ear is capable of responding to sound pressures that span an enormous intensity range. In the frequencies near 1000 hertz (Hz) (where hearing is most sensitive), the ratio of the intensity of a painfully loud sound to the intensity of a barely audible sound is 10^{15} to 1. Ratios such as 1,000,000,000,000,000:1 are too cumbersome to handle in routine calculations, but the logarithm of the ratio (e.g., the log of $10^{15} = 15$) yields units that are more manageable. The 15 logarithmic units that span the range of human auditory sensitivity are called Bels in honor of Alexander Graham Bell, an early investigator of auditory communication. Because it is necessary to make sound pressure measurements with more precision than is possible using the Bel, the Bel is divided into 10 units called decibels. A decibel is the common unit for measuring sound pressure level (SPL) and reflects the log of the ratio between the measured SPL and a reference SPL. The formula for calculating a decibel level is as follows:

$$\text{dB} = 20 \log p_1/p_0$$

where p_1 is the measured SPL, and p_0 is the reference SPL. The lowest sound pressure level that can be detected by the average young adult is $0.0002 \text{ dynes/cm}^2$, and this value is used as the reference SPL, p_0 . Consequently, SPL is a measure of decibels above $0.0002 \text{ dynes/cm}^2$. Table 35.4 shows typical levels of common sounds and noises.

Measurement of noise

Noise is directional and is affected by objects and people in its path. Sound levels vary with distance from the source and are affected by many other factors. Care must be taken to obtain accurate measurements, and numerous noise measurement instruments are available for a range of noise environments and tasks.

The basic instrument used for the measurement of SPL is the sound-level meter. Sound-level meters are made to be held in the hand while readings are taken. Most of these

Sound level (dB)	
	130 Airplane motor
	120 Pneumatic chipper
	110 Loud rock music, sandblasting
	100 Subway train passing
OSHA 8 hr. PEL	90

	0 Human hearing threshold

Table 35.4 The approximate measured level in dB of common noises and sounds. Values of the United States Occupational Safety and Health Administration (OSHA) permissible exposure limit (PEL) and action level are noted for comparison

meters are equipped with at least two weighting systems. The A scale is designed to approximate the sensitivity of the human ear, giving less weight to the lower frequencies of the hearing range. The C scale is almost linear in its weighting, counting all frequencies in the range as nearly equal. The A scale is specified by OSHA in its hearing conservation standard for the workplace and is more commonly used for measurements taken to evaluate noise exposure. Measurements made with sound-level meters are reported in dBA or dBC (C-weighted decibels).

For workplace noise evaluations, OSHA specifies that an instrument meeting the accuracy requirements of a type 2 sound-level meter, as specified by the American National Standards Institute (ANSI), must be used in the slow-response mode. The slow-response mode integrates SPL over a longer period than does the fast-response mode. These instruments, even if equipped with a fast response, are not appropriate for measuring impulse or impact noise (brief, loud bursts of noise, such as those created by a drop forge or a stamping machine).

While the overall dose of noise to workers is of concern, the type 2 sound-level meter measures the SPL at a given moment only. Therefore, the noise dosimeter has been developed to integrate SPL over longer periods. Dosimeters are typically worn by workers for an entire shift. The instrument is small and clipped to a belt or placed in a pocket, and the microphone is clipped to the shoulder to measure almost ear-level noise.

The dosimeter provides an approximation of the total noise dose over time, such as during a work shift. In situations where workers do not spend an entire shift in constant noise of the same quality and loudness, OSHA recommends a dosimeter that calculates a percent of allowable dose on an 8-hour time-weighted average (TWA). The underlying assumption regarding noise dose is that the effect of noise on the target organ (ear) is a function of the noise intensity and its duration. Thus, 100% corresponds to 8 hours spent at levels of 90 dBA or 4 hours

spent at 95 dBA; 50% corresponds to 85 dBA for an 8-hour shift and is the action level triggering the OSHA hearing conservation standard. The assumptions incorporated by these conversions are a 5-dBA doubling rate (although sound energy actually doubles every 3 dBA) and the inclusion of all continuous, intermittent, and impulsive sound levels from 80 to 130 dBA. These assumptions, while convenient for regulatory compliance, may not accurately reflect the way sound causes morphological or physiologic changes in the auditory system.

Combined sound-level meters and dosimeters are sold with built-in computers that calculate and store data. Many will store peak exposures, allow the option of selecting a different noise threshold or doubling the rate, calculate the percent dose, indicate the equivalent time-weighted exposure, or have other options, such as printing out a minute-by-minute history of the entire sampling period.

Octave-band analyzers, networks that separately characterize the noise by its component frequency bands, can be added to some sound-level meters, allowing for a more detailed characterization of the noise composition. This capability is most helpful in designing controls for noise because different frequencies are controlled or attenuated most effectively by different approaches or materials.

CLINICAL EFFECTS OF NOISE EXPOSURE

Noise-induced hearing loss (see also Chapter 20.2)

Noise damages the sensory hair cells in the auditory end organ (cochlea). Once significantly damaged, the auditory sensory cells cannot repair themselves nor can medical procedures restore normal function. The sensory hair cells are responsible for initiating the neural impulses that carry information to the brain regarding the sounds in our environment. The human cochlea has one row of inner hair cells and three rows of outer hair cells. The outer rows of hair cells run the length of the cochlea and have sometimes been viewed as the site of sensitivity for very low-intensity sounds near our hearing threshold. The hair cells responding to the higher frequency sounds are located nearer the basal end of the cochlea, and those most sensitive to lower frequency sounds are found toward the apical end of the cochlea.

Some exposures to noise or other ototraumatic agents lack sufficient intensity or duration to result in permanent damage to the auditory system. At these subtraumatic doses, the auditory system exhibits a temporary shift in hearing sensitivity that returns to normal with time away from the hazardous exposure. However, when the ototraumatic exposure results in the destruction of auditory hair cells, the loss of hearing is permanent. After the sensory hair cells that respond to a given frequency are destroyed, we no longer hear the sounds at that frequency.

Hair cell damage from noise usually affects the rows of outer hair cells before damaging the inner hair cells. The hair cells sensitive to high frequencies in the basal turn of

the cochlea are more susceptible to noise-induced damage than are hair cells in the apical end of the cochlea. As a consequence of the difference in relative susceptibility of hair cells to trauma from noise exposure, the early stage of noise-induced hearing loss usually is characterized by decreased ability to hear very soft high-frequency sounds.

Noise-induced hearing loss usually occurs gradually, unless there is exposure to extremely intense sound. In the early stages of hearing loss, changes in sensitivity resulting from noise exposure may be detectable only by audiometric testing. Without a hearing test to identify the beginning of a loss in auditory sensitivity, the subtle destruction of the auditory sensory cells progresses with continued exposure to noise until the resulting hearing loss begins to impair the person's ability to communicate or hear necessary sounds.

Hearing loss due to combined exposures to noise and other factors

It is clear that some workplace chemicals are damaging to the auditory system and can cause or aggravate work-related hearing loss. These include chemicals having neurotoxic potential, such as organic solvents and heavy metals. Other suspect factors include heat and hand-arm vibration. The scope of this chapter does not permit an overview of this subject matter. However, references on ototoxic chemicals are included in the Further Reading.

NON-AUDITORY EFFECTS OF NOISE EXPOSURE

Excessive exposure to noise is also thought to be an environmental stressor, independent of the problems of hearing loss. Accordingly, most of the research on the non-auditory effects of noise has focused on physiologic functions that may be influenced by the stress induced by noise exposure. The suspected mechanism for stress is heightened activity of the sympathetic nervous system, resulting in increased levels of 'stress' hormones, such as cortisol and catecholamines. These stress-induced physiologic functions include behavioral, reproductive, sleep, and cardiovascular responses.

Psychological effects of noise

Annoyance, irritability, and performance decrement have been associated with noisy work environments. Annoyance is reported more often in response to higher intensity sound levels and longer exposure times. Irritability increases when the noise is unpredictable and uncontrollable.

Loud noise in the workplace has been associated with increased accidents and lower productivity rates. However, the results of laboratory studies have failed to define clearly the effect of noise on task performance. In fact, some levels of background noise have been shown to improve task performance. Noise may also play a role in exacerbating symptoms related to indoor air quality (see

Chapter 50). Increased rates of non-specific symptoms, such as fatigue among building inhabitants, have been associated with increased background noise levels.²

Reproductive effects

The literature concerning the effects of occupational noise exposure on human pregnancy is sparse. Studies in rodents, however, have shown that excessive noise exposure is related to decreased fetal weight and increased litter resorption. These effects occur simultaneously with increases in plasma and uterine catecholamine levels, resulting in vasoconstriction. The reduced blood flow to the uterus can, therefore, cause these adverse reproductive effects. However, experimental studies in large mammals have not demonstrated an effect of noise exposure on the pregnancy outcome.

Clinical studies of noise measurements in utero have shown an average noise attenuation of 10–15 dB at frequencies near 4–5 kilohertz (kHz). Low-frequency sounds (0.125 kHz) have been shown to be enhanced in utero by an average of 3.7 dB. Given the low attenuation, it is plausible that there are direct effects of noise exposure to the fetus.

A cross-sectional Canadian study of auditory damage after perinatal noise exposure investigated the hearing of children aged 4–10 years. Based on maternal noise exposure during pregnancy, a three-fold increased risk was found for high-frequency hearing loss in children whose mothers were exposed to noise of 85–95 dB. There was also a significant increase of hearing loss specifically from low-frequency noise exposure. The study also found an interactive effect with other contributors to hearing loss, including jaundice or incubation at birth. Other factors that may have led to hearing loss after infancy were not controlled for in this study.

However, no clear evidence exists for an effect of noise on most reproductive outcomes. Given the noise levels found in utero, the most plausible adverse effect is auditory damage in children. More studies are needed to confirm this.

Sleep disturbance due to noise

The effect of environmental noise on sleep, while not studied extensively, is a common concern expressed by the public. Some estimates indicate that as much as a third of the urban population rates sleep disturbance as the most annoying effect of noise. Intermittent noise is more likely to decrease the duration of deep sleep while continuous noise may actually increase the percentage of time in deep sleep. Despite these effects on sleep patterns, research has not conclusively shown that sleep disturbance resulting from noise causes chronic health effects.

Cardiovascular effects of noise exposure

As early as the 1970s occupational noise exposure was associated with increased blood pressure, but nearly 30 years

later the role of noise exposure on blood pressure and/or hypertension remains unclear.³ In laboratory animals, brief noise exposure produces an acute elevation of blood pressure and a chronic elevation from long-term noise exposure.^{4,5} Experimental studies in humans have also shown short-term increases in diastolic pressure in subjects exposed to noise between 90 and 100 decibels.⁶ A possibility exists that long-term increases in blood pressure due to noise could lead to chronically elevated blood pressure. The suspected mechanism is increased activity of the sympathetic nervous system and increased levels of hormones, such as cortisol.^{6,7}

Given that exposure to high noise levels is common, any relation between noise and increased blood pressure has potentially large public health significance. Studies suggest an increase in blood pressure of approximately 2 millimeter mercury (mmHg) is due to noise exposure above 85 dBA. It is estimated that a 2 mmHg reduction in diastolic blood pressure would result in a 17% decrease in the prevalence of hypertension, a 6% reduction in the risk of coronary disease, and a 15% reduction in risk of stroke.⁸ Although not conclusive, studies have found positive relationships between noise (or hearing loss) and hypertension. The more relevant studies are reviewed briefly below:

Tarter et al. studied 150 white men and 119 black men in the United States who had been exposed to noise at or above 85 dBA for at least 5 years. Hearing impairment and years worked were both significantly related to blood pressure and the prevalence of hypertension among black workers (32%), but not white workers (22%).⁶

Green et al. studied 162 noise-exposed male workers in Israel. Average diastolic blood pressure (DBP) and systolic blood pressure (SBP) were significantly higher among the high-noise exposed versus (vs) the low-noise exposed. No differences were seen for older workers.⁹

Hirai et al. conducted a study of noise and blood pressure among 868 male Japanese workers. Current blood pressure measurements were compared with measurements from 10 years earlier. There were no noise-associated differences in current blood pressure, blood pressure over time, or current hearing impairment and hypertension.⁴

Zhao et al. evaluated 1101 Chinese female textile workers. Current noise level, family history of hypertension, and a high-salt diet were significant predictors of hypertension, while years worked had no effect.¹⁰

Tomei et al. investigated 75 high-noise exposed and 225 low-noise exposed Italian workers. The high-noise exposed group had significantly increased hypertension (20% vs 8%). Hypertension was also significantly increased in those with hearing loss. The most marked increase in hypertension occurred in those with longer high-noise exposures.

Lang et al. studied 1844 male French workers, of whom 346 were exposed to noise at or above 85 dBA. Mean blood pressure was no higher in the high-noise group. However, it was significantly higher for workers with more than 25 years employment.¹¹

Figaro et al. examined 8078 Italian workers exposed above 80 dB and 733 workers exposed below 80 dB.

Significantly higher blood pressures were found in the high-exposed group, especially for those aged 50–60. The high-exposure group had a significantly greater prevalence of hypertension, especially in older workers.¹²

Hessel and Sluis-Cremer studied 2197 South Africa miners for noise and blood pressure over a 30-year period. These authors found no differences in blood pressure related to noise either cross-sectionally or longitudinally.¹³

Kristal-Boneh et al. conducted a cross-sectional study of 3105 Israeli noise-exposed workers. No effect of noise level was found on blood pressure. However, heart rate increased during the workday for those with high-noise exposures, but not for those with low-noise exposures.¹⁴

Sokas et al. used records to study 2135 men in a variety of companies with high-noise levels in the Middle East. Approximately one-third of these workers had some degree of hearing loss. Hearing loss predicted an increase in resting blood pressure predominantly in the younger-aged group and within certain ethnic groups.¹⁵

Talbott et al. investigated 329 males in a high-noise exposure plant and 314 males in a low-exposure plant. Cumulative noise exposure was a significant predictor of blood pressure at the high-exposure plant, but not at the low-exposure plant.

Melamed and Bruhis studied 35 industrial workers exposed to noise levels above 85 dBA and measured their urinary cortisol. Cortisol, a stress hormone, usually peaks in the morning and then declines during the day. The workers wearing hearing protection experienced decreasing cortisol levels during the day as expected. Those not wearing hearing protection experienced cortisol levels at the end of the day that were similar to pre-work morning measurements and significantly higher than expected.⁷

The literature suggests an effect of noise on hypertension, but the studies are not conclusive. Two studies found effects only in those with long exposures (presumably older workers), while two found effects predominantly in younger workers. One study found effects only in blacks, but not whites.

Vibroacoustic disease

Recent studies have examined the effects of long-term exposure to large pressure amplitude and low frequency (LPALF) noise (noise ≥ 90 dB TWA, ≤ 500 Hz).¹⁶ Such exposures may occur in certain aviation and aerospace settings. A number of extra-auditory effects have been reported, including neurological and cardiovascular degenerative changes. The number of individuals studied to date remains small, and a clear cause-and-effect relationship remains to be established.

PREVENTION OF NOISE EXPOSURE IN THE WORKPLACE

Attempts by industry to reduce noise exposure in the workplace usually focus on reducing the risk of noise-induced hearing loss. Efforts to prevent occupational noise-induced hearing loss are essential when one considers the numbers

of workers exposed to occupational job-related noise and the proportion who suffer hearing loss as a consequence.

Regulations for hearing conservation in the workplace

The Occupational Safety and Health (OSH) Act requires that workers be protected from excessive noise exposure. The original 1971 standard laid the foundation for a control strategy that was updated and detailed in 1983. Although obviously this standard applies only to American workers covered by OSHA, the basic principles apply to all settings in which noise exposure threatens health.

1971 OSHA noise standard

The 1971 OSHA noise standard requires that workers not be exposed to noise in excess of 90 dBA, TWA for 8 hours. Higher dBA levels are permitted (not to exceed 115 dBA), but each increase of 5 dBA reduces the permitted exposure time by 50%, e.g., 95 dBA for 4 hours or 100 dBA for 2 hours. This relationship between noise level and exposure time is referred to as the 5-dB doubling rate. Table 35.5 gives an expanded list of allowable noise exposures. Exposure to impulse or impact noise is limited to a peak pressure of 140 dB. The 1971 standard requires that a hearing conservation program be instituted whenever noise exposures exceed the allowable noise exposure; however, it does not specify the required components of an effective hearing conservation program.

1983 Hearing Conservation Amendment

In 1983, OSHA amended the 1971 noise standard. The 1983 amendment includes details of the components of an effective hearing conservation program and requires that a program be initiated when worker noise exposures exceed 85 dBA, TWA. The OSHA-mandated hearing conservation program includes monitoring noise exposure, periodic hearing testing of noise-exposed workers, applying noise abatement and/or administrative controls, providing hearing protectors to employees, offering an employee education program, and keeping records.

Monitoring

The company is required to identify workers whose noise exposure exceeds the limits defined in the 1971 noise stan-

dard. Workers have the right to observe, or have a representative observe, the noise assessment procedures. Assessment of the noise exposure may be accomplished by using a variety of instruments, e.g., basic sound-level meters, noise dosimeters, integrative sound-level meters, and graphic level recorders. It is possible for people with simple devices and limited training in noise measurement to determine whether the occupational noise environment requires that workers be included in a hearing conservation program. However, it is appropriate to consult a professional who has extensive experience in noise measurement to obtain a precise description of the work area noise map and to determine the effectiveness of noise control or the administrative changes on the workers' noise exposures.

Periodic audiometry

Under the standard, hearing testing must be provided annually at no cost to workers exposed to 85 dBA, TWA or more. Specific procedures are mandated for daily, yearly, and biannual audiometer calibration. Audiometry must be provided by a qualified tester (audiologist, physician, or technician) or supervised by an audiologist, physician, or otolaryngologist. Initial audiograms serve as a baseline reference against which subsequent audiograms are compared. An average shift of 10 dB at 2000, 3000, and 4000 Hz is referred to as a standard threshold shift (STS). If STS is determined to have occurred, the worker must be notified in writing of the STS, retrained in hearing protector use, and refitted with hearing protectors.

Noise control

OSHA requires that 'feasible' engineering or administrative controls be implemented to reduce noise exposures that exceed the permissible exposure limits (PELs). Only if such controls do not reduce noise sufficiently can hearing protection be considered. The methods of preventing workers from suffering hearing loss as a result of exposure to loud noise in the workplace are the following, in order of preference.

1. Noise reduction by engineering controls that decrease the noise emitted to the work environment from sources.
2. Administrative or work practice controls that involve limiting the amount of time each worker spends in a noisy environment so that the overall exposure meets the noise standard.
3. Hearing protection wherein the worker wears an earmuff or plug, attenuating the noise at the ear to a permissible level below the standard.

Engineering controls are vastly preferred because they address the elimination of a hazard, making all the complex programs required to track and limit the damage completely unnecessary. Engineering controls reduce the noise in the environment by a change in the process or its machinery, such as damping a vibrating part, replacing noisy metal gears by quieter plastic ones, muffling an air discharge, or myriad other options. When the noise cannot be eliminated or reduced at the source, enclosures

Duration per day (hours)	Sound level dBA slow response
8	90
6	92
4	95
3	97
2	100
1.5	102
1	105
0.5	110
0.25 or less	115

Table 35.5 Permissible noise exposures

of noise-attenuating material can be constructed to reduce the amount of noise escaping into the environment, thus reducing the number of noise-exposed workers to those who must be close to the source. Noise-absorbing surface coatings or baffles can reduce overall noise levels by reducing reverberation. This is generally only effective when used in conjunction with a method of source reduction.

The effectiveness of noise controls is dependent on the source (type) of the noise and its frequency. Noise reduction is often a complex and difficult task, but much has been learned. Effective controls for more processes are constantly being developed.

Administrative controls are not favored because they are based on the unproved assumption that the effects of noise are linear with respect to time and consistent over frequencies, as weighted in decibels on the A scale. Furthermore, careful limitation of the amount of time each worker spends in noisy areas is extremely cumbersome to enforce. Maintenance workers, for example, are sent where they are needed when they are needed. To restrict an electrician from entering a noisy area to fix a needed production machine because he or she has already received his or her noise quota is difficult.

Hearing protectors

Hearing protection is not an optimal solution. Major drawbacks to hearing protectors are that they must be worn to be effective and that they must fit properly. Many people find hearing protectors uncomfortable and annoying and resist wearing them. To encourage acceptance, a variety of types of hearing protectors should be provided, allowing workers to choose those that are most comfortable. Training is necessary to ensure that hearing protectors are worn correctly. Hearing protection is more effective at attenuating higher frequency noise. Some are designed to be particularly effective against certain frequencies. If an individual already has a high frequency hearing loss, a 'flat attenuation' hearing protector may be more appropriate. The two types of common hearing protection are:

1. Earmuffs that cover the external ear. They also must sit firmly against the head, leaving no opening for the noise to pass through.
2. Ear plugs that fit into the external ear canal. Disposable plugs are made of foam or batting. Premolded plastics in all shapes, colors, and sizes are available, as are custom-molded plugs. They must be correctly inserted.

When hearing protection is required by OSHA, it must be sufficient to reduce noise levels to or below the TWA of 85 dB. The acceptability of a given ear plug or earmuff may be determined using the noise reduction rating (NRR) that is provided with every type of hearing protector. The noise dose, as measured by a dosimeter with a C scale, is converted to a TWA in decibels. The NRR is then subtracted from the dose in decibels, and the result must be less than 85 dB to be acceptable. If no C-weighting scale is available and an A-weighting network dosimeter is used, a factor of 7 dB must be subtracted from the NRR before it is subtracted from the exposure. For example, if the 8-hour

TWA exposure measured on the A scale is 105 dBA and the NRR is 29, the effective attenuation is 29 dB minus 7 dB = 22 dB. The level of protection is then 105 minus 22 = 83 dB, which is acceptable to OSHA. This 'de-rating' of the NRR is employed because the NRR has been found to correlate poorly with the actual attenuation obtained by workers on the job.

Education and record keeping

All employees mandated to be in the hearing conservation program are required to receive education annually concerning the effects of noise on hearing, information regarding the purpose of audiometric testing, and correct personal hearing protection use.

The standard also requires records to be kept of noise assessments (2 years) and audiometric tests (for the period of employment). These records are to be made available upon request to the employee or his/her representative. The records are to be transferred to, and maintained by, new owners, should the company be sold.

CONCLUSION

Since noise-induced hearing loss is a cumulative process, strategies to prevent occupational hearing loss must also take into account non-occupational noise exposures. Education to inform individuals about hazards of exposures to noise from firearms, amplified music, and recreational machinery, including chain saws and snowmobiles, is important. Individuals should wear hearing protection when unable to avoid such noise sources. For other sources of non-occupational noise, such as aircraft and traffic noise, community noise ordinances may provide guidelines about necessary exposure limits, especially during sleeping hours.

Dedication

Dr Derek Dunn died while this chapter was in press. During his long and productive tenure at NIOSH, he was a major force in advocating research and prevention of noise induced hearing loss and was a mentor and friend to many. His passing, in mid-career, was a major loss to the field.

Chapter 36

Baromedicine

Louis F James, Gabrielle Morris, David A Youngblood

INTRODUCTION

Continuing technologic advance has led mankind commercially, academically and recreationally into previously prohibited environments. Ambient barometric and hydrostatic pressure changes have a profound influence on physiology and therefore human performance and health. Baromedicine is still emerging as a discrete discipline. It is a conglomerate of related elements of engineering science, hyperbaric medicine, undersea diving medicine, aviation medicine, space medicine, high altitude medicine, and all of their underlying basic sciences. These disciplines share common concerns stemming from the effects on humans and their activities of significant departures from the ambient pressures experienced between sea level and modest elevations. The body of information it contains has grown rapidly in recent years.

While this co-operative effort has been essential, it has produced some unfortunate difficulties, such as a dozen more or less equivalent units of pressure encountered in the literature, a result of parochial traditions in the contributing disciplines. The subject encompasses some important clinical entities and a few less so. Since Paul Bert's seminal work of 1878,¹ no monograph on the subject has been forthcoming, although the body of information is sufficient to warrant it, and human progress continues to advance on an exponential scale as we continue to press the pressure frontier which is so fraught with risk.

HISTORY

This chapter is intended as an overview, and the more serious reader is directed to the sources listed at the end for more exhaustive treatments of specific aspects of baromedicine. Humans have undoubtedly experienced the effects of large barometric pressure variations since they developed sufficient awareness and ventured up mountains and into and under the sea, but scant early reference to problems encountered exists. In the late 16th century, Spanish travelers in the Peruvian Andes first clearly reported the phenomenon of mountain sickness.² True appreciation, however, began only with the 17th and 18th century formulations of the basic laws of classical physics, leading to understanding of the atmosphere, and consequently, ambient pressure. The inquisitive mind of Robert Boyle in 1670 observed and reported on a moving bubble in the unblinking eye of a snake he had placed in a vacuum chamber, but did not elaborate on the finding.³ The development of underwater diving apparatus for salvage and

construction, and the caisson for bridge and tunnel building in the 19th century exposed large numbers of individuals to increased ambient pressure, with the emergence of decompression sickness, first known as caisson worker's disease, which became well recognized with high attack rates resulting in frequent disability and death. Simultaneously, hydrogen and hot air balloons were invented and, with the extreme altitudes attained, resulted in profound hypoxia and death, even with the experience of simulated altitude training in a pressure chamber and supplemental oxygen aboard.¹

Paul Bert, in France, trained in engineering, law and medicine, became interested in pressure physiology, and systematically investigated it. In 1878, after 8 years of intense work, he published his definitive and seminal work, *La Pression Barometrique, Recherches de Physiologie Experimentale* (Barometric Pressure, Researches in Experimental Physiology)¹, and in so doing became the unquestioned founder of the field of pressure medicine and physiology. The work is a monograph of 1178 richly illustrated pages containing an exhaustive literature review that completely summarized all known and theoretical information on the subject, as well as detailed descriptions of 670 ingenious and meticulously executed original experiments, encompassing the entire pressure spectrum. His discussions were superbly reasoned and his conclusions so sound and comprehensive that they remain scarcely challenged to the present. The work stands today not only as a monumental scientific achievement, but also as an exemplary model of scientific investigation, and there has been no serious attempt to comprehensively update it.

In the intervening century or more since Bert, major strides have been made expanding on his work. Work exposures to depth and decompression rates were adjusted to reduce the incidence of decompression disorders. Workers had long reported amelioration of decompression symptoms upon returning to work under pressure. Although as early as 1854 Pol and Watelle,⁴ in France, recommended repressurization as therapy for decompression sickness, there is no record of it being employed until 1889 when Moir constructed and proved the effectiveness of a treatment chamber.⁵ By 1909 this had been confirmed and reports by Keays^{6,7} had made the use of treatment chambers routine. J. S. Haldane, in 1907, working on commission by the British Royal Navy, published the first theoretically based and successful decompression procedures for diving. His work has formed the basis for all modern refinements.

In the 1920s, aviation medicine was born of necessity and formalized in the 1940s, with the natural extension to space in the following decades. The unanticipated frequency of decompression sickness in aviators flying high-altitude military missions over Europe in the 1940s led eventually to the design of pressurized cabins in commercial and military aviation. The pressure-related discipline of undersea medicine, somewhat younger, was formally established in the 1960s. Although the advantages of 100% oxygen breathing had been known since Bert, it was only then that it was incorporated into decompression sickness treatment protocols, drastically reducing long treatment times and improving outcomes.⁸ Today, the new field of hyperbaric medicine, primarily concerned with the therapeutic effects of tissue oxygen tensions elevated by pressure delivery, has been established.⁹ Altitude (terrestrial) medicine is also coming of age, with increased understanding of low pressure environments.

Even today, however, with a sophisticated understanding of pathophysiology and stringent safety measures, work protocols and on-site treatment facilities in most industrial and military diving operations, decompression illness regularly occurs, resulting in serious permanent sequelae. In recreational diving, with its large number of exposures and where fitness, training and operational safety standards cannot possibly meet those of industry and the military, such mishaps are far more frequent. The hazards of extreme ambient pressure environments will continue to pose a serious challenge far into the future.

PHYSICS

An appreciation of the direct and indirect effects of pressure on human physiology requires a basic understanding of gas physics, including Boyle's, Dalton's, and Henry's laws. Below is a brief description of these. More in-depth treatments of this topic are available in texts devoted to physics.

Boyle's law

Robert Boyle, physicist and chemist of the late 1600s, described the inverse mathematical relationship between gas pressure and volume. Holding temperature and amount constant, as pressure is increased the volume of a gas decreases. Conversely, as pressure is decreased the volume of a gas increases (Table 36.1). A useful form of Boyle's mathe-

matical formula is: $P_1V_1 = P_2V_2$, where P is pressure and V is volume (subscripts denote beginning and ending values respectively).

Dalton's law of partial pressures

Dalton explained the relationship between total gas pressure and the partial pressures of the individual component gases of the mixture, all of which add up to equal the total pressure. Gases in the atmosphere (air), include nitrogen (N_2), oxygen (O_2), helium (He), hydrogen (H_2), carbon dioxide (CO_2), argon (Ar), carbon monoxide (CO), and other trace gases. The partial pressure of each is denoted by the capital letter 'P' in front of the gas symbol. For example PO_2 is the symbol for the partial pressure of oxygen. Partial pressures change relative to depth or altitude. The percent or fraction of a gas in a mixture is denoted by the capital letter 'F' in front of the gas symbol. For example FO_2 is the symbol for the fraction or percentage of oxygen in the gas mixture. The sum of all fractions or percentages must always equal one, or 100%, respectively. The fraction of a gas does not change with depth or altitude. The partial pressure of a gas (Pg) is equal to the total pressure (P) times the fraction or percentage of the gas (Fg):

$$P \times Fg = Pg.$$

Although various mixes of gases are used in commercial diving, the gas mix most commonly used by divers is air, composed almost entirely of nitrogen ($FN_2 \approx 0.79$ or 79%), and oxygen ($FO_2 \approx 0.21$ or 21%) (Fig. 36.1). At the surface, where the total pressure is 1 atmosphere absolute (1 ATA), the partial pressures of oxygen and nitrogen are calculated as follows (for these examples, the pressure unit ATA is used, however other pressure units may be used):

$$\begin{aligned} \text{oxygen: } P \times FO_2 &= PO_2; 1.00 \text{ ATA} \times 0.21 = 0.21 \text{ ATA} \\ \text{nitrogen: } P \times FN_2 &= PN_2; 1.00 \text{ ATA} \times 0.79 = 0.79 \text{ ATA} \end{aligned}$$

At a depth of 33.08 FSW, or 2 ATA, the partial pressures of oxygen and nitrogen are calculated as follows:

$$\begin{aligned} \text{oxygen: } P \times FO_2 &= PO_2; 2.00 \text{ ATA} \times 0.21 = 0.42 \text{ ATA} \\ \text{nitrogen: } P \times FN_2 &= PN_2; 2.00 \text{ ATA} \times 0.79 = 1.58 \text{ ATA} \end{aligned}$$

Determination of partial pressures for gases in mixtures other than air is easily accomplished by applying the partial pressure formula (Table 36.2).

ATA (atmospheres absolute)	Depth (FSW/MSW) or altitude (feet/meters)	Relative volume	Relative bubble diameter (%)
0.5	18,000 feet / 5486 meters	2	126%
0.7	10,000 feet / 3048 meters	1.4	112%
1	0	1	100%
2	33.08 FSW / 10.03 MSW	1/2	79%
3	66.16 FSW / 20.26 MSW	1/3	69%
4	99.24 FSW / 30.39 MSW	1/4	63%
5	132.32 FSW / 40.52 MSW	1/5	58%

Table 36.1 Pressure and volume at altitude and depth. FSW, feet of seawater; MSW, meters of seawater.

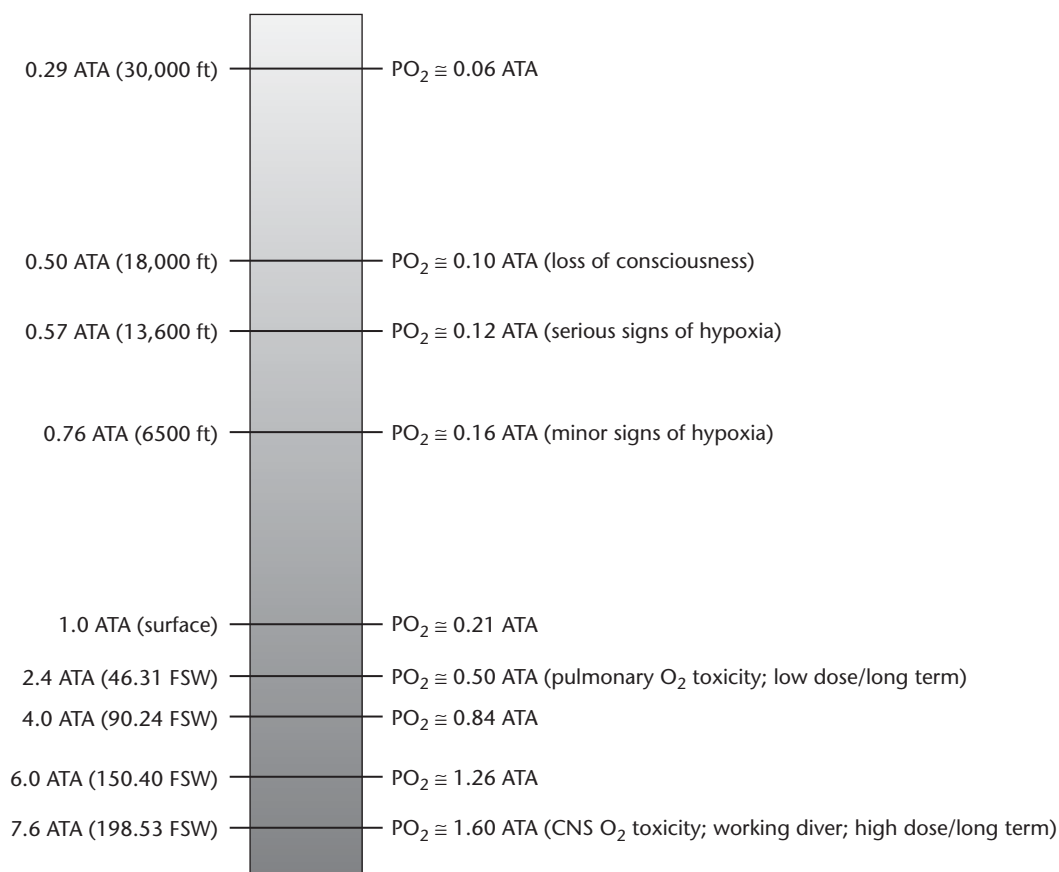

Figure 36.1: PO₂ at altitude and depth

Total pressure ATA (atmospheres absolute)	Depth (FSW/MSW) or altitude (feet/meters)	FO ₂ / PO ₂ (air)	FN ₂ / PN ₂ (air)
0.19	40,000 feet / 12,192 m	0.21 / 0.04	0.79 / 0.15
0.3	30,000 feet / 9144 m	0.21 / 0.06	0.79 / 0.24
0.5	18,000 feet / 5486 m	0.21 / 0.11	0.79 / 0.40
0.7	10,000 feet / 3048 m	0.21 / 0.15	0.79 / 0.55
1	0	0.21 / 0.21	0.79 / 0.79
2	33.08 FSW / 10.03 MSW	0.21 / 0.42	0.79 / 1.58
3	66.16 FSW / 20.26 MSW	0.21 / 0.63	0.79 / 2.37
4	99.24 FSW / 30.39 MSW	0.21 / 0.84	0.79 / 3.16
5	132.32 FSW / 40.52 MSW	0.21 / 1.05	0.79 / 3.95

Table 36.2 Partial pressures of oxygen and nitrogen at altitude and depth. FSW, feet of seawater; MSW, meters of seawater.

Henry's law

Henry's law states that the amount of a gas that dissolves in, or is given off from, a liquid is proportional to the partial pressure of that gas at the liquid's surface. This forms the basis of our understanding of decompression theory and decompression sickness. As an air-breathing diver descends, the ambient pressure increases and the PN₂ in the diver's lung increases according to Dalton's law of partial pressures. This creates a N₂ gradient between the diver's lungs and blood. Per Henry's law, under these conditions N₂ dissolves into the blood. From the blood, N₂ dissolves into other body tissues at varying rates depending on the N₂ solubilities of different tissues (called

compartments). If the diver remains at a particular depth and pressure, eventually N₂ equilibrium will be reached, and the diver becomes 'saturated'. There will be no further gain or loss of N₂ as long as the diver remains at 'saturation' (stable depth and pressure). Most dives do not achieve saturation, as this takes many hours.

At the conclusion of the dive, the diver begins to ascend and ambient pressure decreases. As ambient pressure decreases so does the PN₂ in the diver's lungs, thus creating a N₂ gradient, now in the opposite direction. In response to this gradient, N₂ moves out of the diver's blood. A slow ascent, perhaps with periodic stops (called decompression stops), may allow N₂ to pass from the blood into the lungs without significant clinical bubble formation.

However, a more rapid ascent may allow N₂ bubbles to form in the blood or tissues causing a pathologic condition known as decompression sickness (DCS), or 'the bends'. Dive tables were developed in an effort to provide the diver with guidelines regarding depth, dive time, ascent rate, and decompression stops, which generally aid in the prevention of DCS; however, they do not guarantee against its occurrence. The amount of gas that will dissolve in a liquid or tissue (C), is equal to the solubility constant (k) for the particular liquid or tissue, multiplied by the partial pressure of the gas (P_g, measured in ATA) at the liquid's surface:

$$C = k \times P_g$$

All gases behave in this manner. However, metabolized gases such as O₂ generally do not cause DCS.

FITNESS TO DIVE

Human physiology is affected by changes in pressure. Some effects may be pathologic, potentially causing disease, injury, or even death. Additionally, some medical conditions that may be well managed or relative annoyances on dry land may be life threatening in the underwater environment. Evaluation of fitness to dive is therefore an important component of the occupational medicine physician's role in support of patients who are considering or are already engaged in this activity.

Diving is generally a shared activity, and the interdependency between team divers may place all at risk should one become incapacitated. Unlike recreational diving, which is for the most part an optional activity (i.e., does not have to be done if one is not feeling well or if environmental conditions are not favorable), occupational diving usually demands participation at the convenience of the employer or the needs at hand. Additionally, unlike recreational diving, occupational divers may be called upon to dive in relatively unfriendly conditions. This is particularly true for public safety divers who may dive during conditions in which someone has become lost or injured, or has died.

Approach

In general, any condition that may predispose a potential diver to altered or loss of consciousness, interfere with the ability of gas to expand or contract (per Boyle's law), or cause erratic or irresponsible behavior may be disqualifying. Additionally, SCUBA diving, like any potentially strenuous physical activity, requires a level of general physical fitness appropriate for safe participation.

Age

Minimum age

Though children are not likely to present for occupational diving fitness evaluation, the practitioner may be asked to

evaluate a child for participation in recreational dive training or academic dive activities (summer camps, school programs, etc). Very little data exist regarding how children are affected by hyperbaric exposure and decompression relative to adults. Potential areas of concern include the relatively high prevalence of asthma in children when compared to adults. Additionally, the effects of 'silent' bubbles on bony epiphyses are unknown. It is not known if children are at an inherently greater or lesser risk for decompression illness, or if they experience decompression illness differently than adults. Behavioral issues exist as well. Additionally, the child must possess the capacity to understand and appreciate the risks of diving. It is vital that all divers possess the physical, emotional, and intellectual ability to learn unique skills, become proficient at them, and then judge their appropriate use. Further study is needed in order to address the questions of risk, injury, and long-term sequelae.

Advanced age

By and large, existing diving fitness guidelines focus on medical and physical criteria rather than upper age limit. People who meet the medical and physical criteria are generally deemed fit to dive, regardless of advanced chronological age.

Cardiac

Generally speaking, any organic heart disease may be cause for rejection unless it is considered by a cardiologist to be hemodynamically unimportant. Cardiovascular disqualifiers include ischemic heart disease, all types of cardiomyopathies, hemodynamically significant valvular disease, cyanotic heart disease, and any rhythm disturbance that might cause in-water incapacity.

Murmurs

Innocent murmurs are common in children, and decline in adolescence. The older the subject, the less likely that the murmur is innocent. Therefore, any murmur heard should be presumed 'guilty until proven otherwise'.

Cardiomegaly

Cardiomegaly should be evaluated prior to clearance to dive. The very fit may have large ventricular volumes and therefore 'innocent' cardiomegaly. The physician is cautioned against making this assumption, and an assessment should be done.

Valvular disease

Significant stenosis of valves is generally disqualifying for diving. Patients with valvular stenosis may have difficulty increasing their cardiac output in response to exercise stress. Mitral stenosis is associated with an increased risk for atrial fibrillation and the development of systemic emboli and strokes. Additionally, the physician must consider the likelihood of further deterioration of the valve over time. Immersion causes high central blood volume which, when coupled with mitral stenosis, may lead to increased risk for

pulmonary edema. Aortic stenosis may lead to angina, syncope, and heart failure. Mitral valve prolapse is common and usually not a disqualifying condition, if asymptomatic. The issue of diving after valve replacement is best addressed by a cardiologist. Considerations include post-replacement medications (anticoagulants), associated problems (chamber enlargement, risk for emboli or arrhythmia), chest surgery vs percutaneous pulmonary valvotomy. These cases need to be considered on their own merits.

Hypertension

High blood pressure is associated with multiple conditions including stroke, coronary artery disease, infarcts, angina, aortic aneurysm, peripheral vascular disease, and other end-organ disease. These conditions may cause sudden incapacity, which may be devastating in the underwater environment. The risk for these events increases as hypertension becomes worse or is left uncontrolled. Additionally, some antihypertensive medications such as betablockers may reduce exercise capacity. The National Oceanic and Atmospheric Administration (NOAA) Diving Program 'cut-off' resting blood pressure is 145/90 mmHg on repeated examination.¹⁰

Ischemic heart disease

Patients with symptomatic ischemic heart disease are predisposed to significant problems including angina, sudden death, and arrhythmias. These may cause sudden incapacity. Any evidence of coronary insufficiency or myocardial ischemia is disqualifying. Grafts do not usually result in complete revascularization and about 20% are occluded after about one year. Risk of reocclusion of a single vessel 'opened' by angioplasty is highest during the first 3 months after the procedure. Therefore after successful surgery, patients may be fit to dive after a period of observation.

Arrhythmias

Arrhythmias other than sinus arrhythmia and ventricular extrasystoles should be evaluated by a cardiologist. Other EKG findings of concern include, but are not limited to, pathological Q waves, ST segment elevation and depression, and should be evaluated as well.

Shunts

There is some evidence, though not conclusive, suggesting an association of intercardiac shunts, such as patent foramen ovale, which may allow bubbles to enter the arterial circulation leading to increased risk for decompression illness, particularly arterial gas embolism (AGE).¹¹

Pulmonary

Asthma

Several theoretical concerns exist regarding asthma and diving, including the potential effects of airway obstruction. Traditional concern regards air trapping and the risk

of embolization on ascent. There may be some evidence that asthmatics are over-represented in the statistics from the Divers Alert Network (DAN) data on diving fatalities.¹² However, the data do not clearly support that the cause of the deaths was directly asthma related. It may be that asthmatics are at higher risk for decompression illness. Additional study is needed in this area. Also at issue is whether or not an individual with asthma has adequate exercise tolerance to safely participate in strenuous underwater diving activities. In addition to strenuous exercise, underwater diving typically involves breathing cold, dry air, and the potential for water aspiration, which may trigger an asthmatic episode.

Some diving medicine physicians utilize challenge testing in an attempt to simulate some of the stresses to which divers are exposed. At a minimum, divers with a history of asthma should undergo exercise challenge and spirometry. Those who have significant exercise-induced bronchoconstriction are at increased risk for exercise intolerance and therefore should not dive. Methacholine challenge testing is not as helpful in the determination of diving fitness.

Chest x-rays

Until recently chest films were a routine part of the initial diving fitness evaluation, and at regular intervals thereafter, often annually. While initial evaluation may reveal previously undetected pulmonary or cardiac abnormalities, subsequent radiographs have not been shown to be of significant value. More recent guidelines suggest initial radiography, and thereafter chest radiography should not be carried out as routine, but rather at the discretion of the examining diving physician.¹³

ENT

Ears

The diver must be able to equalize middle ear pressures on demand. This is usually accomplished by a gentle Valsalva maneuver, forcing air through the Eustachian tube into the middle ear. This ability can be confirmed during physical exam by direct otoscopic observation of TM movement with Valsalva maneuver. Both TMs should appear healthy and move crisply with this maneuver.

Perforations not completely healed and closed are disqualifying, and should be evaluated by an otolaryngologist. Likewise, an otolaryngologist's opinion should be sought for potential divers who have undergone surgical tympanic membrane repair or other significant otic procedures. Due to the potential for hearing loss due to barotrauma or DCS, audiometric evaluation is necessary for baseline and periodic assessment.

Acute otitis media is a temporary disqualifier. Once resolved with no indication of residual Eustachian tube dysfunction, the diver may resume diving. Chronic otitis media may be disqualifying, and should be evaluated by an otolaryngologist. Acute mild external otitis is not an absolute disqualifier, though treatment is generally more effective if water exposure is curtailed. Treatment regimes

include antibiotic eardrops, combination antibiotic-topical steroid drops, and topical acidifying preparations including Domoboro's solution, acetic acid drops, and boric acid powder. Divers with recurrent external otitis should be evaluated further, including culture and appropriate antibiotic treatment. Many occupational divers use preparations including Domoboro's solution or boric acid powder in an effort to prevent external otitis. During periods of daily immersion, boric acid powder may be gently puffed into the external ear canal once a day using an ear syringe.

Nose and sinus

In order to allow for pressure equalization, sinus openings must be patent. Polyps or other blockages may lead to inability to equalize with changing pressure. Temporary blockage may occur during upper respiratory tract infections or allergic rhinitis. These conditions are usually only temporarily disqualifying. Chronic or structural blockage should be evaluated by an otolaryngologist familiar with diving medicine. Chronic or seasonal allergic rhinitis are often treated with the long acting 'non-sedating' antihistamines. With adequate control of symptoms, and the ability to crisply autoinflate the middle ears, these conditions are generally not disqualifying. In contrast, treatment with shorter-acting medications such as some over-the-counter cold remedies may relieve symptoms temporarily, even allowing for adequate autoinflation. However there exists a real risk that the medication effects may 'wear off' at depth, allowing blockage, potentially leading to air trapping on ascent and subsequent barotrauma. Therefore, the use of these medications is generally discouraged.

Oropharynx

The diver must be able to hold a regulator mouthpiece securely with adequate bite and lip seal. Dental appliances (dentures, orthodontic devices, etc) must not interfere with this. Teeth in poor repair may contain spaces that may trap air leading to tooth discomfort and barotrauma with changing air pressure.

Ophthalmology

Visual acuity and correction

The nature of the particular task the diver is expected to perform may dictate visual acuity criteria, but at minimum the diver must be able to read his or her gauges underwater.

Diving after refractory correction procedures

Radial keratotomy (RK) involves the making of small corneal incisions in order to correct refractive deficiency. Theoretically, a decrease in the strength and integrity of the cornea may result with subsequent increased risk of eye injury due to blunt trauma or barotrauma such as severe mask squeeze. However, literature search revealed no reports of this actually occurring. Many diving medicine physicians recommend that a diver wait 3 months after an uncomplicated RK procedure before returning to diving. Lasik procedure involves laser-assisted reshaping of

the cornea and subsequent corneal flap replacement. In order to allow healing and absorption of any bubbles beneath the corneal flap, many diving medicine physicians recommend a 2-week wait after an uncomplicated Lasik procedure before return to diving.¹⁴

Corrective lenses

Some divers use masks with built-in prescription lenses. Use of contact lenses poses several concerns. In the event of a flooded or lost mask, contact lenses may be lost. Hard contact lenses may cause corneal irritation, believed due to gas bubbles that form between the cornea and the contact lens. There seem to be fewer problems associated with the use of soft contact lenses, and their use is generally accepted.¹⁵

Other ophthalmologic procedures

Uncomplicated cataract procedures, once fully healed, are generally not considered disqualifying for diving. Healing times vary depending on the cataract procedure, but by 3 months diving is generally permitted.

Diabetes

Insulin-dependent diabetes mellitus (IDDM) is, at this time, generally considered a disqualification for occupational diving. This is due to the potential for a hypoglycemic event and subsequent incapacitation under water. Studies are underway to better understand how diving affects the diver with IDDM, and to better understand the associated risks. It is likely there may be circumstances in which diving, and perhaps occupational diving, with IDDM is not considered disqualifying.¹⁶

Gastroenterologic

Acute conditions such as gastroenteritis are disqualifying until resolved. Chronic gastroenterologic conditions may or may not be disqualifying, and should be considered on a case by case basis. Divers with ostomies generally have little difficulty as long as intestinal gas is allowed to escape or expand unhindered. Of note, 'continent' ileostomy is a type that does not allow gas to readily escape, and is therefore disqualifying. Divers with hernias that may potentially trap gas should not dive until repaired and healed. Gastroesophageal reflux syndrome may be disqualifying if not well controlled.

STANDARDS AND GUIDELINES

Standards and guidelines involving commercial and scientific diving are too lengthy to list here, but are available through the Occupational Safety and Health Administration (OSHA),¹⁷ US Coast Guard (USCG),¹⁸ National Oceanic and Atmospheric Administration (NOAA),¹⁰ and organizations such as the Association of Diving Contractors (ADC)¹⁹ and the American Association of Underwater Scientists (AAUS).²⁰

ALTITUDE: THE HYPOBARIC ENVIRONMENT

Barometric pressure decreases exponentially with increasing elevation such that the sea level value of 760 mmHg is halved to 380 mmHg at 18,000 feet and falls to a mere 0.6 mmHg at 50,000 feet, posing a serious challenge to human physiology. Recent rapid increases in commercial, military and recreational activities at high altitudes have focused increasing attention on them. Human compensatory physiologic mechanisms ordinarily allow for excursions of healthy individuals from sea level to elevations of approximately 8000 feet, at a modest rate, without significant noticeable detrimental effects. Beyond that, problems occur with increasing frequency and severity as the altitude or ascent rate increases. While some of the finer details of the pathogenesis of these problems remain unclear, the basic etiologies can be traced directly to the physical reduction in ambient pressure encountered on ascent and to its rate.

Foremost among the effects of reduced atmospheric pressure is a reduction of available oxygen in the inspired air, leading to tissue hypoxia, with its myriad implications and consequences. The direct effect of reduced pressure *per se* contributes to the risks as well. The sudden or rapid reduction of ambient pressure in the aviation and space operational environments may produce gas embolic phenomena and local mechanical tissue damage by the evolution of free bubbles from supersaturated dissolved gasses or by their introduction into the circulation from the rupture of overpressured pulmonary alveoli. Prolonged travel and activity at high terrestrial altitude results in the risk of developing a variety of subacute or chronic hypoxia-related conditions, some of which have proven debilitating and fatal. Ascending to altitude immediately following hyperbaric exposure, such as in underwater diving, is frequently associated with evolved gas disorders. The difference in the temporal characteristics of terrestrial and aviation activities results in different clinical pictures. The field of altitude medicine contains a vast body of information.

High-altitude illness (HAI)

The more serious reader's attention is directed to excellent exhaustive and scholarly treatments of this subject by Hackett²¹ and Hutgren,²² and especially to Deitz's internet website.²³ The mountaineering axiom, 'It is OK to get altitude illness. It is not OK to die from it'²³ attests not only to the intrepid spirit of these stalwart adventurers, but also to the general prevalence and wide range of severity encountered. The pathophysiology of all its variations is founded in subacute and chronic tissue hypoxia, with varying individual sensitivities of organ systems. The prominent feature is a cascade of events ending in intractable edema. The mechanisms are primarily normal compensatory responses that perform well enough at low altitudes and initially at higher ones, but over time eventually go awry and produce an intolerable physiologic state.

Vascular chemoreceptors mediate hyperventilation and increased cardiac output leading to hypocarbia with uncompensated alkalosis, resulting in increasing vascular and pulmonary alveolar permeability, extravasation, edema and pulmonary hypertension. The most sensitive organs are the lung and the brain.

A marked degree of individual susceptibility exists which approximates a normal Gaussian distribution and is consistent over time, making previous experience the only reliable predictor of future risk. A significant degree of acclimatization can occur in travelers from low altitudes, but it never matches the physiologic performance of indigenous populations, which is presumably due to genetic and/or perinatal adaptation. Three, more or less discrete, clinical pictures are most commonly seen, with differing implications. A handful of essentially benign conditions such as isolated peripheral edema, particularly in women, have been reported and the finer details of this constellation of disorders are still being clarified.

Acute mountain sickness (AMS)

This syndrome is characterized by malaise, fatigue, anorexia, dyspnea, chest wall ache, headache, nausea, vertigo, memory and sensory disturbances, disturbed sleep resulting from dreams and periodic (Cheyne-Stokes) breathing, and occurring usually within 24 hours of arrival at altitude. Some of these symptoms are present in virtually all high-altitude travelers, often without noticeable impairment but debilitating and incapacitating in some, increasingly with altitude and rate of ascent, and leading to attack rates of 70–80% and more. Findings include hyperventilation from increased tidal volume rather than tachypnea, chest rales, tachycardia and arrhythmia, peripheral edema, vomiting, pallor, cyanosis, retinal hemorrhages, ataxia and incoordination, and mental dullness. Some spontaneous improvement may be noted with time but progressive worsening may indicate the onset of one of the next two syndromes.

High-altitude pulmonary edema (HAPE)

To paraphrase the words of C. Gresham Bayne, the lung is the stupidest organ in the body since it knows only one way to react to insult and that is to fill with fluid.²⁴ Such is the case with persistent hypoxemic insult. The only practical difference between HAPE and any other pulmonary edema is etiology. Increased alveolar membrane permeability and pulmonary hypertension result in extravasation and accumulation of fluid in the alveoli, producing impaired gas exchange and deeper hypoxemia. The clinical picture is familiar and consists of fatigue, weakness, rales, dyspnea, tachypnea, tachycardia, cough, frothy sputum (sometimes blood-tinged), cyanosis, incapacitation, stupor, coma, and death. Systems to quantify severity have been developed, but respiratory rates over 30 and approaching 40 are ominous. Management is directed at the cause. This condition must be taken seriously since fatality rates can reach 12% and more, depending on circumstances.

High-altitude cerebral edema (HACE)

The central nervous system manifestations of severe HAI are often encountered without significant pulmonary features, indicating a variation in individual tissue sensitivity to hypoxemia. Edema of the cerebral tissues is the primary contributing factor in HACE, although in some instances simple anoxia may be responsible, and the term high-altitude encephalopathy (HAE) has been considered.

The onset of HACE can be insidious, beginning with mild headache and cognitive, affective, sensory, and motor disturbances with a variety of findings. HACE can progress at a variable rate to frank ataxia, paresis, confusion, dementia, coma and death. Papilledema and elevated cerebrospinal fluid pressures are common but not universal findings, and autopsies have demonstrated cerebral edema, often with hemorrhage. Prompt treatment of mild to moderate cases ordinarily results in eventual full recovery, but delayed treatment or severe cases carry a risk of residual neurologic deficit. The true nature of HACE is still being debated since it is much less frequently encountered than HAPE. Prudence dictates a high index of suspicion for and rapid response to this disorder.

Management of HAI

Prevention and treatment of HAI employ behavioral, pharmacological and pressure measures. Acclimatization by controlling ascent rates markedly reduces the incidence and severity of AMS, but is essentially ineffective in reducing the risk and morbidity of HAPE and HACE, once these complications have occurred. Slower ascent rates are more effective, but operational considerations may press for more rapid ones. Recommendations vary, but 1000–1500 feet per day seems to be a standard with decreasing rates at increasing altitudes. Day-long periods of rest are essential during acclimatization, and absolute bed rest is essential in the treatment of HAI, since physical exertion may drastically lower arterial oxygen tensions and exacerbate the problem. Routine use of oxygen during acclimatization and ascent effectively reduces the risk of AMS, but has little effect on the risk of developing HAPE or HACE. It is, however, essential in the treatment of all three. Oxygen should be applied at high flow rates or, better still, with a demand valve and a tightly sealing oronasal mask when used therapeutically. This equipment is cumbersome to transport, which somewhat limits its usefulness.

The traditional sulfonamide carbonic anhydrase inhibiting agent acetazolamide (Diamox) and, more recently, the corticosteroid dexamethasone (Decadron) have been consistently shown to be useful prophylactically and therapeutically for HAI, although adequate controlled studies are still lacking.²⁵ Both clearly reduce the risk of AMS and ameliorate the symptoms. Acetazolamide mitigates hypocarbia and alkalosis. Adverse effects are mild and tolerable, but its use is sharply limited to a week or less due to rapidly developing tachyphylaxis. Recommended regimens vary from 250 mg to 750 mg daily in divided doses. Dexamethasone ameliorates cerebral edema. At doses of 8–16 mg daily it seems equally effective, with an adverse effect of depression on abrupt secession, which may be successfully averted by tapering.

While no clear benefit of either drug has been demonstrated in treating HAPE or HACE, their use is generally recommended on the grounds that it will surely help some individuals, and is not likely to harm. Numerous trials of diuretics, e.g., furosemide, to combat edema and calcium channel blocking agents, e.g., nifedipine, to moderate cardiac output have failed to demonstrate effectiveness. The sine qua non for the successful treatment of HAI is repressurization. Immediate and rapid evacuation to lower altitude is mandatory but often logistically impossible, particularly with an uncooperative or moribund patient in remote irregular terrain, in potentially adverse weather conditions.

The recent introduction of reliable, simple and effective but sturdy lightweight and portable hyperbaric chambers has undoubtedly already proved lifesaving. Widespread use could conceivably all but eliminate fatalities from HAPE and HACE, were it not for the historical tendency of people to use such technology to extend the limits of the operational envelope, thereby maintaining risk levels. These devices permit on site repressurization with dramatic resolution of even severe symptoms, which enables or greatly facilitates the required eventual evacuation. Treatment times are reported as 2–4 hours for HAPE and 4–6 hours for HACE.²³ The pressure attainable within these chambers is limited by pressure relief valves dependent on the differential across the chamber wall, and is therefore dependent on ambient pressure at the altitude of use.

Altitude decompression illness and acute hypoxia

The operational characteristics of space and aerial flight present a milieu of more rapid and extreme pressure changes than terrestrial altitude activities, which leads to a different set of clinical syndromes. The effect of pressure in this altitude environment has, for many decades, been amply addressed, along with many other important factors, in the discipline of aerospace medicine. Excellent discussions are readily available in standard writings in this field.^{26–29}

Decompression illness

This useful term includes decompression sickness (DCS) and air/gas embolism (AGE). Except for primary etiology, their pathophysiology is much the same, with clinical pictures often indistinguishable, except at times on the basis of history, and their management is virtually identical. More detailed treatment of the subject is found in this chapter under depth medicine.^{30–32} DCS results from free gas evolved from tissues that become supersaturated, primarily with the relatively inert gas nitrogen on ascent to altitude. Bubbles can occur in the circulation or tissues. Most aviation DCS occurs in military and space activities, where exposures are more rigorous than in commercial aviation, but the popularity of diving, with air travel soon after, has produced cases.

Pain-only DCS (Type I) is most frequent, and is characterized by moderate to severe deep aching pain in the joints and bones, primarily of the appendicular skeleton – the

shoulders and knees being common sites. It is presumably produced by local tissue bubbles or embolism from the circulation.

Central nervous system DCS (Type II) is less common but more serious. Spinal involvement predominates, as demonstrated by paresthesia, anesthesia, paresis and paralysis. Brain symptoms are much less common and can take a wide variety of forms including headache, vertigo, ataxia and behavioral changes. Bubbles have been demonstrated in animal and human CNS tissue and circulation. Pulmonary DCS (chokes) accounts for perhaps 10% of aviation DCS cases. It manifests as substernal distress, dyspnea, cough and apprehension. The mechanism is thought to be an overwhelming of the pulmonary circulation by bubbles, leading, again, to pulmonary edema. Other factors, such as hypoxic alveolar gas, probably account for the difference in occurrence rates seen in aviation and diving.

Arterial gas embolism (AGE) is the term used to describe an embolism of gas introduced directly into the circulation from ruptured alveoli. This can be caused by the barotrauma resulting from reduced ambient pressure over trapped gas; risk factors include underlying pulmonary pathology (e.g., asthma and obstructive lung disease), and breathing patterns coupled with rapid ascent or pressure loss. Manifestations are often cerebral and devastating, such as collapse, coma and death, but are also frequently milder, simulating those of Type II DCS such that clinical distinction is sometimes not possible. Skin manifestations of DCI such as rash and subcutaneous emphysema are usually of little significance except to raise the suspicion of more serious accompanying conditions.

Management of DCI

Prevention is accomplished by a variety of effective procedural and mechanical means. The axiom 'Anything will eventually fail, whether man or machine', however, prevails and DCI is an ongoing problem. Breathing 100% oxygen for a period of time prior to exposure removes some dissolved nitrogen from the body and reduces the risk of developing symptoms. Oxygen delivery systems that variably meter percentages and even supply positive pressure depending on altitude are in use and are effective, as are mechanically pressured vessels such as cabins and space suits, all of which provide adequate alveolar partial pressures of oxygen within operational limits. The mainstay of treatment consists of 100% inspired oxygen delivered by mask and, in more severe cases, in a pressurized vessel. Treatment protocols used by the United States Air Force are representative.³⁰ Pain that resolves spontaneously on return to ground level is treated minimally, while the more severe and persistent symptoms require modified United States Navy chamber Tables 5 and 6, involving about 2.25 hours and 5 hours respectively in a hyperbaric chamber.

Acute hypoxia

The brain and heart are the most critically sensitive organs to sudden oxygen deprivation. Complete exclusion of oxygen from inspired gas at sea level leads to loss of

consciousness in minutes and cessation of cardiac activity shortly after, as arterial and tissue oxygen tensions drop precipitously, and death is not far behind. Moreover, exposure to reduced ambient pressure at altitude results in the rapid exit of tissue oxygen through the lungs, accelerating tissue hypoxia markedly. Breathing ambient air suddenly at an atmospheric pressure of 25,000 feet, results in a time of useful consciousness that varies between 3 and 5 minutes, and at 40,000 feet is measured in short seconds. Most commercial flights operate between 30,000 and 40,000 feet and manned military and research operations extend far higher.

Barotrauma

Gas trapped in body cavities, such as dental defects, the middle ear and sinuses, by Eustachian dysfunction or sinusitis, often results in pain, sometimes with transudation, on descent. Except for discomfort, these conditions are seldom of consequence. Sympathomimetic amine decongestants, topically or systemically, are useful in prevention and treatment.

DEPTH MEDICINE

Barotrauma

The undersea and hyperbaric environments are harsh in comparison to others; a mere 33-foot descent beneath the sea is a greater pressure change than 30,000 feet of altitude. Because of these rapid pressure changes, barotrauma becomes the most common occupational hazard of the hyperbaric environment. Barotrauma can occur on ascent or descent where gas-containing cavities fail to equalize with ambient pressure. It ranges from the mild skin 'squeeze' of a dry suit to the catastrophic bursting of a lung.

Ear barotrauma may be confined to the external ear canal if wax, earplugs, or a hood blocks the external meatus. It is usually mild and easily prevented. Middle ear barotrauma of descent is much more common. It is caused by the failure to equalize the middle ear cavity through the Eustachian tube, and if descent continues without equalization, pain becomes intense until relieved by rupture of the eardrum. Unless a dry diving helmet is worn the ruptured eardrum can flood the middle ear with water, causing sudden vertigo.

Vertigo sometimes occurs during descent, when Eustachian tube function is delayed in one ear, but vertigo is more common with middle ear barotrauma of ascent as the unequal expansion of gas within the middle ear stimulates the vestibular end-organ of the inner ear. A 'blocked' ear during ascent can dangerously impede a return to the surface. Occasionally a facial nerve may be affected, causing unilateral facial weakness. It is important to distinguish this condition from a potentially serious case of decompression sickness. Inner ear barotraumata may be a serious consequence of any of the other types of otic barotrauma just described. Since the inner ear is not accessible to viewing with an otoscope, the symptoms are the key to a presumptive diagnosis: tinnitus, ataxia, vomiting, and

vertigo are all associated with inner ear barotraumas, and the diagnosis is confirmed by serial audiometry and electronystagmography.

Inner ear barotraumas may be due to a fistula of the round window with leakage of perilymph from the inner ear into the middle ear, or due to hemorrhage; hence it is important to immediately take the following precautions.

1. Avoid straining, nose blowing, Valsalva maneuver, or any physical exertion that could increase cerebrospinal fluid pressure; avoid diving or flying.
2. Strict bed rest with the head elevated for several days. Diazepam will help control vertigo.
3. Monitor otological changes: if hearing does not improve in 24 hours, if it deteriorates, or incapacitating vertigo is present, consider operative intervention with middle ear exploration and grafting the round and oval windows.

Sinus barotrauma is most often over the frontal sinus during descent, but can occur during ascent, particularly after long dives breathing a dry compressed gas, which causes drying of the sinus mucosa, or if sinus polyps are present. In rare instances, rupture of the sinuses can cause pneumocephalus. The trigeminal nerve may also be affected by sinus barotraumas and cause numbness in the face and upper lip, as well as pain in the upper teeth. Again, it is important to recognize this complex as being associated with sinus barotraumas and not decompression sickness.

Dental barotraumas may be the result of carious teeth or gas spaces in deteriorating fillings. A particularly common form of dental barotraumas of ascent occurs in saturation diving when helium slowly diffuses beneath fillings during weeks at depth then expands during the relatively rapid decompression, causing pain as the saturation complex nears the surface and oftentimes 'popping' the filling out in the process.

'Squeeze' is the common term for the barotrauma caused by relatively rigid appurtenances in contact with a diver, such as masks, suits, or 'hard hat' helmets. Problems usually occur in relatively shallow depths since that is where the greatest changes in relative volume occurs; the most common cause is an uncontrolled descent such as falling off an underwater stage slung under a ship for maintenance work by a diver, but simply leaping over the side without an attentive tender also occurs. At depth, the problem is often due to a failure of the non-return valve. The consequences can be catastrophic.

Pulmonary barotrauma

Pulmonary barotrauma of ascent or 'burst lung' is life threatening. It is more common in sport divers than commercial divers, but it can occur anywhere that free ascent occurs, including breath-hold divers and swimmers who descend to a relatively shallow depth and 'share' a breath of air from a friend's regulator; or in aviators training in underwater escape devices, if they breathe from an emergency gas supply and fail to exhale during ascent. Survivors trapped in submerged automobiles or boats are at risk as

they breathe in a bubble of trapped – and compressed – air and may not know to exhale during an escape ascent.

Pulmonary barotraumas may present as pulmonary tissue damage, pneumothorax, mediastinal emphysema, or cerebral arterial gas embolism – separately or in any combination. Mediastinal emphysema may be deceptively mild in its presentation with voice changes, retrosternal discomfort, dysphagia, and subcutaneous emphysema of the neck and supraclavicular area. Older texts often dismissed mediastinal emphysema as trivial and requiring nothing more than breathing 100% oxygen for a few hours. This author strongly disagrees with this dismissal, since the same pathophysiology is present as cerebral gas embolism. In the field, we take the stance that mediastinal emphysema may herald much more serious involvement and deserves aggressive treatment. Since this often means recompression, be wary of the presence of a pneumothorax, since it may become a tension pneumothorax on ascent. Be prepared to relieve the tension pneumothorax with a suitable needle/catheter attached to a Heimlich valve.

Cerebral arterial gas embolism is the most ominous complication of pulmonary barotrauma, as gas from the ruptured lung enters the pulmonary veins and the systemic circulation with a predilection for the cerebral and coronary vessels, with devastating effects. These patients may show transient improvement, but it is unlikely to be sustained. Do not be lulled into any delay in seeking definitive treatment.

Treatment of pulmonary barotraumas should be prompt and predicted upon a worst-case presentation, i.e., the presence of cerebral arterial gas embolism despite more benign presentations. Since many of these cases will be divers with an unknown amount of inert gas in their tissues, deep recompressions should be avoided. For example, a compression chamber application of 165 FSW could constitute an unrecognized repetitive dive and complicate matters by causing decompression sickness during 'ascent' to the oxygen breathing depth of 60 FSW. A USN Table 6³³ is an excellent compromise under these circumstances. It is important to treat promptly based upon signs, symptoms and suspicion; one must be prepared to provide circulatory and respiratory support in the recompression chamber. Diagnostic studies may be performed later to confirm diagnosis.

Pulmonary barotrauma of descent, 'lung squeeze', is uncommon but can occur in breath-hold diving, failure of a non-return valve in surface supplied diving, or simply descending at a rapid rate with an inadequate gas supply or volume. Recompression is not warranted; 100% oxygen should be provided by mask en route to a definitive care facility.

Inert gas narcosis

Inert gas narcosis is a clinical syndrome caused by increased partial pressure of inert gas, and is characterized by impaired mental status, which for some resembles alcohol intoxication. One of the most memorable descriptions of inert gas narcosis is Jacques Cousteau's accounting of

'rapture of the deep', in which he described his own experiences with nitrogen narcosis (the form of inert gas narcosis experienced by divers breathing air). Depth of onset varies with the individual. For many, narcotic effects become apparent at about 100 FSW, and impairment increases with depth. Signs and symptoms include loss of judgment and skill, a false feeling of wellbeing, lack of concern for job or safety, inappropriate laughter, euphoria, and inability to correctly recall events during narcosis.³⁴ Severe narcosis may result in bizarre behavior, hallucinations, or loss of consciousness. Treatment consists of controlled ascent to a shallower depth, sometimes only a few feet, where the effects rapidly reverse. Commercial divers who must maintain greater depths may avoid or minimize inert gas narcosis by breathing gas mixtures containing helium, which does not tend to cause narcosis, in the place of nitrogen.

CNS oxygen toxicity

CNS oxygen toxicity can occur in divers at depths where the PO_2 equals about 1.6 ATA, or about 250 FSW for the diver breathing air. Susceptibility is largely dependent on activity, and people at rest can usually tolerate a PO_2 of about 2.0 ATA without experiencing symptoms of CNS oxygen toxicity.^{33,34} Time at depth is also an important factor (roughly 5–50 minutes) but there is much variation. The acronym VENTID may help in remembering the associated signs and symptoms: Visual disturbances including tunnel vision; Ear ringing; Nausea; Tingling, twitching or muscle spasms, especially face and lips; Irritability, restlessness, euphoria, anxiety; Dizziness, dyspnea. These signs and symptoms must not be ignored, as they may be closely followed by convulsion, which, while not life threatening in and of itself, but may result in drowning. Convulsion may also occur without warning.

Decompression sickness

Decompression sickness is the presence of gas bubbles in blood or tissues following their release from solution. In the purest sense, the mere presence of these bubbles constitutes disease even if they are subclinical and asymptomatic, inasmuch as their presence is abnormal and may result in impairment to the microcirculation. As these bubbles grow, they may distort and damage tissue directly.

Attempts at classification are confusing and imprecise: their utility is limited to the selection of treatment tables by laymen and the generation of statistics retrospectively. Type I describes 'simple' or 'pain only' decompression sickness, and Type II or 'serious' decompression sickness, which includes symptoms other than pain or skin involvement involving neurological, cardiovascular, respiratory, or gastrointestinal symptoms. Since so-called 'Type I DCS' often evolves to Type II – or may merely reflect an inadequate examination; a more useful classification is to simply describe the organs affected.

To add further confusion to the classification issue we now have Type III DCS, based on the serious decompression

sickness which evolves when gaseous microemboli from pulmonary barotraumas 'seed' the circulation in the presence of an inert gas load from a dive, often with a catastrophic outcome.

The presence of signs or symptoms within 6 hours following a dive should be presumed to be decompression sickness until proven otherwise. Never 'rule out' decompression sickness based on reports that the dive was within the no-decompression limits or that an appropriate table was followed. A subclinical or 'silent' pulmonary microembolism can seed the circulation with microemboli, which will grow in the presence of even modest amounts of tissue supersaturation, sometimes with disastrous consequences.

Presentations of DCS

The most overlooked presentations are fatigue and personality changes. The latter are best determined by questioning friends or family members. Musculoskeletal symptoms are common, often poorly localized, progressing to a dull ache but waxing and waning in intensity. Neurological presentations are varied and may be focal or diffuse; many are thought to be the result of arterialization of venous gas emboli as pulmonary artery pressures increase and right-to-left shunts occur, particularly if a patent foramen ovale is present. Neuropsychologic testing and SPECT scanning may identify cognitive impairment in the aftermath of acute treatment. Low-pressure hyperbaric oxygen therapy may be useful in these brain-injured divers and therapeutic response can be tracked by SPECT scanning. Spinal cord damage, occurring most often in the white matter involving the mid-thoracic, upper lumbar, and lower cervical levels, has also responded to serial low-pressure hyperbaric therapy.

Cerebellar inner ear lesions may be difficult to differentiate acutely if they present as 'staggers' but the vertigo of inner ear DCS is more commonly associated with deep mixed-gas dives. Violent vertigo with nystagmus is sudden in onset, usually while still under pressure in a diving bell or chamber, and is often associated with a shift in the composition of breathing gases. Prompt recompression and oxygen-rich treatment gas can avoid permanent disability, but care must be taken to differentiate inner ear DCS from inner ear barotraumas since rapid compression of the latter could exacerbate the injury. Diazepam is useful in controlling the vertigo and vomiting in cases of inner ear DCS or barotraumas.

Pulmonary DCS, 'the chokes', is an ominous presentation with cough and pain on deep inspiration. A classic finding, little used among today's health-conscious divers, is 'Behnke's sign' – a severe cough triggered by inhaling cigarette smoke. It is important to note that 'the chokes' represents a bubble overload of the pulmonary circulation, since the asymptomatic trapping of bubbles in the pulmonary circulation probably occurs on most non-saturation dives.

Decompression sickness is no longer common among commercial divers with well-tested decompression tables and recompression chambers readily available. Catastrophic cases do occur with equipment failure or 'blow up' (rapid

ascent), and the incidence can approach epidemic level among indigenous diver-fisherman in remote areas of the world. Do not be lulled into a false sense of security by seemingly trivial signs or symptoms. DCS can progress rapidly, and the end-point can be death.

Management of diving accidents

Practitioners of occupational medicine should participate in advance planning for the management of diving and other hyperbaric accidents such as underwater construction, or offshore petroleum exploration, and tunnel projects. Since the physician is unlikely to be on site, it is important to establish a program with the employer to provide medical personnel with hyperbaric training in addition to conventional competence in advanced cardiac and trauma life support. These diving and hyperbaric medical technicians communicate with the supervising physician, offer immediate care, provide a working diagnosis, stabilize, and accompany the patient to the definitive care facility. Accompanying the patient is essential since the hyperbaric exposure may be overlooked in an injured diver or tunnel worker arriving at a busy emergency department and delayed recognition could be disastrous.

Pressure, oxygen, and time are the key elements of recompression therapy. There are no substitutes; emergency transportation to the nearest recompression chamber is mandatory. Even if apparent recovery occurs en route, transportation to the chamber must continue, since recurrences can be serious. By the same token, one should be reluctant to leave the sanctuary of an offshore chamber for an uncertain shore-side hospital destination until certain that any diving injuries have been thoroughly stabilized.

Most cases of barotraumas and decompression sickness in commercial diving operations occur in a decompression chamber or at a site where a chamber is available. As a consequence, definitive treatment – pressure, oxygen, and time – is possible. When a recompression chamber is not on site, first efforts should be toward obtaining telephone consultation, communication with the nearest suitable recompression chamber, and arranging appropriate transportation. On-scene immediate care in the absence of a chamber should be continued until reaching a recompression facility.

1. Provide 100% oxygen by demand valve and a double-seal mask. Do not be concerned about oxygen toxicity. Most previously healthy divers will tolerate this regimen for up to 24 hours with only brief interruptions for food, liquids, etc.
2. Establish intravenous access and maintain adequate intravascular volume, tissue perfusion, and the elimination of inert gas. Normal saline and lactated Ringer's solution are acceptable. Provide fruit juices and balanced electrolyte beverages to maintain urine output at 1–2 mL/kg/hr.
3. If spinal cord decompression sickness is present, an indwelling urinary catheter may be required.
4. Avoid steroids and/or aspirin. Their use is unproven and could be deleterious in certain situations. Consider

diazepam for the control of vertigo and vomiting in inner ear DCS.

Communication and transportation

Depending upon location and circumstances, the consulting hyperbaric physician may be able to direct emergency care and transportation to a chamber or hospital, but in some cases the physician must go to the accident site or chamber. These hyperbaric emergency physicians must be trained and physically fit for prolonged hyperbaric exposure in a chamber in order to provide medical care during decompression. During the trip to the site, on-scene personnel should arrange to communicate with a second shore-based physician to ensure continuity of care.

Emergency evacuation of hyperbaric casualties should be preplanned. If close enough to a recompression chamber, surface transportation may be faster than waiting for an aircraft. If aircraft are unpressurized, the flight should be planned at an altitude of 1000 feet – or less if practicable. When possible, aircraft should be utilized which can maintain sea-level pressure throughout the flight. As a compromise, lightweight portable recompression chambers may be utilized to maintain a minimum of sea-level pressure in unpressurized aircraft.

Coordination is the key to a successful hyperbaric casualty evacuation. The coordinating facility must track every aspect: failure to coordinate has caused casualties to arrive unannounced at a hyperbaric facility shut down for maintenance or where an operating crew has not been notified. Physicians unfamiliar with hyperbaric injuries have innocently delayed recompression while diligently seeking a more familiar diagnosis. The hyperbaric physician and hyperbaric technician accompanying the patient must cut through well-intentioned but misguided delay in order to obtain specific recompression therapy in cases of decompression sickness and arterial gas embolism.

Chapter 37

Biologic Factors

37.1 Animal Exposures

James A Merchant, Peter S Thorne, Stephen J Reynolds

Exposures to animals are an important cause of respiratory disease in the workplace.^{1,2} There are three types of occupational settings that have provided research information on a wide range of exposures arising from animals and their housing environments: epidemiologic data on respiratory symptoms and functional changes, clinical presentation, and prevention strategies. These categories of exposures include (1) concentrated animal feeding operations (CAFOs) for swine and poultry, (2) dairy farming, and (3) exposure to laboratory animals at work and to pets at home.

The US population at risk in agriculture is large, including an estimated 12 million farmers, farm family members who participate in farming, and other agricultural workers, including migrant workers. Of this number, approximately 750,000 persons are exposed in livestock confinement and an estimated 500,000 persons are exposed in dairy farming. Hundreds of thousands work as laboratory animal handlers, technicians, and investigators. The respiratory diseases that arise from animal exposures in these populations include allergic and irritant rhinitis, acute and chronic bronchitis, asthma, allergic alveolitis, bronchiolitis, and toxic pneumonitis. This chapter does not address other occupational diseases arising from exposure to animals, which include occupational dermatoses and zoonotic diseases (see Chapters 29.1, 29.2, and 37.2), nor does it address the significant risk of injury that livestock, dairy farmers, and animal handlers face through their exposure to animals.

OCCUPATIONAL AND ENVIRONMENTAL EXPOSURES

The livestock environment

Technologic improvements in animal husbandry, including the use of enclosed and controlled environments, have substantially increased the efficiency of livestock production, especially for swine and poultry, over the last 30 years. Because of the intensive nature of these farming practices, workers are exposed to high concentrations of air-borne dusts and gases.³ Enclosed livestock facilities typically consist of simple one-story, pole barns with windows or curtained walls and fans for ventilation. Temperature, feed quality, and other factors are monitored and adjusted by the farmer to facilitate efficient animal growth. Capacity may range from several hundred animals per building, in some swine facilities, to more than 50,000 chickens in some poultry facilities. In the case of both swine and chickens, manure is collected in pits or lagoons,

located either under or adjacent to the building. Manure in turkey facilities typically accumulates directly on bedding material, consisting of wood chips, sunflower hulls or peat, and may not be cleaned out for several years. Workers may spend up to 40 hours per week inside these facilities. Tasks include supplying, checking and cleaning feed and watering systems, culling dead or ill animals, inoculating, collecting blood samples, cleaning manure systems and pumping out manure pits, tilling bedding (turkey facilities), mixing and applying antimicrobials and insecticides, and moving animals out of these confinement facilities for shipment.⁴

Environmental agents measured in swine and poultry barns include a complex mixture of organic dusts, microorganisms, and irritant gases.⁵ Dusts have been found to contain plant material (bedding and feed); animal-derived particles (skin cells, hair, feathers, droppings, urine); bacteria and fungi; microbial toxins (endotoxins); feed additives including antibiotics and other antimicrobials; pesticides; and ammonia, hydrogen sulfide, methane, nitrogen oxides, and odoriferous vapors from microbial action in manure.⁶ Air sampling studies have found total dust concentrations typically range from about 4 to 40 mg/m³, with respirable dust levels much lower, ranging from 0.5 to 5.0 mg/m³. Daily time-weighted average concentrations often exceed the current Occupational Safety and Health Administration (OSHA) permissible exposure limit (PEL) of 15 mg/m³ for total nuisance particulates and 5 mg/m³ for respirable dusts.⁷ Endotoxins, lipopolysaccharide portions of the cell wall of gram-negative bacteria, have been measured at levels ranging from 1 to 3000 ng/m³, again often well in excess of a proposed guideline of 9 ng/m³.

Air-borne concentrations of culturable bacteria have been found to range from 10⁴ to 10⁷ colony-forming units per cubic meter of air (CFU/m³), and although total viable fungal concentrations usually have been low (less than 500 CFU/m³), isolated findings of much higher concentrations (exceeding 50,000 CFU/m³) have been reported. Hydrogen sulfide, a potent respiratory irritant and toxin, which has the odor of rotten eggs, is produced by anaerobic bacterial activity in manure pits. Hydrogen sulfide levels typically remain far below 10 parts per million (ppm), but agitation of liquid manure pits, which is often necessary for pumping, may release short-term concentrations high enough to kill workers and animals (700 to 2000 ppm). Ammonia, a highly reactive and alkaline irritant gas produced from microbial degradation of urea and uric acid, has been found at concentrations higher than 100 ppm in some poultry operations,

far in excess of the current OSHA PEL of 25 ppm averaged over an 8-hour time period, and may exceed the short-term (15-minute) exposure limit (STEL) of 35 ppm.^{8,9} Ammonia levels tend to be much lower in confined swine operations, typically closer to 5 to 10 ppm. Air-borne concentrations of dusts and gases are highest during activities such as tilling bedding, pumping out manure pits, and during animal handling. Seasonal effects are also evident, with air-borne concentrations of these agents being much higher during the winter, when buildings are closed.

The dairy environment

The dairy barn environment consists of numerous air-borne substances arising from a diversity of operations that occur in the course of daily dairy farming. Each of the principal tasks – feeding, milking, manure handling, distribution of bedding, silage handling, and tillage – is associated with its own spectrum of potentially hazardous agents. Dairy farming has recently experienced considerable consolidation with fewer but larger operations and increasing automation. Exposures encountered by dairy farmers are characterized by continuous exposure to moderately high bioaerosols punctuated by very high short-term dust exposures.¹⁰ Mixing and distribution of feed may generate dusts that are heavily laden with bacteria, fungi, microbial toxins, and feed additives, such as vitamins, minerals, and medications. Bedding, chopping, and pitch-forking of hay may produce levels of air-borne fungi and thermophilic bacteria as high as 10^{10} organisms/m³, accompanied by grain mite and pollen exposures.¹¹

Other sources of bedding, such as sawdust or shredded newspaper, may also introduce high bioaerosol levels. Silo loading is associated with potentially lethal exposures to nitrogen oxides, whereas silo unloading can lead to extremely high exposure to micro-organisms and their toxins, potentially leading to organic dust toxic syndrome (ODTS) or farmer's lung disease (FLD, an allergic alveolitis).¹² Manure handling is associated with exposures to endotoxin dust and bacteria, as well as urine proteins, ammonia, and hydrogen sulfide. Air-borne dust concentrations in milking parlors are lower than in stanchions, but may constitute higher breathing zone concentrations of antigenic cattle epithelium. Many dairy farmers do not have parlors and milk their cows in the barn, often while they feed. Infrequent, but high exposure tasks include silo or grain bin clean-out and silo uncapping when total dust exposures often exceed 150 mg/m³. Approximately once daily, lime (CaCO₃) is spread to control micro-organisms in a process that produces high short-term exposure. This material may contain fibrogenic crystalline minerals, including asbestos.

Air-borne total dust levels during routine operations typically fall in the range of 0.2–4 mg/m³ in winter, when barn ventilation is reduced to conserve heat, and are somewhat lower in summer. Respirable dust levels account for a highly variable proportion of this dust, depending on the tasks performed during the sampling period, but generally represent less than 30% of the total dust. When bedding is dropped from a loft, chopped or pitch-forked, total dust

concentrations increase by an order of magnitude. Bioaerosol sampling in a sample of 25 Wisconsin dairy barns found culturable mesophilic bacteria at a geometric mean concentration of 1.8×10^6 CFU/m³, thermophilic bacteria at 3×10^3 CFU/m³, and fungi at 6×10^4 CFU/m³. In the United States, the air-borne fungi typically include common environmental molds such as *Aspergillus*, *Penicillium*, *Fusarium*, *Mucor*, *Cladosporium*, and *Alternaria*, in addition to several yeast genera. Assessment of total micro-organisms, both culturable and non-culturable, has shown that up to 90% of the air-borne micro-organisms may be non-culturable. The largest study of levels of air-borne endotoxin in dairy barns reported a geometric mean inhalable endotoxin concentration of 74 ng/m³, with substantial variability (range of 4–3480 ng/m³). Mycotoxins present in air-borne conidia (mold spores) have rarely led to measurable concentrations in air samples, although we have detected deoxynivalenol (vomitoxin) and fumonisin B1 at 1–5 micrograms/m³.

A number of studies have tested the serum of dairy farmers and found elevated levels of immunoglobulin reactivity to fungi, thermophilic bacteria, and storage mite antigens.¹³ Recent studies have identified storage and predator mites in dairy barn dust samples including *Lepidoglyphus destructor*, *Acarus siro*, *Tyrophagus putrescentiae*, *Caloglyphus berlesei*, *Chortoglyphus arcuatus*, *Glycyphagus ornatus*, and *Euroglyphus maynei*. In addition, specific radioallergosorbent test (RAST) inhibition assays have identified air-borne levels of *L. destructor* reactivity as high as 12 micrograms/m³.

Exposures to excessive levels of gases and vapors also occur in dairy farming. During silo filling, nitrogen oxides are formed through enzymatic degradation of plant nitrates, producing NO, NO₂, and N₂O₄. Exposure to nitrogen dioxide is of particular concern and, from hours to several days after filling the silo, it often exceeds the PEL of 3 ppm and may be as high as 2000 ppm. Ammonia concentrations in the vapor phase in dairy barns often exceed the PEL of 25 ppm, with additional exposure from ammonia adsorbed to dry aerosols. In addition to these exposures, dairy farmers, like other farmers, are frequently exposed to gas or diesel engine exhaust, pesticide aerosols, welding fumes, and a host of other occupational aerosols and vapors that may be produced in the many tasks involved in farming.

The laboratory animal environment

Animals raised for meat production account for 99.7% of the total use of animals in the United States. The other 0.3% (some 15 million animals) are used in research and toxicologic testing. Of these laboratory animals, 97% are birds, reptiles, amphibians, and rodents. The most commonly used mammals are mice, rats, hamsters, guinea pigs, and rabbits. Other species in common use include gerbils, opossums, ferrets, cats, dogs, sheep, swine, and non-human primates. Non-mammalian species commonly handled by laboratory animal workers include pigeons and other birds, reptiles and amphibians, and cockroaches.

Aeroallergens are associated with all of the above-named species. These immunogenic bioaerosols arise from urine proteins, salivary proteins, epithelial cells, fecal proteins

(especially avian) or sebaceous secretions. In addition to these allergens, laboratory animal workers come in contact with microbial bioaerosols, endotoxins, and antimicrobials and other chemicals used in cleaning operations. Concentrations of dust from feed or bedding materials also can be significantly elevated. Certain tasks, such as cage washing, often have been identified as producing high levels of immunogenic dust.¹⁴ During cage cleaning, the soiled bedding material (commonly shredded paper, wood shavings, or ground corn cob) is dumped into a waste receptacle so that danders, urine proteins, micro-organisms, and fecal material become air-borne. Although total dust exposures are higher when fresh bedding is placed in cages, exposures to these dusts are less immunogenic and, therefore, less likely to lead to respiratory symptoms.

For animal handlers, cross-shift total personal dust concentrations typically range from 0.1 to 1.5 mg/m³, whereas respirable levels range from below detection to 0.2 mg/m³.

Concentrations of rat urine aeroallergens have been measured in rat facilities at about 1 µg/m³, with 70% of the aerosol being respirable. Laboratory animal technicians, who most commonly develop allergies to rodent species, frequently cite performance of animal surgery or euthanizing animals as processes that exacerbate their symptoms. Animal bites are common and are one likely route of sensitization to animal proteins.

CLINICAL EFFECTS

Adverse health effects that may arise from these several animal exposures include bronchitis, asthma, bronchiolitis, allergic alveolitis, chemical pneumonitis, pulmonary edema, and organic dust toxic syndrome (ODTS) (Table 37.1.1). The epidemiology and clinical presentation are only briefly

reviewed in this chapter as more detailed accounts on upper airway disorders (Chapter 20.3), asthma (Chapter 19.2), irritant bronchitis (Chapter 19.4), hypersensitivity pneumonitis (Chapter 19.6), and acute inhalational injury (Chapter 19.5) are found elsewhere in this text. Although the prevalence and distribution of respiratory diseases vary between these three types of exposures, they all share a common characteristic of exposure to the bioactive constituents of organic dust, the primary cause of airway inflammation.

Health effects arising from livestock exposures

The most common respiratory manifestation of airway inflammation from exposure in animal confinement facilities is bronchitis. Chronic cough has been found in 45–75% of workers and chronic phlegm has been found in 35–50% of workers in studies of Iowa swine confinement workers, which is consistently higher than that for non-swine confinement farmers (35% and 15%, respectively).^{7,15,16} Symptoms of chest tightness (20%) and breathlessness (10%) also are more common among confinement workers than among non-confinement farmers (5% and 2%, respectively).¹⁷ The pattern of symptoms is similar among poultry farmers, but the prevalence is typically lower.¹⁸

A study of 303 Canadian poultry farmers found a significant difference in symptoms among workers in caged chicken rearing barns compared to those in barns with floor raised birds.¹⁹ Symptoms reported for caged system and floor system workers were: cough (35% and 25%), phlegm (30% and 25%), wheeze (10% and 5%), and shortness of breath (25% and 20%). These symptoms are all found to be higher among workers who smoke cigarettes, which is less common among farmers than blue collar workers. It has been shown that swine confinement farmers are more likely than other farmers to have significant cross-shift decrements in expiratory flow rates, and airway hyper-responsiveness and clinical asthma are not uncommon in this working population.^{20,21} Cross-sectional studies of swine confinement workers have demonstrated evidence of more chronic airways obstruction compared with other farmers, and prospective evaluation has found that cross-shift decline in FEV₁ was a significant determinant of progressive loss of lung function over time.^{22,23}

While there is evidence that removal of affected workers from exposure influences the results of these studies, cross-shift declines in FEV₁ have been found to be a significant predictor of annual decline in FEV₁.^{24–26} The vast majority of farmers with bronchitis are able to continue to work in livestock confinement operations; however, those with airway hyper-responsiveness or asthma are rarely able to continue this type of work.²⁷ If asthmatic farmers are unable to hire workers to run their confinement operations, they may be forced to close down their livestock facilities, usually at a considerable cost, and are often unable to continue farming.

Two toxic exposures have been observed among CAFO workers. ODTS has been found in about 10% of Iowa swine confinement farmers.¹⁵ This syndrome is most common among new workers or following an especially high exposure

Occupation	Exposure	Respiratory conditions
Swine farmers Poultry farmers	Organic dust	Chronic bronchitis
	Animal particles	Asthma
	Bacteria and fungi	Bronchiolitis
	Microbial toxins	Toxic pneumonitis
	Feed additives	Rhinitis
	Pesticides	Organic dust toxic syndrome
Dairy farmers	Irritant gases	Chronic bronchitis
	Organic dust	Asthma
	Feed additives	Allergic alveolitis (farmer's lung)
	Thermophilic bacteria and fungi	Bronchiolitis
	Microbial toxins	Toxic pneumonitis (silofiller's lung)
	Storage mites	Rhinitis
	Pesticides	Organic dust toxic syndrome
	Irritant gases	Rhinitis
Laboratory animal handlers, technicians, and investigators	Organic dusts	Organic dust toxic syndrome
	Animal proteins	Rhinitis
	Bacteria and fungi	Asthma
	Microbial toxins	Allergic alveolitis (rare)
	Biocides and cleaning chemicals	Chronic bronchitis

Table 37.1.1 Exposures and respiratory conditions among workers exposed to animals

in a confinement facility.²⁸ It also is reported among these farmers when they clean out grain bins, which often results in high exposure to moldy grain. Symptoms, which begin 4–12 hours after exposure, include cough, fever, myalgia, fatigue, and occasionally, dyspnea. This flu-like illness rarely requires hospitalization. A second toxic exposure that has been reported on numerous occasions is toxic pneumonitis, often with acute respiratory distress syndrome (ARDS), most commonly associated with agitation or pumping of liquid manure out of a pit. High concentrations of hydrogen sulfide gas exposure may result in respiratory distress, followed by ARDS and often death. Farmers who have survived such an episode describe hearing all of their animals hitting the floor at the same time (none survive) and having to run from the building to avoid this lethal exposure. Farmers who recover from ARDS are typically left with bronchiolitis obliterans, airway hyper-responsiveness, and severe pulmonary impairment.

Several recent studies have found that growing up on a farm, especially if exposed to farm animals in early life, decreases the risk of allergic disease, including atopic asthma. While not all studies have found this to be consistently the case, some studies suggest that endotoxins may be conveying a protective effect through modulation of the immune response, resulting in lower rates of atopy and allergic diseases including allergic rhinitis, airway hyper-responsiveness, and asthma. However, as asthma is a multifactorial disease, numerous risk factors must be assessed, including the livestock environment. Such assessments are often lacking or incomplete in published papers on this topic. When children work in CAFOs they will experience the same types of exposure as other farm workers, and thereby experience an increased risk to asthma despite any modulation of the immune response.

Clinical effects arising from dairy farming exposures

As with swine and poultry livestock farmers, the most common clinical finding is that of chronic bronchitis arising from exposure to organic dusts and other irritants in the dairy environment. However, the inter-relationship between symptoms and exposures is complex. A series of studies of Wisconsin dairy farmers have found that those with antibodies to organisms (*Saccharopolyspora rectivirgula*, *Thermoactinomyces vulgaris*, *Saccharomonospora viridis*, *Aspergillus fumigatis*, *T. candidis*, and *T. sacchari*) thought to cause farmer's lung disease (FLD) had a significantly higher prevalence of chronic cough and phlegm, a finding that might be explained by larger dairy herds and their higher microbial exposures.

Serologic assessments of Wisconsin dairy farmers by immunoassay have found that a positive serology to one or more of these organisms occurred in as many as 75% of individuals in of one large population-based cohort. Acute respiratory symptoms, including cough, fever, chills or dyspnea, occurring 4–12 hours after exposure to moldy hay or silage, were found in 17% of these dairy farmers, most of whom were seropositive. There is some evidence that those with

acute respiratory symptoms with dairy barn exposure are more likely to be sensitized to storage mites. However, many of these episodes occurred with silo unloading or chopping of bedding with very high exposures, and are most likely to represent ODS rather than the acute phase of FLD.¹² Because these symptoms are relatively common among dairy farmers, and because the frequency of a positive FLD serology is so high, it is difficult to distinguish between an acute episode of FLD and ODS. Bronchoalveolar lavage in a nested-case-control study of this population showed little evidence of a lymphocytic response (evidence of FLD) among antibody-positive farmers with acute respiratory symptoms. This finding is consistent with the finding of a low prevalence of 4.2 cases per 1000 of clinically confirmed cases of chronic FLD in the original study of this large cohort. Serology status was not associated with diminished lung function in this population. Apart from the well-documented finding that dairy farmers with confirmed FLD have progressively diminished lung function with continued exposure, dairy farmers have been found to have surprisingly well-preserved lung function, even after years of exposure.

The other significant lung disease that is occasionally observed among dairy farmers is toxic pneumonitis, and occasionally ARDS, from inhalation of oxides of nitrogen in a recently filled silo (silo filler's lung). Although this exposure, which is now widely recognized among dairy farmers, occasionally results in fatal ARDS, it more commonly causes toxic pneumonitis, which may result in residual airway hyper-responsiveness and asthma. Both ODS and silo filler's lung occur following filling the silo. ODS typically occurs with removal of the moldy silage on top of the plastic cap placed over the fermented silage, and is characterized by a febrile illness, with numerous constitutional symptoms occurring 4–12 hours after exposure. Silo filler's lung usually occurs hours to several days following filling of the silo. Exposure most commonly occurs when the farmer enters a partially filled silo and is exposed to the brownish, highly irritating nitrogen oxide gases. The onset of symptoms of cough and breathlessness may be delayed for several hours and is dependent on the extent of exposure, but the febrile and constitutional symptoms typical of ODS do not develop. Immediate, often intensive, medical treatment is necessary for silo filler's lung but is rarely needed for ODS.

Clinical health effects resulting from exposure to laboratory animals

A number of cross-sectional epidemiologic studies of allergies to laboratory animals have shown a prevalence of allergy (allergic rhinitis, asthma, skin wheal formation or urticaria) to laboratory animals ranging from 15% to 33%.^{29–31} The prevalence of asthma in these studies has ranged from 1% to 12%. Authors frequently noted that asthmatics and others sensitized to laboratory animals often were transferred because of their sensitization or removed themselves from this occupational exposure.³² Allergic alveolitis is rare but has been reported from exposure to rat urine. Workers exposed to laboratory animals

have been found to be significantly more likely to have work-related symptoms of coughing, wheezing, and chest tightness than controls who have not been exposed to animals. Exposed workers also have been found to have airway hyper-responsiveness more often, and to have positive skin tests to a number of common laboratory animals including rats, mice, guinea pigs, hamsters, and gerbils.³³ Symptoms of laboratory animal allergy often are associated with a history of atopy.

Exposure assessments strongly suggest that the incidence of laboratory animal allergy is dose related.^{34,35} Recent studies using RAST-inhibition assays for animal antigens now provide a quantitative approach for assessment of dose-response relationships and a methodology to monitor strategies aimed at reducing these immunogenic exposures. Workers with laboratory animal allergy are frequently found to be sensitized to several animal species. Previous sensitization to animals as pets, most commonly to cats, becomes evident among new employees exposed within the first days on the job. Workers who are atopic are much more likely to become sensitized, especially at low levels of exposure. Among workers not previously sensitized, the latent period until sensitization may begin in weeks and is usually less than 1 year. There is now evidence that environmental control of these immunogenic exposures delays or prevents sensitization in some laboratory workers.³⁶ There is further evidence that endotoxin exposure is a determinant of respiratory symptoms among laboratory workers not sensitized to mice, thereby extending the need also to control this exposure.³⁷

MANAGEMENT AND PREVENTION

Epidemiologic studies of workers exposed to animals provide the keys to management and prevention of these respiratory diseases. There is evidence of a dose-response relationship between exposure and respiratory effects in all three of these occupational settings. It also is clear that early recognition of asthma, toxic pneumonitis, and allergic alveolitis (although very uncommon) is critically important to treatment and management of workers with these conditions.³⁸ Finally, use of dust control, appropriate work practices, and personal protective equipment to reduce or eliminate exposures is important in all three of these occupational settings.

Management of affected individuals

The most common respiratory conditions arising from these exposures are chronic bronchitis and ODS, both of which are manifestations of airway inflammation. Management of individuals with these conditions necessarily and primarily involves reduction of their exposure to organic dusts and other irritants and, if the individual is a smoker, smoking cessation. Because control of exposures in agricultural settings is difficult, management of the farmer with chronic bronchitis usually involves careful and continuing use of

appropriate respiratory protection. Negative pressure respirators or powered air-purifying respirators often are useful and are especially important in settings that involve very heavy exposures. The worker must be instructed in the maintenance, repair, and replacement of filters and the respirator. Although most workers are able to continue to work with the help of respiratory protection, those with significant airway obstruction, asthma, frequent expectoration, and those who find wearing a respirator unacceptable may require transfer to less dusty environments. In the case of farming, this approach may prove difficult or impossible.

Each of these occupational settings may result in occupational asthma. As with other forms of occupational asthma, it is important that the worker be separated from exposures that will exacerbate and worsen the worker's asthma. For this reason, farmers and laboratory workers exposed to animal environments that are thought to cause asthma must be counseled, very seriously, about the risks of continued occupational exposure. With farmers, it may be possible for them to delegate enough of the high exposure tasks that they can continue farming with respiratory protection and appropriate medical management. Some workers with laboratory animal allergy may be able to continue work with the use of appropriate personal protective clothing and an efficient respirator. However, if the asthma continues, these workers will need to be removed from animal exposures. This may require a costly career change for some farmers, for full-time animal handlers and for investigators who work directly with laboratory animals.

Management of toxic pneumonitis and ARDS requires the physician always to be alert to these rare respiratory disorders among farmers. Intensive care may be necessary and early intervention with steroids is important, a treatment that must often continue for several weeks following presentation. Medical management with steroids, leukotriene inhibitors and bronchodilators for asthma, a frequent sequela of toxic pneumonitis, often is necessary. With successful treatment, lung function may improve over a period of several months to 2 years. Workers with mild cases of toxic pneumonitis often make a full recovery, but more severe cases and those who had ARDS are typically left with significant, irreversible impairment.

Prevention

Prevention of respiratory disease among those exposed to animals requires a variety of approaches. Because some agricultural exposures are life threatening or may cause acute toxic injury, it is critically important that farmers understand and recognize the exposure risks in certain agricultural settings. All farmers with manure pits must be made aware of the very significant risk of potentially fatal exposures to hydrogen sulfide gas with agitation and pumping of liquid manure. Under no circumstance should a farmer ever enter a pit. If a pit must be entered, an air-supplied respirator with a full face piece must be used. This may entail working with the local fire department or hazardous materials unit. Farmers should work in pairs when pumping pits, remove their animals from the building over the pit,

and ventilate the pit and building during pumping. Similarly, dairy farmers must be made aware of the potentially fatal exposure to oxides of nitrogen they may face if they enter a recently filled silo. This practice should be avoided, if at all possible. Dairy farmers should work in pairs in loading and unloading silos, use safety harnesses, and employ effective respiratory protection if entering the silo is necessary. An air-supplied respirator should be used if a silo filled with nitrogen oxide gas must be entered, and an efficient negative pressure or powered air-purifying respirator should be used during silo uncapping.

At the present time, there are no specific dust standards for exposures in these work settings. There are US OSHA standards for control of hydrogen sulfide and ammonia, but enforcement of standards in farming is virtually nonexistent. Because there is evidence of dose-response relationships between some of these exposures and some measures of respiratory disease, efforts should always be made to reduce exposures, which often can be high.⁷ Occupational exposure limits for total dust (2.8 mg/m³) and ammonia (7.5 ppm) have been recommended by researchers for livestock confinement buildings. Engineering controls such as the use of more efficient ventilation systems, canola oil sprinkling systems in animal confinement facilities, and improved manure management practices, often can significantly reduce exposures to organic dust and irritant gases and vapors.³⁹⁻⁴¹ Improved work practices that include use of appropriate personal protective equipment, more frequent cleaning of animal quarters, and routine use of negative pressure respirators or powered air-purifying respirators in dusty areas, can help reduce exposure to these several agents.⁴²

Industrial hygiene controls are being instituted more frequently in an attempt to control exposure to animal allergens among laboratory animal workers. These controls include use of negative-pressure or powered air-purifying respirators for high-risk tasks, increased general exhaust in animal care facilities, carefully balanced ventilation systems that direct airflow from clean areas to dirty areas, performance of animal surgery and necropsy in laminar flow or fume hoods, and use of specialized cage-dumping stations that are equipped with high-efficiency particulate air filters and operate under negative pressure.⁴³ All of these measures can reduce aeroallergen exposures significantly. Under some conditions of positive pressure, certain caging systems designed to maintain experimental animals in a pathogen-free environment increase the aeroallergen levels in the animal suite and result in higher exposures to workers. Such caging systems should be fitted for direct exhaust or should be located in a room with higher air exchange rates.

37.2 Plant and Vegetable Exposures

James A Merchant

Exposure to plant dusts, or vegetable dusts, as they are commonly called, and their products represents perhaps the earliest and still the most prevalent form of occupational and environmental exposure to respiratory hazards. These exposures vary in their nature, their concentration, their health effects, and their relative risk. In the United States, where agriculture now involves less than 2% of the population, those with significant occupational and environmental exposure to these hazards still number in the millions. In developing countries, 50–70% of the population may be engaged in agriculture. Most of what we know about respiratory conditions arises from occupational studies, but community exposures to plant dusts have been documented to cause environmental asthma. Allergic rhinitis and asthma, both of which arise from occupational vegetable dust exposures, also result from exposure to grass and tree pollens, ragweed, and other common aeroallergens, and are common in the general population, but may be considered occupational hazards among those sensitive individuals whose jobs expose them to aerosols of these plants. Similarly, many plant exposures may result in a wide range of dermatologic conditions. These conditions are addressed in Chapter 29.

OCCUPATIONAL AND ENVIRONMENTAL EXPOSURES

A classification of occupational and environmental respiratory exposures to plant materials, commonly exposed occupations, and reported health effects is found in Table 37.2.1. Although this classification is not exhaustive, it does provide a useful summary of the variety and exposure settings of plant materials.

Exposure settings

There is a common pattern to occupational and environmental exposures to plant products. The largest population at risk is that engaged in agriculture. Plant exposures typically begin with harvesting of agricultural products. Harvesting of plants may result in significant respiratory exposures, including those transporting grain products for storage or to terminals for further transport for processing. Agricultural harvesting is typically a family affair, involving wives, children, and elderly, often retired farmers. Seasonal migrant farm workers and other seasonal workers also are exposed. Although all of these agricultural subgroups have some respiratory exposure, they have a far greater risk of traumatic injury (see Chapter 31).

Storage of plant products on the farm may result in still other respiratory exposures. Commodity prices often dictate whether the farmer will sell his or her crop, or store it on the farm or in the local elevator. Storage on the farm may result in very significant exposures to spoiled grain, especially when grain bins are cleaned out, or to moldy silage when a

silo is uncapped. Another important silo exposure arising from fermentation of silage are oxides of nitrogen. Vegetable dust exposure also occurs with grinding of grain for feeding of livestock and in handling processed grain in the form of animal feed. Antibiotics, often added to feed as growth promotants, and other antimicrobials add further potential respiratory hazards. Those who work in grain elevators typically face a very substantial exposure to grain dust. Grain handlers also are frequently exposed to respiratory irritant and neurotoxic fumigants, including carbon disulfide and methyl bromide, which often are used to suppress pest infestation of grain.

A second population at risk is community residents living in proximity to grain-handling facilities. Studies of epidemic asthma in New Orleans suggested that grain dust was the cause, and soybean dust was documented to cause epidemic community asthma in Barcelona arising from unloading and processing of soybeans. The extent to which transportation, storage, and processing of plant materials may contribute to community asthma is still poorly understood and is a priority for environmental health research.

The third major population at risk of exposure to plant products is the processors. Although grain and wood products are not subject to processing in the agricultural setting, plants yielding vegetable fibers typically are. The ginning of cotton to remove cottonseed results in the initial occupational exposure to cotton dust. Similarly, the retting of flax, especially traditional water retting, and the initial step in processing grain may also result in very substantial exposures. These agricultural operations remove vegetable material arising from the leaf and stem of plants, but they also result in entrainment of vegetable dust in the vegetable fiber or grain. As a result, the initial processes used in textile processing and grain milling may result in high exposures to these vegetable dusts. As textile, grain, and wood products move down the processing line, substantially greater numbers of workers are potentially at risk.

The fourth category of those exposed to these products is the end-users, including certain occupational groups and some consumers who may be environmentally exposed. Although these occupational groups, and especially the environmentally exposed consumers, have not been extensively studied, asthma is well documented among those using flour for baking and those using certain wood products for furniture making and woodworking. As a result, exposure to vegetable dusts remains an important source of occupational and environmental respiratory disease, including allergic rhinitis, asthma, bronchitis, airway obstruction, and rarely, hypersensitivity pneumonitis.

Environmental measurement

Assessment of environmental exposures to plant products involves both characterization of the constituents and

Dust types	Occupations	Respiratory conditions
<i>Vegetable fibers</i>		
Cotton	Ginners, textile workers, bedding and upholstery workers, and rope and twine makers	Byssinosis
Flax		Acute febrile syndromes
Soft hemp		Non-specific airway obstruction
Sisal		Chronic bronchitis
Jute		Rhinitis
Hard hems		
Sunn (Indian hemp)		
Henequen		
Mauritius hemp		
Manila		
St. Helena hemp		
Kapok		
<i>Grain dusts</i>		
Corn	Farm workers, grain handlers, millers, bakers, food processors	Occupational asthma
Rye		Hypersensitivity pneumonitis
Spring wheat		Acute febrile syndromes
Durum wheat		Non-specific airway obstruction
Barley		Chronic bronchitis
Oats		Rhinitis
Rice		
Soy bean		
Castor bean		
<i>Wood dusts</i>		
Western red cedar	Sawmill workers, carpentry, cabinet making, furniture making, wood processing	Occupational asthma
California redwood		Hypersensitivity pneumonitis
Cedar of Lebanon		Non-specific airway obstruction
Cocobolla		Chronic bronchitis
Iroko		Rhinitis
Oak		
Mahogany		
Abiruana		
African maple		
Tanganyika aningre		
Central American walnut		
Kejaat		
African zebra wood		
<i>Other plants</i>		
Coffee	Cutters, packers, blenders, processors	Occupational asthma
Black tea		Non-specific airway obstruction
Herbal teas		Chronic bronchitis
Tobacco	Printers and gum manufacturers	Rhinitis
Gum acacia		
Gum tragacanth		

Adapted from World Health Organization Study Group. Recommended health-based occupational exposure limits for selected vegetable dusts. Report Series 684. Geneva: World Health Organization, 1983.

Table 37.2.1 Respiratory conditions among workers exposed to vegetable dusts

quantitation of the exposure. Exposures to vegetable dusts are complex. With harvesting of plant products, some inorganic soil particles are retained, and become a part of the occupational or environmental exposure. Although the occupational aerosol arises predominantly from the plant itself, it is commonly contaminated with micro-organisms, most commonly gram-negative bacteria and their endotoxins, as well as fungi and their glucans and other mycotoxins. Other contaminants include insects, such as grain weevils and storage mites; hairs, feathers, and excreta of rodents and birds; and residual antimicrobials and agricultural chemicals, including fertilizers, pesticides,

herbicides, fungicides, and fumigants. Vegetable dusts also may contain constituents of weeds that contaminate the plant crop; these may be irritants or sensitizers in themselves.

The sampling strategy adopted for assessment of these exposures depends on the aim of the survey.¹ The most common approach has been measurement of total dust using a personnel sampling device with an open-faced filter. Work in the agricultural setting and in storage of plant products often results in massive exposures to the vegetable dust and its contaminants. For instance, exposures to total dust in farming and grain handling typically range from 2 to 3 mg/m³ to well over 100 mg/m³ in some instances. Exposure concentrations in the processing of plant products typically range from 0.5 mg/m³ to greater than 10 mg/m³. In some settings, such as the cotton textile industry, studies have demonstrated that total dust measurements often contained highly variable fractions of respirable dust and, therefore, have not been considered reliable indicators of risk. The vertical elutriator was developed and used as an area sampler to measure inhalable dust (15 micrograms in aerodynamic diameter), the biologically active fraction that penetrates the large and small airways. This sampling device has proved to provide reliable measurements of vegetable dust in the manufacturing setting, but it is not suitable for agricultural or general environmental assessment of these exposures in which use of total dust samplers is still preferred.

Research studies have developed a variety of sampling techniques to capture, quantify, and speciate bacteria and fungi contaminating vegetable dusts. Sampling filters have been found to be satisfactory sampling media for assessment of endotoxin and certain mycotoxins. Entomologic assessment of insects and mites that commonly contaminate these exposures is now giving way to the use of immunochemical testing, which is both more sensitive and quantitative. Endotoxins have been found to be important biologically active ingredients of plant exposures and, in the case of cotton dust, have been shown to be related in a linear dose-response fashion to decline in lung function across a work shift. Storage mites increasingly are being found to be important contaminants of plant products and to be responsible for some of the allergic rhinitis and asthma among those persons exposed.

CLINICAL EFFECTS

The various health effects that arise from exposure to vegetable dusts are summarized in Table 37.2.1. They will be only briefly discussed here because more detailed accounts on upper airway disorders (Chapter 20.3), asthma (Chapter 19.2), byssinosis and other cotton-related lung diseases (Chapter 19.3), irritant bronchitis (Chapter 19.4), and hypersensitivity pneumonitis (Chapter 19.6) are found elsewhere in the text. Although these health effects vary somewhat depending on the specific plant exposure, the nature of the contamination of the plant material, and the concentration of the exposure, occupational and environmental exposures to plant products cause both acute

and chronic conditions or diseases.² Ramazzini³ first made this observation in 1705:

‘... for there flies out of this matter a foul mischievous powder, that entering the lungs by the mouth and throat, causes continual coughs and gradually makes way for an asthma. . . . But in the long run if they find their affliction grows upon them they must look out for another trade; for ‘tis a sordid profit that’s accompanied with the destruction of health’.

Acute health effects

Acute health effects, especially from high exposures to respirable plant products, are common.^{4,5} Acute health effects may be divided into those characterized by symptomatic responses and those that may be characterized predominantly by functional responses. Although those who are symptomatic often have a measurable functional response, there is considerable variability between those who present with functional abnormalities and those who present with symptoms. Acute health effects characterized by symptoms include both irritant and allergic rhinitis, irritant and allergic asthma, and febrile and constitutional symptoms typical of organic toxic dust syndrome (OTDS). Functional abnormalities include decline in expiratory flow rates over a work shift and/or work week and heightened airway responsiveness following an occupational exposure as short as 1 week.

Acute upper airway symptoms

Occupational exposure to certain vegetable dusts results in inflammation and drying of the nasal mucosa. This problem commonly leads to a diminished sense of smell, to a chronic irritant rhinitis, and occasionally to chronic sinusitis and recurrent epistaxis. Some of the exposures listed in Table 37.2.1 result in a specific IgE response and allergic rhinitis among some exposed individuals. Nasal lavage of exposed workers typically demonstrates an inflammatory response.

Acute lower airway symptoms

Nearly all workers with high exposures to vegetable dusts exhibit a dry cough, and many develop chest tightness. Both of these symptomatic responses are dose related, are more frequent among smokers, and occur more commonly after an absence from work. Textile workers, who usually do not work weekends, commonly exhibit these symptoms at the beginning of the work week; for instance, Monday cough and chest tightness are the clinical hallmarks of byssinosis.^{6–10} With further exposure during the work week, the worker appears to develop a tolerance to the dust, and experiences diminished or no cough or chest tightness on Tuesday or later in the week. With further exposure and lung impairment, chest tightness may occur each day of the work week. New workers or visitors to these work sites, who have a history of asthma, may develop severe asthma after a single significant exposure to vegetable dust, even if the individual has not experienced asthma for several years. Workers who develop asthma almost always remove them-

selves from these jobs or are identified by medical surveillance programs and moved to jobs that reduce the risk of exposure.

Acute febrile syndromes

Two febrile syndromes have been described among workers exposed to vegetable dusts. It is likely that they differ only in the concentration and circumstance of exposure and share a common etiology: exposure to mycotoxins and endotoxins from gram-negative organisms that are indigenous to vegetable dust. Among workers regularly exposed to high concentrations of vegetable dust for the first time, or after a prolonged absence from exposure, an acute febrile response is often observed for the first several days of employment. This febrile illness, sometimes called mill fever or grain fever, is accompanied by constitutional symptoms of myalgias and fatigue. With further exposure, the worker is said to become ‘seasoned’ and these symptoms typically disappear.

Among workers exposed to plant products that are heavily contaminated with micro-organisms, such as moldy grain, moldy hay or spotted cotton – especially in poorly ventilated areas such as grain bins, silos or box cars – a severe febrile illness may ensue. With high exposures, workers experience very high rates of a flu-like illness consisting of fever, chills, myalgias, arthralgias, fatigue, cough, and occasionally, shortness of breath. These symptoms predictably begin 6–8 hours after exposure and often continue for many days, but rarely require hospitalization and respiratory assistance. It is common for the affected worker to complain of fatigue for several days or weeks following this illness. This syndrome is now recognized as organic dust toxic syndrome or OTDS. The much rarer, acute phase of farmer’s lung disease (FLD, an allergic alveolitis) may also arise from exposure to fungi, thermophilic bacteria, or both. However, FLD differs from OTDS in that it may occur from lower exposures, does not occur in clusters, is progressive with continuing exposure, and may lead to a chronic granulomatous lung disease.

Acute functional responses

Workers exposed to vegetable dusts have been observed to have modest declines, usually 5–10%, in expiratory flow rates over a work shift.¹¹ Of all of these measures, FEV₁ has been found to be the least variable and, hence, the most reliable indicator of this response. As a result, cross-shift change in FEV₁ has become a commonly used test for medical surveillance and epidemiologic studies (Fig. 37.2.1).¹² As with acute lower respiratory symptoms, a decline in FEV₁ is related to concentration of inhalable dust and endotoxin in a linear dose–response fashion.^{13,14} Although smoking has not been consistently found to have an effect on this measure, it does appear to enhance this response at higher levels of exposure. It has been observed that the FEV₁ and the forced vital capacity (FVC) often are proportionally reduced, with an increase in residual volume (RV) indicative of air trapping. While lower respiratory symptoms of chest tightness and declines in expiratory flow rates are common among exposed workers,

Mean \pm SEM * $p < 0.05$ compared with initial assessment. (From James AL, Zimmerman MJ, Ee H, et al. Exposure to grain dust and changes in lung function. *Br J Ind Med* 1990; 47:466–72.)

Figure 37.2.3: Bronchial responsiveness, expressed as log of dose of methacholine provoking a 20% fall in baseline FEV₁ (log PD₂₀) for grain handlers (triangles) and non-exposed subjects (circles) at initial assessment and at end of each week of work. Mean \pm SEM * $p < 0.05$ compared with initial assessment. (From James AL, Zimmerman MJ, Ee H, et al. Exposure to grain dust and changes in lung function. *Br J Ind Med* 1990; 47:466–72.)

these responses are not necessarily found in the same worker.

Recent studies have demonstrated that although symptoms and the decline in FEV₁ observed following these exposures usually resolve within a day or two, (Fig. 37.2.2) airway hyper-responsiveness commonly persists (Fig. 37.2.3).¹⁵ Prospective studies of respiratory symptoms and lung function suggest that those with acute respiratory symptoms are at greater risk of the development of chronic airway obstruction from chronic exposure to vegetable dusts.¹⁶

Chronic health effects

With prolonged exposures to vegetable dust, as commonly occurs in the cotton textile industry and among grain handlers, some workers will develop chronic bronchitis and irreversible airway obstruction.^{17,18} While not as easily demonstrated as are acute health effects, these chronic effects also are dose related.

Data from the cotton textile industry indicate that even low doses of cotton dust (below the OSHA standard of

0.2 mg/m³) may not be fully protective, especially if the worker continues to smoke.^{14,19} Although chronic bronchitis frequently occurs within the first few years of employment, significant airway obstruction usually is not observed until after 10 years of employment. With prolonged occupational exposure to moderate or high concentrations of these vegetable dusts, some workers may develop severe and disabling chronic airway obstruction. Cigarette smoking has been found to be an important additive risk factor to both chronic bronchitis and chronic airway obstruction among these workers. Although removal of workers with acute responses from these exposures makes prospective evaluation of this question more difficult, those with the acute responses of chest tightness and significant cross-shift declines in FEV₁ do appear to have accelerated annual declines in FEV₁. This observation adds to the importance of recognition of acute responses to vegetable dusts for both clinical and preventive applications. Thus with improved dust control in the cotton textile industry, which resulted from a standard based on acute dose-response data, the proportion of workers with chronic airway diseases has significantly declined.

MANAGEMENT AND PREVENTION

Epidemiologic studies of workers exposed to vegetable dusts have provided very good guidance for clinical management. Many of the tests employed in epidemiologic studies have been applied to medical surveillance programs for exposed workers. Similarly, some of the environmental measurement techniques, notably the use of the vertical elutriator in the cotton textile industry, have been adopted for environmental monitoring of some of these workplaces. Because both acute and chronic health effects are dose related, dust control is the foundation for all other elements of management and prevention. With increasing confidence that acute health effects are predictors of chronic health effects for these exposures, dose-response studies of acute respiratory symptoms and changes in lung function are gaining greater importance as indicators of appropriate permissible limits (PELs).

Management of affected individuals

Management of workers affected by these exposures is extremely important. Medical surveillance methods mandated by the United States OSHA Cotton Dust Standard still provide useful guidance. Exposed workers should have annual medical evaluations during which respiratory symptoms, smoking status, and FEV₁ before and after a Monday work shift should be documented. Those with acute respiratory symptoms or significant and replicable declines in FEV₁ (>5%) should be transferred to a low dust exposure area and monitored at least semiannually. Workers with significant airway obstruction (FEV₁ less than 2 standard deviations [SDs] of predicted) should similarly be transferred to low-exposure areas. Those workers who exhibit rapid declines in lung function or moderate to

severe airway obstruction (<60% of predicted for race, sex, age, and height) should be referred for a full pulmonary evaluation to determine their eligibility or need for reassignment to a job involving no exposure to vegetable dust and/or workers' compensation.

Workers who develop clinical asthma from their exposure to vegetable dust must be evaluated very carefully. Some with asthma may be transferred to low-dust areas, which may result in asthma control. Respiratory protective devices may be useful with mild asthma. If such a move appears to be successful, these individuals must be followed closely (at least every 3 to 6 months) to assess respiratory symptoms and lung function. With worsening asthma or a progressive decline in lung function – even at a low level of exposure – it is then very important to transfer the worker to a work area that is free of vegetable dust and other respiratory irritants. For some, asthma may be so severe that continued work is not possible, even in an area that is free of respiratory irritants. In these cases, the only recourse may be to assist the worker in seeking workers' compensation.

Prevention

Prevention of acute and chronic health effects arising from exposure to vegetable dusts and assessment of risk depends on assessment and control of dust levels. Dose-response studies of several vegetable dusts, including cotton and mixed grains, have resulted in recommended PELs for each of these exposures. In the United States cotton textile industry, in which assessment of dose has depended on use of the vertical elutriator, OSHA has set a PEL of 0.2 mg/m³ for exposure to cotton dust in preparation and yarn processing areas, and a PEL of 0.75 mg/m³ for slashing and weaving areas where biologically inactive, but inhalable, material is added to the process.¹⁴ Over the decades that have followed regulation of cotton dust, considerable progress has been made by the cotton textile industry through the use of new technology, exhaust ventilation, and improved work practices. Based on dose-response studies of grain handlers, which have depended on measurement of total dust, the American Conference of Governmental Industrial Hygienists (ACGIH) has recommended a Threshold Limit Value (TLV) of 4 mg/m³ for mixed grain dust. Based on the documented adverse health effects, these dose-response relationships, and the risk of grain dust explosions, concentrations of grain dust have been reduced over time (Fig. 37.2.4).

Routine medical surveillance of workers with these exposures is also necessary. The medical surveillance plan implemented through the US OSHA Cotton Dust Standard has proven to be both practical and effective in management of workers with adverse health effects. As dust is controlled, the numbers of workers with adverse health effects decrease, and these medical surveillance programs become more easily managed. Other aspects of prevention include attention to work practices to reduce exposure, appropriate use of personal protective equipment, notification of workers regarding the risks of these and other hazardous exposures, and appropriate record keeping of both medical and

Figure 37.2.4: Proportion of personal dust samples (total grain dust) measuring greater than 4 mg/m³ (dark bars) or greater than 10 mg/m³ (pale bars) for Vancouver terminal grain elevators 1974–1989; total number of samples overall = 781 (100). environmental data. In settings where dust control is not possible, as often occurs in farming, the appropriate use of respirators can diminish exposure. Finally, prospective epidemiologic studies of these vegetable dust exposures and their respiratory disease outcomes will refine our understanding of the natural history of health effects arising from these exposures, improve techniques to measure biologically relevant dose, and yield more innovative dust control and prevention methods.

Chapter 38

Psychologic Stressors and Work Organization

James W Grosch, Steven L Sauter

Job stress is an everyday reality for many workers and a growing concern in the field of occupational safety and health. This is especially true in light of recent changes in the workplace (e.g., increasing work hours; non-standard employment practices) and increasing evidence that stress has serious implications for worker health. Although job stress is still a subject of some uncertainty to many occupational safety and health professionals, research over the past four decades has taught us much about the sources, effects, and prevention of stress in the workplace.

This chapter begins with a brief historical perspective on job stress and then presents an overview of current knowledge organized around three fundamental questions.

- What is job stress?
- How is job stress related to occupational safety and health?
- How can the adverse effects of job stress be reduced or prevented?

JOB STRESS: HISTORICAL PERSPECTIVE AND OVERVIEW

The field of occupational stress coalesced in the 1960s, arising amidst growing concerns over worker alienation, job dissatisfaction, and mental health problems, concerns which originated during the Industrial Revolution, with the implementation of mass production technologies and the re-design of jobs. Mass production methods and the introduction of scientific management principles at the end of the 19th century resulted in the simplification and fragmentation of jobs into highly repetitive and routine tasks, and the treatment of workers as commodities motivated purely by economic rewards.

The well-known Western Electric Hawthorne studies¹ and other studies beginning in the 1920s, however, drew attention to the fact that social and psychologic factors that had been given little attention served as important motivators for workers. The Hawthorne investigators realized that the increased attention, feedback, and freedom from supervisory control given to workers in the context of studies on the effects of lighting and other physical environmental factors had an important independent effect on productivity. These landmark observations paved the way for what would later become the human relations movement and efforts to 'humanize' the workplace. They also set the stage for a new field of research on the effects

of social and psychologic aspects of work on the satisfaction, health, and mental health of workers.

In 1935, Robert Hoppock surveyed the entire population of New Hope, Pennsylvania, and discovered substantial occupational differences in satisfaction, with unskilled manual laborers exhibiting the least satisfaction and professional and managerial workers exhibiting the most satisfaction.² In studies of automotive workers in the 1940s, Walker and Guest found that the rigid pacing and fragmentation of work in the automotive assembly line led to high levels of stress and discontent among workers.³ Ciulla reported annual turnover of 100–250% in automobile assembly work in the early decades of the 20th century.⁴ Observations similar to Walker and Guest's findings were reported in other industrial settings by Kornhauser in his seminal book *Mental health of the industrial worker*.⁵

Before long, theories and models of occupational stress began to emerge in both the US and Europe. Research in Sweden by Bertil Gardel, Lennart Levi and their colleagues at the Karolinska Institute identified the lack of control and limited opportunities for learning and social interaction characteristic of industrial work as important risk factors for stress and illness among workers.⁶ Notably, these factors occupy a central place in the present day 'demand-control' model of job stress popularized by the work of Robert Karasek.^{7,8} Robert Kahn drew attention to work roles (role conflict and ambiguity) as risk factors for job stress in the early 1960s⁹ and, together with colleagues at the University of Michigan Institute for Social Research, pioneered epidemiologic studies and theoretical developments in job stress in the US. Particularly notable in this regard was the highly influential study of job stress and health that investigated the impact of nearly two dozen facets of job demands in 23 occupations on somatic complaints and psychophysiologic outcomes.¹⁰

Job stress research subsequently flourished in the US and Europe. Beehr¹¹ observed that prior to 1972 not a single entry could be found under the heading 'occupational stress' in the index of 'Psychological Abstracts', but the number of abstracts then grew exponentially. In the US, much of this growing momentum could be attributed to leading figures such as Alan McLean of the Center for Occupational Mental Health, Cornell University, who worked with industry, labor, and government organizations to host major conferences on stress at work in the 1960s and 1970s.¹² The US Department of Health,

Education and Welfare also played a key role. In 1965, a task force appointed by the Surgeon General expressed concern that 'millions of American workers, as a direct result of their occupations, are exposed to health damage . . . increasingly from psychological stress' and appealed for greater attention in the occupational health field to this problem.¹³ In 1971 a task force was convened by Elliot Richardson (then Secretary of the Department of Health, Education and Welfare) and in 1974 issued the highly acclaimed report *Work in America*¹⁴ that concluded that workers and society are bearing serious medical costs that have their genesis in preventable workplace stressors. In this same period, Congress passed the Occupational Safety and Health Act that gave broad recognition to behavioral factors and stress as etiologic agents for occupational disease and injury, and charged NIOSH with the responsibility for investigating these factors.¹⁵

Today there exists widespread appreciation of the threat that stress poses to the health of workers and organizations. In the US, nearly half the states legitimize 'mental injury' from stressful working conditions as a compensable condition under workers' compensation,¹⁶ and these types of claims grew dramatically throughout the 1980s until legislative reforms reduced their numbers. Northwestern National Life Insurance (now Reliastar) reported that stress-related disability claims comprised 13% of all disability claims processed in 1990 – up from 6% in 1980.¹⁷

Most recently, concerns have been expressed that the rapid restructuring of jobs and the workforce evidenced in the tumultuous 1990s and continuing today may further heighten the risk of stress among workers.¹⁸ Data from the Families and Work Institute, for example, show a marked increase from 1977 to 2001 in the percentage of workers who report that they work very hard (70–88%) and never have enough time to get things done on the job (40–60%). During roughly this same period, prime-age working couples increased their annual work time by nearly 700 hours.¹⁹ Although available information fails to confirm an increase in reported job stress in the last decade, the prevalence of reported job stress during this period remains high. US representative data obtained from the General Social Survey show that the percentage of workers who reported their jobs to be 'often' or 'always' stressful was 39% in 1989 and 36% in 1998.²⁰ These figures are in reasonable agreement with other recent data suggesting that stressful working conditions are very prevalent. For example, in the 1991 Northwestern National Life study, 40% of workers reported their jobs to be 'very' or 'extremely' stressful. In 1997, the Families and Work Institute reported that 26% of workers said they were 'often' or 'very often' burned out or stressed by their jobs, and 36% felt 'often' or 'very often' used up at the end of the day.²¹

These high levels of reported stress take on special significance in the presence of recent data on the economic and health burden of stress in the American workforce. Data from the Bureau of Labor Statistics Survey of Occupational Injuries and Illnesses show that lost-time cases due to job stress are among the most serious in terms of the length of the disability period. In 1997, the median absence period

was 23 days, more than four times the median for all other injuries and illness.²² Adding to these data is sobering information on increased healthcare utilization among workers reporting high levels of stress in the workplace. In a 1998 study of 4600 employees, healthcare costs were 46% greater for workers reporting high levels of stress compared to workers reporting low levels of stress. The increment rose to nearly 150% for workers reporting high levels of both stress and depression.²³

Together with improved recognition of the scope and organizational costs of stress in the workplace, research has led to a better scientific understanding of the stress process – risk factors, mechanisms, safety and health effects, and of interventions to prevent stress at work. In following sections of this chapter current knowledge on these topics is summarized, beginning with an overview of different conceptual approaches to stress and the stress process.

WHAT IS JOB STRESS?

As concern about job stress has grown, the different ways in which stress is defined and conceptualized have expanded.^{24–26} These approaches, in emphasizing different elements of the stress experience, provide a sense of how our understanding of job stress has evolved over the past few decades.

Job stress as a response

Perhaps the most obvious approach is to focus on how the body responds to a threatening situation. In this case, stress is viewed as a dependent variable and conceptualized in terms of changes that an individual experiences in physiologic, emotional, and behavioral functioning. Walter Cannon, an early investigator of the physiologic aspects of emotion, described the 'flight or fight response' that typically occurs when an organism perceives a threat. Although this response can be adaptive in some situations, Cannon argued that it can also be harmful, particularly when it involves the repeated activation of the sympathetic nervous system and the endocrine system.²⁷

Hans Selye extended this physiologic perspective and introduced a triphasic model, called the general adaptation syndrome, to describe an individual's response to a stressful situation.²⁸ In the alarm phase, the body reacts with an increase in adrenal activity, as well as cardiovascular and respiratory functioning. During the resistance stage, the individual either takes action to overcome the external threat or learns to adjust to it. Finally, if continued wear and tear on the body takes place, exhaustion occurs involving a depletion of physiologic resources and an increased likelihood of illness or disease. Underlying this model is Selye's definition of stress as a 'non-specific response of the body to any demand made upon it'.²⁸ Although we now know that there can be subtle differences in how the body reacts to different types of external threats,²⁹ Selye's model provides a useful first step in understanding how repeated stress can result in disorders,

such as cardiovascular disease, musculoskeletal problems, hypertension, and immune-related deficiencies.

Job stress as a stimulus

An alternative perspective is to view stress as being ‘out there’ or part of the external environment. This approach has its roots in engineering and the focus on understanding what happens when an outside force or demand is applied to an object. In this case, stress is an independent variable that produces harm when an individual’s tolerance level is exceeded. Symonds³⁰ summarized this view when he stated that ‘stress is that which happens to the man, not that which happens in him; it is a set of causes not a set of symptoms’. Much of the impetus for this perspective comes from early industrialization when the primary concern regarding worker health centered on the physical work environment (e.g., heat, noise, social density) that could be measured objectively. This view has contributed to the cataloging of different sources of job stress and a desire to develop objective measures that do not necessarily depend on individual perception.

Current models of job stress

Defining job stress solely in terms of either a response or a stimulus has inherent limitations. Both of these approaches are static, overly simplistic, and reflect only one component of the stress experience. They largely ignore individual differences that can moderate the impact of stressful conditions, as well as perceptual and cognitive processes that may ultimately determine how a worker interprets and responds to a stressful situation. Most contemporary theorists agree that job stress is best thought of as an interaction between a person and his or her work environment. In other words, job stress does not lie solely in the individual or in the situation, but rather, in the degree of ‘fit’ between the two.^{31,32} Job stress terminology has also come to reflect an interactionist perspective, with ‘stressor’ referring to adverse events in the work environment and ‘strain’ referring to the physiologic and emotional responses to those events.

Despite a general consensus on job stress as an interaction, contemporary theories of job stress vary with regard to the features in the person or work environment they emphasize. These theories can be viewed as falling onto a continuum that ranges from a *clinical perspective*, which emphasizes primarily individual-level processes, to a *public health perspective*, which emphasizes job and organizational-level factors. To some degree, this continuum still reflects the response and stimulus biases of earlier approaches, but it also provides a much richer view of the range of factors that need to be considered in understanding the causes and consequences of job stress.

Clinical perspective

Clinical models of job stress acknowledge the importance of the individual in the stress process, and factors such as coping and stress management tend to play an important

role in prevention strategies. One area receiving a great deal of attention is the appraisal process, or how an individual evaluates the environment, the threats it may pose, and ways of coping with those threats. Lazarus^{33,34} argued that appraisal is a fundamental element of the job stress experience and proposed two different types: primary appraisal in which an individual initially determines whether or not a situation presents a risk (stressful or not), and secondary appraisal in which an individual determines the availability of different coping options for dealing with the stress.

Appraisal is conceptualized as a dynamic, or transactional, process that develops over time through an ongoing relationship between an individual and the work environment. Lazarus’s theory also focuses on identifying different types of coping strategies.³⁵ For example, workers may adopt a coping strategy that is problem focused and involves an attempt to alter the situation by changing either one’s behavior or some aspect of the environment. Alternatively, workers may choose an emotion-focused strategy that involves an attempt to regulate or manage the strain experienced from a particular event. This basic dichotomy has inspired other experts on stress to develop more elaborate taxonomies of coping strategies that can be found in the literature (e.g., Pearlin et al³⁶). Most authors emphasize that there is no single best coping strategy, and effectiveness must be evaluated in light of individual characteristics and the specific work context.

The emphasis on appraisal and coping advocated by Lazarus can be found in a number of theories on job stress, usually referred to as ‘transactional’ models of job stress. Cox and Mackay,³⁷ for example, proposed that stress occurs when there is an imbalance between the perception of environmental demands and a worker’s ability to cope with those demands. The impact of this imbalance is determined through a five-stage sequence that includes: cognitive appraisal of work demands, a judgment of one’s ability to cope with the demands, awareness of changes in wellbeing, evaluation of the effectiveness of coping strategies and, finally, stress that affects future perceptions of work demands and selection of coping strategies. Consistent with Lazarus’s view, the emphasis rests with understanding how workers perceive, interpret, and individually react to their environment.

A more current approach to job stress focusing on the individual is advocated by Siegrist,³⁸ who goes further than Lazarus in targeting specific features of the work environment. Siegrist proposed that chronic strain results from a perceived imbalance between the efforts required of an individual and the rewards he or she receives for that effort. In other words, strain occurs when there is a combination of high effort and low reward at work. Siegrist defined effort as consisting of both extrinsic (e.g., work demands and pressure) and intrinsic (e.g., coping pattern) dimensions. Rewards were measured by combining the financial, self-esteem, and status outcomes a worker receives from a job. According to the model, an imbalance between effort and rewards (i.e., high effort/low reward condition) produces ‘a state of emotional distress with

special propensity to autonomic arousal and associated strain reactions'. Initial findings indicate a significant link between perceptions of effort/reward imbalance and cardiovascular risk factors, such as hypertension and altered lipoproteins. Although additional research is needed to further evaluate the assumptions of the Siegrist model and its applicability to other health outcomes, this approach highlights the importance of an aspect of the workplace – namely, the perceived fairness of costs and benefits experienced by employees – that is seldom emphasized in other theories of job stress.

Public health perspective

Public health models of job stress differ from clinical models in that they tend to place more emphasis on the work experience itself as a risk factor for job stress, and work reorganization as the primary strategy for preventing stress at work. Two factors in this tradition that have long been associated with heightened levels of strain are excessive work demands and lack of control over one's work environment. A widely recognized model incorporating both of these dimensions was proposed by Karasek⁷ and is referred to as the demands–control model.

Figure 38.1 presents this model in terms of four different combinations of control (also referred to as 'decision latitude') and demands (high versus low). A key prediction of the model is that demands and control interact so that workers falling into quadrant IV (high demands, low control) experience the highest levels of job strain and an increase in the risk of illness (e.g., cardiovascular disease). However, workers in quadrant III, with active jobs, who experience high demands *and* high control, are at less risk of strain. In other words, a high degree of control offsets the harmful effects of high work demands. The other two quadrants are also seen as producing reduced strain, although workers in quadrant I may report problems associated with monotony or boredom. Unlike the Siegrist or Lazarus models, the demands–control perspective does not place much emphasis on individual differences or worker attempts to cope with the strain they experience. Karasek's model has been widely tested and has received a moderate level of support, although empirical evidence for an inter-

active effect (in contrast to an additive effect) between control and demands is generally weak and inconsistent. In addition, the model has recently been expanded to include the dimension of social support, which is seen as a factor that can reduce the harmful effects of a job that has high demands and low control.

Many other organizational-level factors have been implicated with regard to worker strain. For example, Robert Kahn and his colleagues emphasized the importance of *role demands* that workers face.⁹ These demands include stressors such as *role ambiguity* (i.e., lack of clarity about work expectations) and *role conflict* (i.e., incompatible work demands) and have been linked to a variety of adverse health outcomes.²⁶ *Job insecurity* has also received a great deal of attention, particularly as organizations downsize their workforces and increasingly rely on temporary, or contingent, workers. Much of this research focuses on unemployment (actual or anticipated) and its association with outcomes such as poor health, depression, and suicide.³⁹ Specific work practices such as *shift work* and *long working hours* have also been studied with regard to their potential negative impact on workers.

In order to include a broad range of variables in a single framework, researchers have developed process models that draw on variables from a variety of theories and empirical studies.^{40–42} Figure 38.2 illustrates the NIOSH job stress model developed by Hurrell and Murphy.⁴² This model views stress as an interaction between working conditions, or stressors, and individual worker characteristics that results in acute strain reactions which, if continued over time, lead to illness and injury. Job stressors include those already described (e.g., control, role demands), as well as variables taken from other theoretical perspectives.

An important feature of the NIOSH model is the identification of factors that can moderate or buffer the health impact of job stressors. For example, personality can play an important role in how an individual reacts to a stressful environment. Two personality constructs receiving increasing attention in recent years are the Type A behavior pattern and self-efficacy. Type A individuals are characterized by high levels of competitiveness, achievement striving, time urgency, and aggressiveness. Individuals displaying this pattern, and particularly those with high levels of hostility, may be more prone to develop cardiovascular heart disease.⁴³ In contrast, individuals with high self-efficacy are confident in their abilities and believe they are capable of successfully completing a given task. Research indicates that this quality may help individuals remain resilient in the face of stressful working conditions.⁴⁴ Despite these moderators, the emphasis of the NIOSH model rests with organizational and job-based stressors, which are viewed as having the most significant and direct impact on the acute reactions and illnesses ultimately experienced by workers.

Figure 38.1: The demand and control model of job strain. (Adapted from Karasek R, Theorell T. *Healthy work: stress productivity and the reconstruction of working life*. New York: Wiley & Sons, 1990).

Conclusions

Of all the theories reviewed thus far, none has met with universal acceptance. Indeed, a number of methodologic

Rights were not granted to include this figure in electronic media.

challenges remain if our understanding of job stress is to progress in the future. These include the further development of improved measures for assessing risk factors for stress at work (e.g., assessments by coworkers, managers, objective measures) and greater reliance on prospective studies that follow workers over time. However, current theories of job stress provide different focal points that are useful in diagnosing and treating stress-related problems. Whether we adopt a clinical or public health perspective, job stress needs to be viewed as a complex interactive process involving both the workplace and the individual that, if left unchecked, can have serious consequences for a worker's health and safety.

HOW IS JOB STRESS RELATED TO OCCUPATIONAL SAFETY AND HEALTH?

Potential pathways linking job stress and health outcomes

Before discussing specific outcomes associated with job stress, the different pathways through which stress may affect safety and health should be addressed. Figure 38.3 presents a model based on the work of Cohen and Rodriguez,⁴⁵ who focused on understanding the link between psychologic and physical disorders. The model is intended to be heuristic in nature and makes no attempt to include all possible variables or pathways affecting the development of a particular health disorder (e.g., individual differences and cultural variables are omitted). However, the four pathways identified in the model provide a useful conceptualization of how stress can result in health

disorders that has implications for both treatment and prevention.

Biologic pathways

Changes in physiologic functioning represent the most direct pathway between stress and health and have been studied in both human and animal subjects. These changes can be categorized as either non-specific (occurring with most affective states) or specific (occurring with some affective states more than others). Two non-specific changes involve the activation of the sympathetic-adrenal-medullary (SAM) system and the hypothalamic-pituitary-adrenocortical (HPA) axis. SAM activation involves sympathetic arousal and release of adrenaline and norepinephrine from the adrenal medulla, two catecholamines that stimulate organ systems throughout the body, leading to a heightened state of physiologic activation (e.g., increased heart rate, blood pressure, skin conductivity, and respiration). HPA activation, on the other hand, is characterized by the release of three main hormones. Initially, corticotropin-releasing hormone is secreted by the hypothalamus, causing the pituitary gland to release adrenocorticotropic hormone. This stimulates the adrenal cortex which, in turn, releases corticosteroids. One of the most important corticosteroids is cortisol, which works to increase the level of fatty acids and glucose in the blood stream. Research suggests that excessive activation of SAM and HPA contributes to a variety of disorders, including coronary heart disease, essential hypertension, increased susceptibility to infectious disease, atherosclerosis, and chronic inflammatory responses, such as rheumatoid arthritis.⁴⁶

Physiologic changes can also show specificity with regard to the nature of the external threat. For example, research

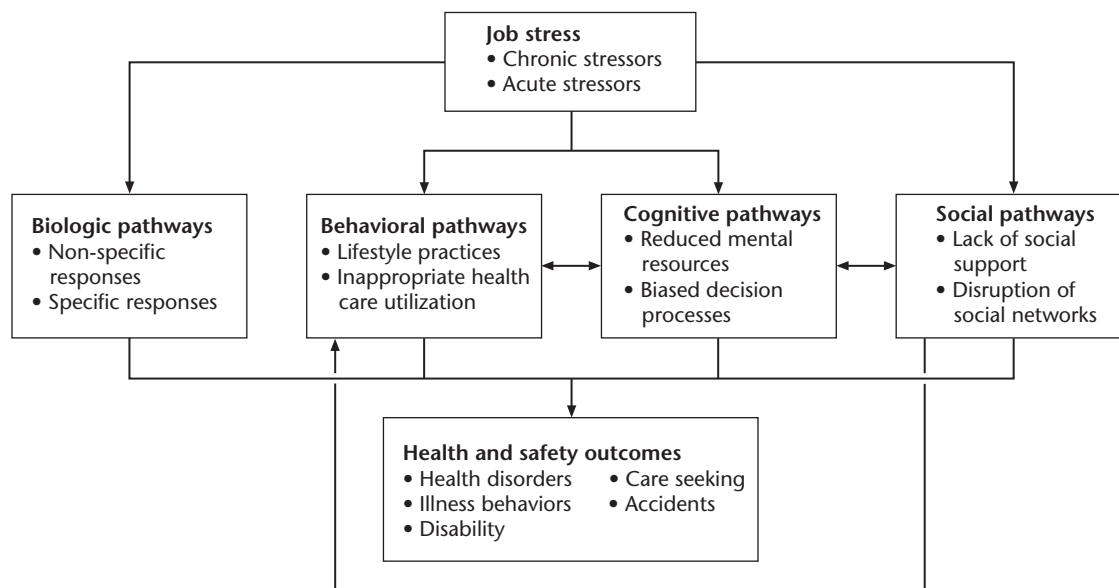

Figure 38.3: Pathways linking job stress to health and safety outcomes (based on a model developed by Cohen S, Rodriguez MS. Pathways linking affective disturbances and physical disorders. *Health Psychol* 1995; 14:374–80).

suggests that anxiety-producing situations are associated with increased levels of adrenaline, whereas increased levels of noradrenaline are associated with aggression-producing situations.²⁹ Similarly, in terms of specific job stressors, Frankenhaeuser⁴⁷ has proposed that the body's response is different for work that is demanding versus work in which there is a lack of control. In the former case, adrenaline levels are thought to increase; in the latter case cortisol levels are also raised because the worker is more likely to feel distress or unhappiness.

Behavioral pathways

Stressful situations and events can also lead to behaviors that make an individual more vulnerable to health problems. These behaviors can be viewed as maladaptive coping strategies that may provide some relief in the short term, but hold serious health consequences over the long term. The list of behaviors linked to job stress includes smoking,⁴⁸ alcohol consumption, lack of exercise, poor diet,⁴⁹ being overweight,⁵⁰ non-medical drug use,⁵¹ and poor sleeping habits.⁵² In addition, stress at work may influence whether or not an individual seeks out appropriate healthcare services for a problem, and the degree to which workers are willing and able to follow safety practices at work that should reduce the risk of accident or injury.

Cognitive pathways

Job stress can also influence how an individual thinks about or appraises a given situation at work. This appraisal process includes specific beliefs that develop about the harm or threat posed by an event, its causes and controllability. In terms of health perception, research suggests that stress can lead to different biases in how a worker interprets various physical symptoms and decides at what point it is appropriate to seek diagnosis or treatment.⁵³ Also,

cognitive responses to stress can result in mental fatigue and a reduced ability to attend to other tasks. As a result, there may be less time and energy to focus on other demands, leading to arousal, reduced performance, and other symptoms of strain.

Social pathways

The value of social support from family, friends, and coworkers has long been studied by stress researchers. Although social support is often included in job stress models as a moderator variable (see Fig. 38.2), it can also be viewed as an outcome variable that is itself influenced by job stress. For example, stress can reduce an individual's ability to maintain or build social networks that provide the necessary resources for coping with difficult situations.⁵⁴ When social networks are disrupted, an individual may have less incentive to follow good health practices and may be less likely to seek care for a given health problem.

An important feature of Figure 38.3 is that the four pathways described above interact, so that, for example, a change in social functioning might produce a change in cognition and behavior which, in turn, increases susceptibility to a physical illness over time. This model highlights the complexity of the stress process and the fact that job stressors have a variety of avenues through which they can influence a worker's health and safety. The actual pathways a job stressor activates are undoubtedly influenced by many factors at both the individual and organizational level.

Safety and health outcomes affected by job stress

In addition to identifying pathways, a good deal of research has focused on identifying the potential outcomes

associated with job stress. A brief overview of this research is provided below and is divided into three broad categories: physical health, mental health, and organizational-level outcomes.

Physical health outcomes

Cardiovascular heart disease (CHD) Much of the research on CHD focuses on the two job stressors identified in the Karasek model (see Fig. 38.1): work demands and job control. For example, in a large prospective cohort study of British civil servants, low job control, both self-reported and externally assessed, was associated with an increased risk of new coronary heart disease. This risk remained after adjustment for lifestyle and personality factors, suggesting that the job control–heart disease association is independent of personal characteristics.⁵⁵ Numerous other studies have examined the importance of job control and job demands with regard to a broad range of CHD outcomes, including high blood pressure, angina, myocardial infarction, elevated concentrations of fibrinogen, and subclinical carotid atherosclerosis. Overall, the findings suggest that a significant role is played by both of these job stressors, although there are notable exceptions (e.g., Hlatky et al⁵⁶) and methodologic issues exist regarding how demands and control should be defined and measured.⁵⁷ Research on other job stressors has found increased CHD risk for specific work practices, such as shift work and overtime work, as well as for more general psychosocial factors, such as reduced job complexity and social support, and job insecurity.⁵⁸

Musculoskeletal disorders Some of the most common job stressors that have been studied with regard to musculoskeletal disorders include mentally demanding work, monotony, reduced coworker and supervisor support, time pressure, reduced job control and reduced opportunities for rest breaks. Overall, evidence suggests that these types of stressors are associated with work-related low back pain and, less consistently, with work-related upper extremity disorders.⁵⁹ These findings are impressive given the range of different research methodologies that have been employed. However, more remains to be learned regarding the biologic pathways through which job stress produces musculoskeletal problems, and the degree to which job stressors and physical demands interact.⁶⁰

Immune deficiency disorders Numerous studies suggest that the physiologic changes associated with stress (e.g., release of cortisol) can have a serious impact on the immune system. Laboratory research has established that psychologic stress can produce changes in the level of antibodies in the blood and the level of many white blood cells.⁶¹ Exposure to even brief periods of stress may influence levels of natural killer cells and lymphocytes. Changes in immune functioning, however, are very complex and seem to depend not only on the type of stressor, but also on what type of coping strategy the individual is using to deal with the situation. Health problems that have been linked to stress-induced immune suppres-

sion include asthma, rheumatoid arthritis, a wide range of infectious diseases, and recovery from illnesses such as pneumonia and the flu.⁴⁶ Although one might expect that immune suppression would be linked to increased risk for cancer, there is little direct evidence to support this association.⁶²

Gastrointestinal problems A good deal of research has focused on the relationship between stress and the development of ulcers caused by factors such as pepsinogen levels or inadequate secretion of bicarbonate and mucus. In a review of this literature, Suls concluded that, although humans exposed to acute stress in the context of severe physical trauma are prone to ulcers, the evidence for an association with psychologic job and life stressors is weak.⁶³ Evidence that job (or life) stress causes elevated levels of pepsinogen and acid secretion, or that ulcer patients experience more work stressors is inconsistent. Additional research has recently focused on irritable bowel syndrome (IBS) and non-ulcer dyspepsia (NUD). Again, evidence for a link with job stress is weak. Although IBS and NUD patients tend to report greater anxiety levels, it is not clear whether this is a precursor or a consequence of gastrointestinal ailments.

Mental health outcomes

Emotional distress and depression There is a substantial body of research examining the link between job stress and different indices of emotional distress, including depression, anxiety, and fatigue. Some of these studies are conducted at the occupational level and report that certain occupations (e.g., machine operators, painters, kitchen workers) experience higher levels of depressive symptoms than other occupations.⁶⁴ Attempts to identify workplace factors that underlie these differences have focused on a wide variety of job stressors, including control/autonomy, time pressure, job security, work demands, role conflict and ambiguity, and perceptions of fairness. In a review of this literature, Jex and Beehr⁶⁵ concluded that measures of emotional distress (or affect) are one of the strongest correlates of job stress. Additional longitudinal research is needed, however, to more carefully examine the causal nature of this relationship.

Burnout Job burnout can be considered a special case of emotional strain and is characterized by feelings of cynicism, exhaustion, and inefficacy.⁶⁶ Burnout has been studied principally with regard to human service professionals (e.g., teachers, nurses, social workers) who develop strong emotional relationships with clients or coworkers as part of their work. The causes of job burnout vary somewhat with the occupational group being studied, but include many of the stressors reviewed earlier in this chapter. Particular attention has been given to the importance of role conflict, lack of autonomy, and the absence of social support.²⁴

Suicide Much of the research on risk factors for suicide has focused on the role of specific life events, including those that occur in the workplace. In several studies,

changes at work that affect job security, such as losing a job, are associated with an increased risk of suicide or attempted suicide.^{39,67} Since suicide is a rare event, most of this research has relied on the retrospective analysis of large archival datasets. As a result, it is difficult to rule out the role of other factors, such as prior mental health status or social support, which might also increase suicide risk. In any event, the link between suicide and work events (e.g., layoff, demotion) appears to be at least as strong as that between suicide and non-work events (e.g., illness of a spouse, death of a close friend).⁶⁸

Organizational-level outcomes

Job dissatisfaction, absenteeism, and turnover Probably the most widely cited organizational-level response to job stress is job dissatisfaction. Although research indicates that these two variables are strongly correlated, this finding may also reflect a certain degree of conceptual overlap in terms of what each variable is attempting to measure. Job stress has also been consistently associated with employee withdrawal behavior, in the form of increased absenteeism, turnover, and willingness to retire early.²⁶

Job performance A recent review reports that the link between job stress and job performance varies greatly across studies and, on average, does not appear to be particularly strong.⁶⁹ One reason for this conclusion is that job performance is a multidimensional concept, with not all dimensions showing the same relationship with stress. Evidence suggests that performance dimensions containing either an emotional or a social component are more likely to be associated with stress. Examples include counterproductive behaviors at work (e.g., stealing), organizational citizenship behaviors (e.g., helping coworkers), and workplace aggression. Interestingly, these are aspects of a worker's behavior that are only rarely covered in traditional performance reviews, suggesting that organizations need to adopt a broader perspective of what constitutes good job performance.

Accidents As with job performance, the relationship between job stress and accidents is complex. An important model linking job stress to an increased risk of workplace accidents has been developed by Murphy et al.⁷⁰ The first stage of this model focuses on acute, short-term reactions experienced by workers under stress (e.g., anxiety, fatigue, low motivation). These reactions, in turn, lead to decreased worker capacity (e.g., slower reaction time, inattention, impaired reasoning) and a greater likelihood of engaging in unsafe work practices (e.g., improper equipment operation, risky behavior). Unsafe work practices increase the probability of near misses and accidents, two events that can also function as a source of stress, thus reactivating the cycle. Although each step of the model has empirical support, more research is needed to further identify workplace factors that moderate the relationship between job stress and accidents. Recently, one factor receiving attention is safety climate, which refers to the shared perceptions of workers about the level of safety in

their organization. Research suggests that certain job stressors (e.g., excessive work demands) lead to a poor safety climate and an increase in accidents.⁷¹

Healthcare expenditures Research suggests that workers who report being troubled by stress are also more likely to have higher healthcare expenditures.²³ Whether this finding is because stressed individuals experience more health problems requiring treatment, or are more inclined to seek medical attention for the conditions they do experience (or both) is in need of further study. In this research, stress is often measured as a global response (e.g., Are you concerned about stress at work?). As a result, more information about the actual features of the workplace that produce this response and the need for increased healthcare services is needed. Additional evidence for a link with healthcare expenditures comes from intervention research that shows a beneficial impact of health promotion programs (which include a focus on stress reduction) on healthcare utilization.⁷²

HOW CAN THE ADVERSE EFFECTS OF JOB STRESS BE REDUCED OR PREVENTED?

Although this chapter focuses on job stress and the adverse effects of prolonged physiologic arousal, it has long been acknowledged that some degree of arousal and activation is necessary in order to reach optimum levels of performance.³² But when job stress becomes too intense or persistent over time, many serious health consequences can result. A major challenge facing organizations is to develop strategies for reducing or preventing job stress before it impacts health and safety. As with job stressors, job stress interventions can be viewed as falling along a clinical–public health continuum, in which the focus gradually shifts from the worker to the organization.

Types of interventions to reduce job stress

Clinical perspective

Sometimes referred to as ‘stress management training’, the clinical approach focuses on making individuals more resilient to the demands of the work environment, often by modifying how a worker responds to a given stressor. Because this strategy does not eliminate the stressor, it is categorized as involving either *secondary prevention* (i.e., reducing the effects of the stressor) or *tertiary prevention* (i.e., providing treatment).⁷³ In either case, this approach represents a form of ‘damage control’ in which the outcomes, rather than the sources, of job strain are addressed. Intervention techniques based on this approach are derived principally from clinical and counseling psychology. As a result, these techniques tend to be fairly generic and applicable to wide variety of situations, not just those in the workplace.⁷⁴

Examples of clinical intervention techniques include:

- Progressive muscle relaxation training
- Cognitive-behavioral skills training (e.g., modifying the appraisal process, time management)
- Biofeedback training
- Meditation
- Employee assistance programs (EAPs) (e.g., counseling services)
- Health promotion or 'wellness' programs (e.g., exercise programs, health education).

For all of these interventions, the principal goal is the same: to help workers modify their appraisal of stressful situations and/or deal more effectively with the symptoms of stress. These interventions typically involve sessions that last for an hour or more and are offered on a regular (e.g., weekly) basis. They can range from a few days of training or treatment to many weeks. Stress management training is also commonly offered in the context of EAPs and health promotion programs, and the organization usually makes a commitment to provide appropriate facilities and personnel, unless the services are offered off site.

A recent review of the research literature on clinical-based interventions found moderately strong evidence that these techniques help reduce stress related symptoms and somatic complaints, at least in the short term.⁷⁵ Less convincing evidence, however, exists for an improvement in job or organizational-relevant outcomes, such as absenteeism and job satisfaction. Given that clinical interventions do not involve an actual modification of the work environment, this finding should not be too surprising.

Murphy⁷⁵ concluded that the question of which intervention technique works best depends on the specific outcome under consideration. For example, biofeedback seems to have its strongest impact on physiologic outcomes (e.g., blood pressure), whereas cognitive-behavioral skills training shows better results for psychologic outcomes (e.g., anxiety). In addition, the most positive findings across various health outcomes were obtained with a combination of two or more techniques. The pairing of progressive muscle relaxation with cognitive-behavioral skills training was the most frequently reported combination. Finally, there is some evidence that clinical interventions can reduce healthcare costs, although additional studies are needed to further examine this potential benefit.

Public health perspective

The public health approach focuses on either eliminating or modifying sources of stress in the work environment. This strategy can be described as *primary prevention*, in that the goal is to change some aspect of the organization or job itself. At least in theory, primary prevention would seem preferable to the clinical approach since it targets factors earlier in the stress process.

Elkin and Rosch⁷⁶ summarize a wide range of public health interventions, including those that:

- Redesign the task
- Establish flexible work schedules
- Increase employee participation in decision making

- Change or redefine job roles
- Provide social support and feedback
- Restructure work units and lines of authority
- Establish fair human resource policies.

These interventions focus on changing some of the most commonly experienced workplace stressors, such as lack of control, excessive workload, job insecurity, role conflict, or poor interpersonal interactions. To implement them generally requires more resources and a greater long-term commitment from an organization than clinical interventions, since they usually cannot be introduced without affecting an organization's overall culture. Although these interventions target common job stressors, they are also adopted for non-stress reasons, such as a desire to improve organizational effectiveness or increase worker productivity.

Research on the effectiveness of public health interventions lags behind that on clinical interventions, largely because attempts to systematically change organizational factors are far less common.⁷⁴ The preference for clinical interventions reflects a number of factors, including a concern for the costs and risks associated with organizational change, and the view held by some managers that job stress is an individual problem rather than an organizational one. Research studies that do exist on public health interventions often have methodologic flaws (e.g., lack of appropriate control groups), making determination of causal relationships difficult. Although there is some evidence that techniques such as increasing worker participation in decision making can reduce strain, two recent reviews found that organizational interventions have not been clearly shown to substantially affect symptoms like distress or anxiety.^{77,78} This conclusion may partly reflect the difficulty of applying rigorous research designs to actual work settings, or to a mismatch between the type of intervention studied and the methods used to evaluate its effectiveness.¹⁸ More research is clearly needed before we know which public health interventions hold the most promise for reducing job strain.

Guidelines for interventions to reduce job stress

One issue that is clear from current research is that no single intervention should be seen as a panacea. By their nature, interventions, whether focused on the worker or the organization, are complex processes that sometimes produce unintended effects. As a result, how an intervention is implemented is probably as important as the type of intervention that is chosen.⁷⁹ A few simple guidelines for implementing job stress interventions include the following.

1. Follow a careful planning process

An intervention is more likely to succeed if it is the result of a thorough analysis of job stressors and strains. Cooper et al²⁴ recommend conducting a *stress audit* that involves collecting detailed information via self-report questionnaires (e.g., occupational stress inventory), interviews,

observations, archival data, and even diaries kept by workers. The goal is to identify both individual and organizational factors that function as stressors and assess their impact on levels of strain experienced by workers. The next step involves selecting *targeted interventions* that are specific to the stressors that have been identified. This may require choosing between a clinical or public health strategy (i.e., primary, secondary, or tertiary prevention); however, in many cases it may be desirable to combine elements from both approaches. Finally, it is important to conduct a *focused evaluation* of the intervention, choosing criteria that examine a variety of specific outcomes, and not just a global improvement in wellbeing.

2. Involve workers in the design and evaluation of the intervention

A critical factor in an intervention's success is that workers need to accept the program and feel that it adequately addresses their needs and concerns. All too often, interventions are implemented by consultants or managers without adequate worker input. Involving workers takes advantage of their knowledge of the workplace and focuses attention on the process through which an intervention is selected and implemented. It is worker perception of this process that often determines the long-term viability of a program.

3. Obtain support for the intervention from all layers of the organization

A related factor is the need to build commitment for an intervention from all levels of an organization, including management, unions, and employees. If an intervention is implemented in isolation, without buy-in from all groups, it is likely to be perceived as a token gesture. Organization-wide support communicates that job stress is a serious issue that all sides are willing to take responsibility for addressing.

4. Base intervention on a conceptual model

An intervention is likely to fail if it focuses only on symptoms and does not adequately address the underlying problem(s) affecting workers. A conceptual model provides a useful framework for capturing the complexity of the stress process, and identifying the short- and long-term consequences of stress, potential moderating variables, and the nature of the relationship between stressors and strains. A number of conceptual models for stress interventions are currently available (such as those described earlier in this chapter), but these models remain underutilized by practitioners.⁷⁴

Additional guidance for organizations on implementing and evaluating job stress interventions can be found in several sources, including *Stress at work*,⁸⁰ *Tackling work-related stress*,⁸¹ and *Research on work-related stress*.²⁵

CONCLUSIONS

As organizations and work practices continue to evolve, job stress and its effects on workers will inevitably remain

a concern. Although more needs to be learned about the relationship between job stressors and strains, sufficient evidence exists to conclude that job stress can adversely impact occupational safety and health and that a variety of interventions are available for reducing or preventing job stress. After four decades of research, we have also gained an increased appreciation of the complexity of the stress process itself and the variety of ways in which worker safety and health can be affected. On a broader level, an understanding of job stress is crucial to the goal of creating 'healthy organizations'⁸² in which worker safety and well-being go hand in hand with an organization's concern for productivity and profit.

Chapter 39

Metals and Related Compounds

39.1 Aluminum

Oyebode A Taiwo

EXPOSURE SETTINGS

Aluminum is the most abundant metal that occurs naturally in soil and constitutes about 8% of the earth's surface. It is not found in its metallic state, but in combination with other elements and compounds, including oxygen, fluorine, and silica. Bauxite, the principal source of aluminum, consists of a mixture of minerals formed by the weathering of aluminum-bearing rocks and occurs primarily in tropical and subtropical areas. Commercial bauxite deposits exist currently in Australia, South America and the West Indies. These deposits are extracted by open-cast mining. Aluminum production from extracted bauxite involves three main steps: (1) refining of bauxite to yield alumina, (2) electrolytic reduction of alumina to yield aluminum, and (3) aluminum casting into ingots.

Bauxite refining to yield aluminum oxide or alumina uses the Bayer process, whereby bauxite is digested under high temperature and pressure in a strong solution of caustic soda (sodium hydroxide). The resulting hydrate is crystallized and calcined to alumina in a kiln. Alumina is then reduced to aluminum by the Hall-Héroult process during which alumina is dissolved in molten cryolite (sodium aluminum fluoride) contained in a large carbon or graphite lined steel container known as a pot. An electric current flows between a carbon anode made of petroleum coke and pitch and a cathode formed by the lining of the pot. Molten aluminum is deposited at the bottom of the pot during this process and is siphoned off for use in casting ingots.

There are two main types of aluminum smelting technology – Söderburg and Pre-bake. The Söderburg technology uses anodes baked in the pot itself, while the Pre-bake technology uses anodes that are pre-baked in a separate facility. During reduction the pot emits fumes that contain hydrofluoric acid, sulfur dioxide, carbon, alumina and fluoride dusts. Polyaromatic hydrocarbons (PAHs) are also emitted, with higher PAH emissions found in Söderburg pots compared to Pre-bake pots. The aluminum produced is cast into ingots for subsequent manufacturing use.

Aluminum and its alloys enjoy widespread use in the construction, automotive, and aircraft industries. The electrical industry also makes use of aluminum for overhead distributions and power lines, electrical conductors, and insulated cables and wires. Aluminum is a common constituent of jewelry and cooking utensils and is also used extensively in packaging, including food containers, aluminum foil and beverage cans. Aluminum powder is used in paints, protective coatings and pyrotechnics production. Aluminum compounds are also used as: aluminum

chloride in rubber and wood preservative manufacturing; aluminum borate in glass and ceramic production; aluminum chlorhydrate as an ingredient in deodorants; aluminum isopropoxide in soap and paint production; and aluminum trioxide as an absorbent and abrasive. In addition to its presence in many manufactured products, aluminum is universally present in variable and often trace amounts in food and water.

CLINICAL EFFECTS

Acute

There is little evidence to suggest that aluminum exposure by any route, i.e. inhalation, dermal, or gastrointestinal, is associated with any significant acute health effects.

Chronic

The occupational respiratory disorders associated with chronic exposure to aluminum dust and fumes include potroom asthma, chronic bronchitis, pulmonary fibrosis, and granulomatous lung disease. Potroom asthma, a syndrome characterized by both immediate and late asthmatic response, is associated with work in aluminum production. The annual incidence has been estimated to be approximately 2%, with prevalence as high as 10% in long-term workers. The specific mechanism is not known; however, fluorides and other respiratory irritants encountered in this environment have been suggested as the cause (see Chapter 19.2).^{1,2} Non-specific airway response to dust characterized by cough and mucous production has also been described in workers in aluminum production; cross-sectional studies of these workers have shown decrement in lung function over many years.³

Aluminosis or Shaver's disease – a rare progressive pneumoconiosis of historic interest, characterized by upper lung predominance, peripheral emphysema, and frequent pneumothoraces – has been attributed to chronic aluminum exposure. Recent evidence suggests that exposure to aluminum oxide may also induce pulmonary fibrosis. However, exposure to a mixture of other dusts at low levels (free silica and asbestos) may explain this pathology (see Chapter 19.11).⁴

There are case reports in workers exposed to aluminum dust presenting with alveolitis and granulomas similar to those found in sarcoidosis and chronic beryllium disease.⁵⁻⁷ This disease is characterized by a T lymphocytic alveolitis principally composed of CD4+ (helper) lymphocytes, but

differing from sarcoid by the identification of aluminum within the granulomas. Blastic transformation of the patient's peripheral blood lymphocytes in the presence of aluminum compounds has also been reported.⁸ These findings suggest that this pathologic picture may represent an early stage of aluminum-induced fibrosis. The existence of aluminum-induced lung disease remains controversial, in part because of its extensive use and the rarity of the lung disease attributed to this metal, making the significance of isolated case reports unclear.

The aluminum reduction process has been associated with excess lung and bladder cancer incidence. This increased cancer risk is related to the polyaromatic hydrocarbons used and generated in the reduction process.^{9,10} This is covered more extensively in Chapters 44, 30.1 (lungs) and 30.3 (bladder).

Aluminum has been implicated as a potential toxic agent in the etiology of various neurologic disorders. Its neurotoxicity has been studied most extensively in dialysis patients who have developed dialysis encephalopathy, the clinical presentation of which includes speech impairment, dementia, apraxia, myoclonus, asterixis and focal seizure. These patients also develop a related microcytic anemia, as well as a severe form of osteomalacia that is resistant to calcium and vitamin D therapy.¹¹ Autopsy findings in these patients have shown elevated levels of aluminum in brain, liver and bone. The source of aluminum exposure has been traced to the water used to prepare the dialysate and orally administered aluminum phosphate binders.¹² Dialysis encephalopathy is largely preventable by elimination of aluminum from the dialysate; however, a few cases still occur from contamination of the dialysis fluid and consumption of aluminum-containing drugs.

There has been considerable interest in the potential role of aluminum in causing Alzheimer's disease. Identifying potential genetic and environmental risk factors for Alzheimer's disease is an active area of research. Some studies have reported high concentrations of aluminum in the brains of patients with Alzheimer's disease, while others have not.¹³⁻¹⁶ A number of epidemiologic studies have reported a positive association between the prevalence of Alzheimer's disease and aluminum levels in drinking water, while other studies have not.¹⁷ The amount of ingested aluminum from drinking water is very small in relation to other dietary sources; therefore, a direct toxic effect is unlikely.

'Potroom palsy', a progressive neurologic disorder characterized by incoordination, poor memory, impairment in abstract reasoning and depression, has been described in aluminum potroom workers.¹⁸ Studies of other potroom workers have reported subclinical tremors, impaired visuospatial organization and a slight decline in psychomotor tempo.¹⁹ Exposure to toxins in the potroom of the aluminum plant is the suspected cause of these neurologic symptoms; however, the exact causative agents are not known. Other studies have shown no difference in neurological function between potroom workers and comparison workers.^{20,21} In conclusion, aluminum remains a plausible,

but as yet unproven, cause of neurologic disease, based on limited but intriguing experimental, pathologic, and epidemiologic evidence.

DIAGNOSIS, EVALUATION AND TREATMENT

Biologic monitoring of exposure to aluminum usually is limited to quantification of parent compounds in blood and urine. Similar sensitive methods for detecting levels at low doses (parts per billion) also are available for other body tissues, but these are usually reserved for experimental purposes. Mean levels of aluminum in plasma or serum in those without occupational exposure have been reported to be less than 10 µg/L. Levels in workers exposed to aluminum have been found to be considerably higher (two or more times), with the highest levels of blood aluminum found in those undergoing dialysis (100–200 µg/L).²² Urine levels also are consistently higher in exposed groups and likely reflect a longer period of recent exposure than do those from blood, although studies have been inconsistent in this regard.²³ More important, there is no evidence that measured plasma or urine aluminum levels are an adequate reflection of either respiratory or neurologic toxicity.

Based on current evidence, asymptomatic workers exposed to aluminum fumes or dusts should undergo periodic evaluation of respiratory symptoms and spirometry testing. The development of respiratory symptoms or presence of abnormal lung function should prompt further evaluation including chest radiographs. Workers with unexplained neurologic symptoms should also have a full neurologic evaluation, including consideration of neuropsychologic testing.

The primary approach to prevention is the institution of engineering control measures to reduce respirable levels of aluminum in the workplace. Treatment measures are limited to removal of workers with early respiratory or neurologic disease from further exposure.

Acknowledgment

This chapter is an update of Chapter 30.1; Aluminum, by Linda Rosenstock which was published in the 1st edition.

39.2 Arsenic

Alfred Franzblau

EXPOSURE SETTINGS

Almost all arsenic for human use is obtained in the form of arsenic trioxide (As_2O_3), a byproduct of smelting of ores of copper, lead, or zinc. Worldwide production is 75,000 to 100,000 tons per year.¹ Arsenical compounds are encountered in a broad spectrum of industrial settings, including smelting, manufacture of glassware, specialty industrial chemicals, creation of alloys of lead and copper, and semiconductors, but 80% is used in agricultural applications such as pesticide manufacturing and application, wood preservatives, and feed additives for cattle. The first widely used manufactured pesticide was copper acetoarsenite (in the mid-19th century). NIOSH estimates that approximately 900,000 workers have potential occupational exposure to arsenic each day.

In the occupational setting inorganic arsenic compounds, such as arsenic trioxide, are usually absorbed via inhalation of air-borne dust. Arsine (AsH_3), a gas at room temperature and pressure, deserves special mention because of its unique acute toxicity. The organic arsenicals, e.g. pesticides, have greater potential for transcutaneous absorption.

Ingestion usually is only a significant route of exposure outside the workplace, particularly ingestion of ground water contaminated with inorganic arsenical compounds, usually from natural sources. Ingestion of arsenic-contaminated water has attracted increased attention in recent years because of concern related to potential health effects, and the large numbers of people exposed, especially in countries such as Bangladesh, India, Pakistan, and China. Ingestion of foods that naturally contain arsenic, particularly fish, shellfish, or seaweed, is also a major source of arsenic exposure, although the species of arsenic usually present in these sources are relatively non-toxic (e.g., arsenobetaine). Environmental exposure to arsenic has been documented to occur via inhalation of air-borne arsenic-containing dust among residents living downwind from large industrial sources of arsenic emissions, such as arsenic smelters.²

Arsenical compounds occupy an interesting historical position because of their frequent use as medicines and poisons. Arsenicals were used to treat syphilis (e.g., arsphenamine) in the first half of the 20th century, and Fowler's solution (1% potassium arsenite) was used for psoriasis and asthma until the 1960s. Arsenic trioxide is nearly tasteless, has the appearance of sugar, and is lethal in small doses, and so for centuries was a preferred homicidal and suicidal agent.¹ Lewisite, a vesicant war gas, was first used in World War I. Table 39.2.1 summarizes the different arsenical species, their chemical formula, and usual source of exposure.

CLINICAL EFFECTS

Acute

Acute arsenic intoxication usually occurs via ingestion of arsenic, specifically arsenic trioxide, with homicidal or

suicidal intent, although there have been reports of unusual cases resulting from occupational or environmental exposure.³ The minimal lethal dose is 100–200 mg of As_2O_3 . Arsenic pentoxide (As_2O_5) is approximately half as toxic as the trivalent form, although the clinical syndrome produced is identical (much of the pentavalent arsenic is converted to the trivalent form in vivo). The onset of symptoms can vary from minutes to hours, depending on whether the arsenic is in solution, and recent food consumption. Inorganic arsenic compounds are acute gastrointestinal irritants, leading to nausea, vomiting (possibly with blood), and abdominal cramps. Electrocardiographic abnormalities reflecting myocardial toxicity consist of broadening of the QRS complex, flattening of T-waves, and ST segment depression. Patients may develop severe central nervous system toxicity manifested by encephalopathy. Death is usually the result of circulatory collapse due to fluid and electrolyte loss.

If the patient survives the immediate acute effects, the person is at risk of developing numerous delayed systemic toxic effects. Painful peripheral neuropathy, appearing one or two weeks after an acute ingestion, is initially sensory with a stocking-glove distribution, but can progress to include sensory and motor deficits. Following cessation of exposure the neuropathy usually worsens for a number of weeks and then stabilizes. Subsequent improvement is slow, and recovery may never be complete. Severe cases have been confused with Guillain-Barré syndrome.⁴

Reversible bone marrow suppression, with leukopenia and granulocytopenia, anemia, increased relative eosinophil count, and megaloblastic changes in the marrow can occur. Cutaneous effects vary from nothing to slight erythema to exfoliative erythroderma. Mees lines (sharply demarcated transverse white lines in the nails) usually appear 2–3 weeks following an acute exposure. Mild to moderate elevation of liver enzymes can occur.

Arsine (AsH_3) is a colorless gas with a slight garlic odor. Following acute exposure, there is an asymptomatic period lasting up to 24 hours; the duration of latency is inversely proportional to the degree of exposure. Initially, patients describe headache, lightheadedness, weakness, nausea, and vomiting. The classic triad consists of abdominal pain, hematuria, and jaundice due to arsine-induced intravascular hemolysis. The liver may be enlarged on examination. The usual cause of death is acute renal failure resulting from precipitation of free hemoglobin in renal tubules. If the patient survives the acute event, peripheral neuropathy, Mees lines and other sequelae may appear as noted above.

Chronic

Chronic arsenic exposure, usually related to inorganic arsenic such as arsenic trioxide, induces a multi-organ system disease, with primary non-malignant effects on the skin, nervous system, and vasculature. A number of stud-

Name	Chemical formula	Usual source of exposure	Urinary metabolite
Arsenic trioxide	As ₂ O ₃ or As ₄ O ₆	Smelting/industrial sources/naturally occurring in drinking water	As ₂ O ₃ Monomethylarsonate Dimethylarsinate
Arsenic pentoxide	As ₂ O ₅ or As ₄ O ₁₀	Smelting/industrial sources/naturally occurring in drinking water	As ₂ O ₃ and As ₂ O ₅ Monomethylarsonate Dimethylarsinate
Arsine	AsH ₃	Industrial applications/semiconductor manufacture/accidental formation	Monomethylarsonate Dimethylarsinate
Monomethylarsonate	CH ₃ AsO(OH) ₂	Metabolic product of inorganic arsenic exposure	Mostly excreted unchanged as monomethylarsonate and some dimethylarsinate
Dimethylarsinate	(CH ₃) ₂ AsO(OH)	Metabolic product of inorganic arsenic exposure	Mostly excreted unchanged as dimethylarsinate
Arsenobetaine	(CH ₃) ₃ AsCH ₂ COOH	Common arsenical species found in certain sea foods	Mostly excreted unchanged as arsenobetaine
Gallium arsenide	GaAs	Used in semiconductor manufacture	Not water soluble and poorly absorbed; mostly excreted in feces
Lewisite	ClCH=CH-AsCl ₂	War gas (vesicant)	–

Valence states:

0 metallic arsenic

Table 39.2.1 Common arsenic species, usual sources of exposure and urinary metabolites

Figure 39.2.1: Arsenical keratoses, common on palms and soles after oral ingestion of arsenicals. These lesions are premalignant, but skin cancers also occur in patients without keratoses or hyperpigmentation. (Reprinted with permission from Braverman I. Skin signs of systemic disease. Philadelphia: WB Saunders, 1971.)

ies have shown an increased risk for diabetes with chronic, high exposures.⁵ Non-malignant cutaneous effects include follicular and eczematous dermatitis due to a direct irritant effect, Mees lines, hyperpigmentation or melanosis (interspersed with small areas of depigmentation), and arsenical keratoses usually on the palms and soles from systemic absorption (Fig. 39.2.1).⁶

Clinical and pathologic findings of the peripheral nerves are similar to changes observed following acute exposure (i.e., an axonopathy), but slower and more insidious in onset.

Peripheral vascular disease may appear initially as Raynaud's phenomenon, and progress to acrocyanosis and frank gangrene, so-called 'blackfoot disease' which

has been described in Silesia, Taiwan, and, most recently, Bangladesh.^{7,8} More recent studies have linked chronic, high-level arsenic exposure to hypertension, increased mortality from heart disease, and cerebrovascular disease,^{9–12} although the mechanisms are not well understood. An increased risk of myocardial infarction has been detected among arsenic smelter workers.

Additional non-malignant chronic toxic effects can include megaloblastic bone marrow suppression; liver enlargement, elevated serum liver enzymes, and possibly cirrhosis; and possible central nervous system effects including impaired cognition and personality changes.

Skin and lung cancer are the most well-established malignant effects of chronic arsenic exposure. Basal cell carcinomas, squamous cell carcinomas, and Bowen's disease have been reported with a positive dose-response relationship at high levels of exposure in drinking water,^{6,13} as well as with occupational exposures. A characteristic feature of arsenic-associated cutaneous malignancies is their origin, which is frequently multicentric and on areas of the body typically not associated with UV exposure-related skin cancers. There is no known relationship between arsenic exposure and melanoma.

Increased risk of lung cancer has been well documented among arsenic-exposed workers, including arsenic smelter workers and workers involved with arsenical pesticides,^{14,15} further discussed in Chapter 30.2. Studies of non-occupationally exposed cohorts, primarily persons exposed via arsenic in drinking water, have reported increased rates of cancer at multiple sites, primarily bladder, kidney, lung, liver, and hemopoietic malignancies.^{12,16–19}

Some authors have suggested that the potential cancer risks to the general population from arsenic in drinking water, even at levels at or below the current EPA arsenic maximum contaminant level (MCL) of 50 micrograms/liter, may be substantial – in the same range as environ-

mental tobacco smoke and radon in homes.²⁰ The Safe Water Drinking Act Amendments of 1996 mandated that the EPA must promulgate a new regulation for arsenic in drinking water in the future. Any new regulation, such as 10 micrograms/liter (the concentration for arsenic in drinking water recommended by the World Health Organization), or lower, will be costly. A major challenge is that risk estimates at low levels of exposure are based almost entirely on extrapolation of results from studies conducted outside the United States among persons exposed to arsenic levels in water that were much greater than the current MCL of 50 micrograms/liter, typically greater than 150 micrograms/liter, and as high as 2000 micrograms/liter.

DIAGNOSIS, EVALUATION, AND TREATMENT

There are no significant long-term mobilizable stores of arsenic in the body, and the half-life of arsenic in urine following low to moderate exposure is approximately one day; higher exposures result in some prolongation of half-life. Thus, biologic monitoring of chronic arsenic exposure is difficult even just a few weeks after cessation of exposure. Biologic monitoring of urine is useful for documenting current overexposure to arsenic compounds. The best approach is to collect a 24-hour urine specimen, although a spot urine sample can be useful. The total volume should be noted, and measurement of arsenic, creatinine, and specific gravity (the latter two allow correction for renal function and hydration, respectively) should be performed.

Ideally, the specimen should be obtained following two or three days abstention from known arsenic-containing food items, such as shellfish or seaweed. A 'normal' urinary arsenic concentration is less than 100 micrograms/liter, and the concentration will usually be less than 30 micrograms/liter in the absence of significant consumption of the arsenic-containing foods noted above. Assay techniques that can distinguish toxic arsenic species from those derived from ingestion of seafood exist, but are usually more expensive.

Because of the availability of sulfhydryl groups in keratin, absorbed arsenic tends to bind to hair and nails. The slow growth of these structures makes them useful as integrated measures of exposure to arsenic during the preceding months (normal: less than 1 microgram arsenic/gram). However, these tissues can be contaminated by external exposure, and so should be handled carefully and the results interpreted with some caution. Because of rapid clearance, the concentration of arsenic in blood is difficult to interpret and therefore is not a useful index of exposure.

Chelation with dimercaprol (British Anti-lewisite, or BAL), D-penicillamine, or dimercaptosuccinic acid (DMSA) can promote the excretion of absorbed arsenic in the setting of acute intoxication. Although chelation serves to accelerate the alleviation of acute symptoms, there is little evidence that such therapy has any impact on the chronic consequences of acute arsenic poisoning (e.g., peripheral

neuropathy or encephalopathy²¹). Following ingestion, attention should be directed toward gastrointestinal lavage and fluid and electrolyte replacement. There is no clear role for chelation in treatment of persons with chronic arsenic exposure. Early maintenance of high urine flow will reduce the risk of acute renal failure in persons with arsine exposure.

PREVENTION

Industrial arsenic exposure is prevented by appropriate engineering controls. Biologic monitoring of urine arsenic can assess the adequacy of such controls. Persons with a history of occupational exposure to arsenic smelter dust are required by OSHA to obtain regular chest radiographs, although the efficacy of such screening has not been demonstrated. Persons with arsenic exposure that has resulted in chronic non-malignant cutaneous changes (e.g., hyperkeratoses, hyperpigmentation) should have regular skin examinations to detect early malignant changes, and are at increased risk of skin and possibly various internal cancers. In the general environment most absorption of toxic arsenic species results from ingestion of contaminated drinking water; therefore testing of water supplies will detect exposure.

39.3 Beryllium and Cobalt

Kathleen Kreiss

BERYLLIUM

Exposure settings

Beryllium is a lightweight metal that is transparent to x-rays and has neutron-moderating properties that make it an integral part of nuclear applications in weapons, energy, and research. It lends unique properties of high strength to metals to which it is alloyed, chiefly beryllium copper, with a beryllium content of 2–4%. Beryllium oxide is an insoluble salt with high heat conductivity, which leads to its use in specialty ceramics and in chip manufacture for semiconductors. Soluble beryllium salts are intermediates in beryllium refining and alloy manufacture. Historically, beryllium phosphors were used in fluorescent light manufacture. Their use was discontinued in 1949 because of the recognition of chronic beryllium disease in that industry.

Beryllium exposure occurs in nuclear industries, metal reclamation, beryllium ceramics manufacture, and beryllium extraction. In addition, metal workers and users of alloys, such as dental laboratory technicians, may be exposed to beryllium. In alloys, the beryllium content may be unknown or unrecognized as a hazard.

Since beryllium was recognized as a lung hazard in Europe in the 1930s, beryllium exposure–response relationships have been puzzling. Beryllium disease is an immunologic, cell-mediated hypersensitivity reaction, and most beryllium-exposed workers never develop lung disease. The few (5–15%) workers who develop beryllium disease usually have a disease latency of years,¹ that makes reconstruction of prior exposures difficult. However, beryllium disease has occurred in persons with only very limited exposure to beryllium, sometimes for very brief periods.² Within beryllium-using industries, cases of beryllium disease have occurred among secretaries, security guards, and even persons working in plants previously using beryllium containing materials without ongoing production.^{1,3–5} Among beryllium disease cases, no relationship exists between tissue burden of beryllium and severity of disease.

In addition to bystander cases within industry, environmental cases of beryllium disease historically occurred among residents living close to exhaust stacks of beryllium extraction plants and among those with household exposure to dust-laden work clothes of beryllium workers.^{1,6} Modeling of beryllium concentrations from stack effluents estimated environmental exposures to be three orders of magnitude less than in the plant, but the prevalence of beryllium disease in the plant and environments were similar. More recently, substantial lowering of air concentrations below the 2 µg/m³ permissible exposure limit did not decrease incidence of beryllium sensitization in new employees compared to employees previously exposed to higher air concentrations also below the exposure limit.² The failure to protect new employees by lowering air concentrations raises concern that skin exposure may affect sensitization risk.

These environmental, household, and industrial bystander cases signify the difficulty in ascertaining whether a biologically significant beryllium exposure has occurred in the workplace or in a patient with granulomatous or interstitial lung disease. All patients with sarcoidosis should be evaluated for the possibility of previous occupational or environmental beryllium exposure.⁷ Within beryllium-using industries, surveillance for beryllium disease is appropriate for the populations with passive, intermittent, or inadvertent beryllium exposure, as well as for the traditional beryllium worker. Since beryllium metal and oxide particulate is biologically persistent, persons leaving the beryllium industry remain at risk for beryllium sensitization and disease the rest of their lives.

Although quantitative exposure–response relations are puzzling, cross-sectional studies of beryllium workers nearly always document process-related risk.^{2–5,8} High-risk processes do not always have the highest beryllium mass concentrations in air.⁸ This observation suggests that exposure characteristics apart from air-borne mass are more pertinent risk predictors.

Measurement

The current OSHA permissible exposure limit for beryllium of 2 µg/m³ time-weighted average was derived in 1949 by analogy to another toxic metal, lead, in rough proportion to the relative atomic weights of the two metals. The short-term (30 minute) exposure limit is 25 µg/m³, and some Department of Energy nuclear facilities had a housekeeping standard of 25 µg/ft² for surface contamination. The time-weighted average exposure historically recommended by NIOSH is 0.5 µg/m³. Recent workplace surveillance documents beryllium disease with average exposures well below these standards and sensitization within a few months of employment at exposures near the detection limit of methods used for workplace air sampling.² Most studies using qualitative or quantitative estimates of historical exposures have not demonstrated that cumulative exposure or exposure duration is a risk factor for disease,^{3–5,8} but average or peak exposure may be important, particularly in plants with uniform size distributions across processes.^{2,4,9}

Total beryllium concentration in air does not predict hazard, and alternative exposure metrics such as submicrometer particle number concentration appear promising^{10,11} as risk factors for beryllium disease. Indices of skin contamination and integrity are currently under evaluation as predictors of sensitization risk. Among the sensitized, latency is important for disease expression,^{2,3} but it is not yet clear whether the exposure requirements for beryllium disease differ from those for sensitization.⁹

Clinical effects

High levels of exposure to beryllium salts were thought to result in acute toxic pneumonitis in the 1940s, which

was frequently self-limited, but sometimes progressed to irreversible chronic beryllium disease. Contact dermatitis affected a large percentage of workers early in the development of the extraction industry in the United States. The pathophysiology of acute beryllium disease remains unclear, and cases have not been reported in several decades. Its disappearance has been attributed to control of industrial exposures after the standard was developed.

The chronic granulomatous lung disease recognized today occurs among persons who develop lymphocyte reactivity to beryllium. Prevalence rates of sensitization in cross-sectional workforce screening are commonly about 10% if blood samples are split between two laboratories.^{2,4,8,12} Among the sensitized, disease rates at the time of initial clinical evaluation vary between about 40% and 100%, with additional disease cases developing over years of follow-up. Sensitized workers with short latencies since first beryllium exposure are less likely to have beryllium disease.² Whether all beryllium-sensitized persons develop lung disease with follow-up is still unknown. Beryllium metal, alloy, and salts are implicated in the risk of sensitization and chronic beryllium disease (see also Chapter 19.7). Beryllium-contaminated wounds may require surgical excision of a granulomatous tissue response.

Beryllium-exposed cohorts and beryllium disease cases have a small excess risk for lung cancer,^{13,14} and the International Agency for Research on Cancer has designated beryllium and beryllium compounds as human carcinogens. Quantitative exposure–lung cancer relationships are evident for average and maximum beryllium exposures and for cumulative exposure when historical exposure estimates are lagged 10 and 20 years.¹⁵

Clinical evaluation

Beryllium-exposed workers who develop cough, exertional dyspnea, or interstitial abnormalities on chest x-ray study need clinical evaluation for chronic beryllium disease (see also Chapter 19.7). In the setting of interstitial lung disease, the diagnosis can be made if cell-mediated immunity to beryllium is demonstrated by an abnormal lymphocyte proliferation test to beryllium salts (BeLPT) in either a blood sample or bronchoalveolar lavage sample. Blood samples sometimes are normal in cases of pathologically confirmed beryllium disease, and lavage samples are sometimes normal in smokers with excess lavage macrophages, which interfere with the lymphocyte response. Prior coordination with the laboratory performing the lymphocyte proliferation test is critical because cells must be cultured within 24 hours. Pathologic confirmation of granulomatous lung disease or lymphocytic alveolitis may be necessary in cases in which interstitial lung disease is not otherwise demonstrable by chest x-ray study or physiologic testing. The pathologic diagnosis usually can be made on transbronchial biopsy and bronchoalveolar lavage.

Asymptomatic beryllium-sensitized workers identified in workplace screening with the BeLPT typically undergo clinical evaluation with bronchoalveolar lavage and transbronchial lung biopsy. Those with beryllium disease re-

quire careful follow-up to ascertain when treatment should begin. Those with only sensitization require follow-up for development of disease. The natural history of beryllium sensitization and disease is under active study in relation to exposure and genetic characteristics.

Prevention

Primary prevention of beryllium sensitization among new employees has proven refractory to lowering beryllium air concentrations, apart from some modest effect in specific processes such as machining, in which sensitization rate has been decreased following enclosure and local exhaust.² The regulatory limit of 2 µg/m³ does not protect against sensitization. In the absence of a quantitative basis for risk assessment, employers must consider a combination of engineering controls at the exposure source, scrupulous surface cleaning to lower potential skin contamination and resuspension, and personal protective equipment to reduce respiratory and dermatologic exposures to as low as reasonably achievable. Prevention of lung disease depends on prevention of sensitization and a beryllium lung burden.

Screening workforces for beryllium sensitization with the blood beryllium lymphocyte proliferation test is the cornerstone of prevention. Exposure surveillance does not assure a safe workplace. To date, no workforce of at least 100 employees screened with the beryllium lymphocyte proliferation test has been reported to be free of sensitization cases. To prioritize prevention needs, blood screening data should be linked with work and task history to document whether specific processes confer increased risk of beryllium sensitization and disease. Since past beryllium and process experience results in persistent risk, employers should consider sensitization in new employees as sentinels for inadequate current prevention efforts. In the beryllium industry, screening without surveillance analyses of risk factors results in missed opportunities to guide prevention efforts.

In the past, workplace surveillance for chronic beryllium disease has included a review of respiratory symptoms, a chest examination, spirometry, chest radiograph, and sometimes diffusing capacity. These tests are all insensitive in comparison to the blood lymphocyte proliferation test, which identifies persons with subclinical beryllium disease as well as those persons at high risk of developing beryllium disease because they have become sensitized. The traditional tests are best reserved for symptomatic workers who sometimes lack a blood lymphocyte proliferation response; in these instances, objective abnormalities on chest radiograph or longitudinal decreases/abnormalities in pulmonary physiology can support referral for bronchoscopic biopsy and lavage to establish a diagnosis of beryllium disease.

Screening of beryllium-exposed workers for cell-mediated hypersensitivity with BeLPT has a role in both primary and secondary prevention. Primary prevention requires seeing each sensitization case as a call for prevention based on linking screening information with exposures and task-based risks in surveillance. For secondary preven-

tion, beryllium-sensitized workers without lung granulomas should probably be restricted from further beryllium exposure and followed carefully for the development of beryllium disease. Similarly, beryllium-sensitized workers with subclinical lung granulomas should be removed from exposure and followed to determine the need for treatment with corticosteroids.

No established role for biologic monitoring exists other than the BeLPT. Specifically, urine beryllium determinations have not proved useful or well correlated with exposure or risk of disease. Indeed, tissue and body fluid levels often are below detection limits in persons with beryllium disease.

Genetic characteristics are associated with beryllium disease risk¹⁶⁻¹⁸ and are under intense investigation. Although the crude marker of HLA-DP^{glu69} confers a 5–10-fold risk of disease in some cohorts, the 30–40% prevalence of this set of alleles in worker populations results in poor positive predictive value. As many as a quarter of beryllium disease cases in population-based case series lack one of these alleles, limiting negative predictive value as well. Until allele-specific risk information becomes available, genetic analyses may not be of most value in confidential genetic counseling of prospective employees. It is not yet clear whether genetically susceptible beryllium workers can decrease their historically incurred risk by lowering or ceasing beryllium exposure. Counterbalancing the considerable ethical and discrimination issues surrounding genetic analyses of workers in a non-research setting is the prospect that longitudinal studies can define exposure–response relations for the substantial proportion of beryllium workers with enhanced susceptibility. Scientists also hope that genetic mechanistic information may open up more specific therapies for primary and secondary prevention of beryllium disease.

COBALT

Exposure settings

Cobalt is a hard magnetic metal that is used in alloys for permanent magnets, tool steels requiring high strength, and diverse metals in the electrical, automobile, and aircraft industries. Cobalt is used as the binder in cemented tungsten carbide, also known as hard metal, which is employed in wear-resistant tools, drill tips, and abrasives. Cobalt compounds are used as pigments; dryers for lacquers, paints, inks, and enamels; catalysts in polyester resin systems; animal feed additives; and foam stabilizers. Cobalt is found commonly in the glass, ceramic, photographic, printing, dental laboratory, and electroplating industries.

The industries in which cobalt-related respiratory disease occurs include tungsten carbide manufacturing and tool grinding, diamond polishing, porcelain painting, and cobalt extraction. Cobalt-related dermatitis is described in most of these industries, ceramics manufacturing, use of and manufacturing of printers, manufacturing of animal feed, and in European cement workers.

Measurement

The current US permissible exposure limit for cobalt is 50 $\mu\text{g}/\text{m}^3$, and the American Conference of Governmental Industrial Hygienists has proposed a limit of 20 $\mu\text{g}/\text{m}^3$. Whether these exposure limits protect the hypersensitive individual is unknown. Also unknown is the precise dose and route of exposure that results in hypersensitivity. Chronic airflow limitation effects occur with cobalt exposures well below the proposed standard.^{19,20} No exposure standards exist in the United States for cobalt compounds.

Clinical effects

The occupational chest illnesses associated with cobalt exposure include giant cell pneumonitis, interstitial fibrosis, asthma, impaired ventilatory function, and non-inflammatory cardiomyopathy. Exposure–response relationships for cobalt are puzzling. In part, this may be because different cobalt-associated diseases may have different exposure–response relationships. Giant cell pneumonitis (see Chapter 19.7) occurs with hard metal exposure and in diamond polishing in which cobalt is used as a bonding agent for microdiamonds; however, this hard metal disease (cobalt lung in diamond polishers) does not seem to occur with cobalt exposure in the absence of particulate.²¹ Asthma and giant cell pneumonitis are likely caused by specific immunological mechanisms, which occur at low prevalence and with variable latency. The characteristics of the sensitizing dose resulting in these diseases are largely unexplored. Cobalt-contaminated coolants used in the wet grinding of hard metal have been associated with a higher risk of hard metal disease, chest symptoms, and pulmonary function decrements despite very low cobalt levels, possibly because ionized cobalt aerosols are more biologically effective.^{19,22} Ionized cobalt aerosols may not be associated with higher risk for cobalt asthma.²³ Non-specific pulmonary function decrements appear to be exposure related.²⁴

A 1940 report of hard metal disease documented a 30% prevalence of radiologic abnormalities in hard metal workers. Such high prevalences are no longer found in cross-sectional studies in the United States or Japan, where prevalences of cobalt-related lung disease (asthma and/or interstitial disease) of 0.6–7% have been found. Diamond polishers who have been exposed to cobalt alone have prevalences of occupational lung disease (both asthma and fibrosis) of almost 1%.²⁰

Cobalt dermatitis sometimes is accompanied by cell-mediated immunity, which can be documented with cobalt-specific lymphocyte proliferation tests. No consistent correlation exists between skin sensitization, demonstrated by patch testing, or cobalt dermatitis and cobalt-related lung disease. Cobalt was historically used to stimulate erythropoiesis in the treatment of anemia and may cause mild marrow stimulation after occupational or environmental exposure. Cardiomyopathy resulting from cobalt exposure, outside of several outbreaks in drinkers of beer to which cobalt had been added, has very rarely been reported.²⁵

Some evidence exists that cobalt is a human carcinogen for lung cancer. The International Agency for Research on Cancer classified cobalt and its compounds as possible human carcinogens in 1991. Since that time, both positive and negative findings have been reported.²⁶⁻²⁸

Clinical evaluation

Bronchoalveolar lavage has shown diverse cellular abnormalities among cases of hard metal disease, including abnormalities in asymptomatic exposed workers suggestive of subclinical alveolar effects.²⁹ The diagnosis of cobalt lung/hard metal disease is confirmed by the demonstration of characteristic multinucleated giant cells in bronchoalveolar lavage fluid or lung biopsy. Interstitial fibrosis in cobalt workers has a non-specific pathology. No specific immunologic tests are known to be associated with cobalt lung disease, although this is an area of investigation. Cobalt-associated asthma has been demonstrated by specific inhalation challenge and, infrequently, by cobalt-specific antibody. Cobalt dermatologic sensitivity can be confirmed by patch testing and, in some cases, by cobalt-specific lymphocyte transformation tests using blood samples. The demonstration of cobalt cardiomyopathy in beer drinkers was epidemiologic and relied on examination of tissue levels in fatal or heart transplanted cases; clear clinical criteria for attribution of cardiomyopathy to cobalt do not exist.

Prevention

Engineering controls to lower cobalt exposures appear to have lowered historical prevalences of cobalt-related interstitial fibrosis, and epidemiologic evidence exists that abnormalities found on x-ray study are more prevalent among persons with high average exposures. However, cases exist following short and low exposures, consistent with an immunologic mechanism. The risk of cobalt asthma may be related to the exposure level, as reflected in attack rates by process group in hard metal workers, even when mean cobalt measurements were below the previous standard of 100 $\mu\text{g}/\text{m}^3$.

No specific screening tests exist to identify those at risk of cobalt-related respiratory disease before exposure, although hard metal disease has been statistically associated with genetic alleles for the HLA-DP β 1 chain sharing a glutamic acid at position 69.³⁰ For workers developing cobalt-related asthma, giant cell pneumonitis, or less specific interstitial fibrosis, removal from cobalt exposure is mandatory. The natural history of cobalt-related lung disease is variable, with some cases of asthma or interstitial disease improving with cessation of exposure, and a substantial minority progressing despite exposure cessation and treatment.^{31,32} Hard metal disease has recurred in a unilateral transplanted lung despite no further exposure nor documented spillage from the native affected lung,³³ suggestive of an autoimmune mechanism.

Cobalt dermatitis is a hypersensitivity reaction, and prudence dictates minimization of skin contact in the unsensitized individual and avoidance in those persons

responding to cobalt in patch tests or lymphocyte transformation tests. Cobalt particulate has been shown to penetrate skin, as reflected in cobalt urinary excretion.³⁴

Surveillance for cobalt asthma and interstitial lung diseases should include a review of respiratory symptoms, spirometry, diffusing capacity, and chest radiographs. In symptomatic workers, cross-shift spirometry, peak flow measurements, and tests of specific or non-specific bronchial reactivity may be helpful in establishing the relation of asthma to exposure and removal from exposure. Pulmonary function testing, including diffusing capacity, and radiographs are often insensitive indicators of interstitial disease,^{35,36} and normal results should not affect the threshold for diagnostic evaluation in cobalt-exposed workers with dyspnea on exertion or persistent cough (see Chapter 19.7).

Biologic monitoring for cobalt exposure using blood or urine samples has been performed in studies of cobalt exposure. Urine excretion of inhaled cobalt has multiphase kinetics that does not allow easy correlation between end-shift urinary and ambient air levels, particularly for insoluble forms of cobalt. For soluble cobalt compounds, measurement of urine or blood cobalt at the end of the work week may be useful in assessing recent exposure.^{34,37}

39.4 Cadmium

Alfred Franzblau

EXPOSURE SETTINGS

Cadmium was first isolated in 1817, and it has no known nutritional function in man. No ore is mined specifically for its cadmium content. Cadmium (Cd) is derived as a byproduct from smelting of other metals, primarily zinc, with some derived from ores of copper and lead.¹ In recent years recycling of cadmium from nickel-cadmium batteries has become more significant. Usage patterns of cadmium have changed in the last two decades, with increased use in batteries and reduction in other uses. Currently, the largest application of cadmium is in nickel-cadmium batteries (70% in the United States). Other major uses include stabilizers in polyvinyl chloride plastics, such as cadmium stearate (17%); plating and coatings on ferrous and non-ferrous metals (8%); specialized alloys, particularly copper; some specialized electrical devices; and pigments (e.g., cadmium sulfide, cadmium sulfoselenide).¹ Occupational exposure has been documented in each of these processes.

An important application, particularly from the perspective of occupational exposure, is cadmium in silver solder and in welding electrodes, although most solder no longer contains cadmium. Cadmium has a low boiling point (765°C), so welding on cadmium-plated materials, or use of cadmium-containing solder or welding electrodes, creates cadmium fume and the potential for acute pulmonary toxicity. The EPA has banned cadmium-related fungicides from many uses.

Cigarettes normally contain 1–2 micrograms Cd per cigarette, due to naturally occurring Cd in tobacco leaves, of which approximately 5–10% can be absorbed.² Hence, smokers have greater exposure and higher body burden of cadmium compared with non-smokers, and cadmium biomarkers are correlated with the number of cigarettes smoked per day.³ The cadmium content of each cigarette may be increased up to 20 micrograms in a contaminated work setting. Increased ingestion of cadmium can also result from contamination of food in the work environment.

Skin absorption of cadmium is negligible, and gastrointestinal absorption is usually about 5% of the ingested amount. The latter can be increased to 20% with iron deficiency or low calcium intake. Pulmonary absorption, which is the main route of occupational exposure, can be up to 50%, depending on particle size and solubility. For most people who are non-smokers and who do not have occupational exposure, the primary route of absorption is via ingestion, estimated to be about 30 micrograms/day.¹ Certain grains will selectively concentrate cadmium present in soil or water.⁴ Thus, environmental contamination with cadmium can result in substantial human over-exposure due to ingestion of contaminated foods.^{5,6} At least one major episode of clinical cadmium-related toxicity has been traced to this route of exposure (itai-itai disease in Japan⁵).

CLINICAL EFFECTS

Acute

Inhalation exposure to cadmium fumes, usually associated with welding or silver soldering, can result in a syndrome that can be confused with metal fume fever (MFF). It may be possible to identify cadmium as a possible etiologic factor since cadmium fumes have a characteristic yellowish color, while zinc fumes are white. Clinical effects can be delayed up to 24 hours. Symptoms include shortness of breath, fever, weakness, and respiratory insufficiency. With mild exposure, these effects may resolve within a few days, similar to MFF. Following more intense exposure, patients will not improve after one or two days, and may develop acute chemical pneumonitis and pulmonary edema, with typical findings on physical examination and laboratory test results (rales, hypoxia, elevated leukocyte count, patchy infiltrates on chest radiographs, impaired gas transfer). If death from respiratory insufficiency does not occur, recovery can be prolonged, and permanent (restrictive) pulmonary dysfunction may result.⁷

Cadmium salts are direct irritants to the gastrointestinal mucosa. Ingestion of large quantities causes nausea, vomiting, abdominal cramps, diarrhea, and shock from fluid loss. Symptoms develop within minutes of ingestion.

Chronic

The kidneys are the critical target organs among persons with chronic cadmium exposure. Other reported effects include pulmonary emphysema; slight anemia; liver dysfunction; disruption of calcium, phosphate and vitamin D metabolism with consequent osteoporosis, osteomalacia and formation of calcium renal stones; anosmia and possible ulceration of the nasal septum; yellowing of teeth. Increased risk of lung and prostate cancer have been suggested but not proved.

Absorbed cadmium is initially transported in the blood, primarily within red blood cells, to other tissues. The major repositories are kidney, liver, and muscle; these three tissue depots can account for up to 70% of the body burden. Cadmium stimulates the production of a low molecular weight binding protein, metallothionein, which binds the metal in tissue, plasma, and within red blood cells. Cadmium released from tissue, in the form of cadmium-metallothionein complex, is filtered at the renal glomerulus, and the complex is efficiently reabsorbed in the proximal renal tubules. Reabsorbed cadmium accumulates in proximal renal tubular cells. If the cadmium within renal tubular cells exceeds a certain threshold (approximately 100–300 micrograms Cd/gram wet weight of renal tissue), the cells are damaged, and function is impaired. The clinical result is decreased capacity of proximal tubu-

lar reabsorption, initially with loss of 'tubular' proteins in urine. The latter include β -2 microglobulin, retinol binding proteins, and N-acetyl- β -glucosaminidase (NAG). In addition, there is marked increase in urinary excretion of cadmium due to loss of cadmium that had been sequestered within renal tubular cells that were damaged.

With more pronounced damage to renal tubules, the proteinuria is increased, and there is also loss of other components of glomerular filtrate, such as calcium, phosphate, amino acids, other acids, and glucose. 1-Hydroxylation of 25-hydroxy-vitamin D₃ may be impaired, since this occurs within tubular cells. Eventually, glomerular function can become compromised, resulting in albuminuria, decreased glomerular filtration rate, and elevated serum creatinine. Once initiated, these processes may not be reversible (depending on severity), and, in fact, may progress even following cessation of exposure, although cadmium-induced proteinuria rarely exceeds 2 grams per day.⁸

Increased incidence of calcium-containing renal calculi has been documented to occur among occupationally exposed groups, particularly among those with longer, more intense exposure (hence greater body burden) and renal dysfunction.⁹ Overt bone disease, i.e., osteomalacia, osteoporosis and pseudo-fractures, related to hypercalciuria, hyperphosphaturia, and decreased 1-hydroxylation of 25-hydroxy-vitamin D₃ has also been recorded, although these tend to occur in conjunction with decreased dietary intake of calcium and hormonal effects such as post-menopausal status. The latter was the case in Toyama Prefecture, Japan, where people consumed rice grown in fields that had been irrigated with cadmium-contaminated industrial effluent. The major clinical presentation, proteinuria with osteomalacia and bone pain, occurred primarily among postmenopausal women and was termed 'itai-itai' (ouch-ouch) disease. More recently, lower-level environmental (as opposed to industrial) exposures to cadmium have been associated with increased risk of bone fractures,¹⁰ and increased excretion of NAG, β -2 microglobulin, and retinol binding proteins.¹¹

Inhalation of cadmium fumes appears to contribute to the development of emphysema, chronic bronchitis, and COPD among exposed workers, independent of cigarette smoking.¹² A history of acute, cadmium-induced chemical pneumonitis is not required, and this effect appears to be dose related.

The anemia observed in association with cadmium exposure has been a mild, reversible depression of hemoglobin. The mechanism is not entirely clear, but there is evidence suggesting that cadmium interferes with iron absorption, and may have a slight hemolytic effect.

The liver is one of the major sites of cadmium deposition. Liver dysfunction is uncommon, but can manifest as slight elevation of hepatic enzymes in serum.

Epidemiologic cohort studies have identified an elevated risk of death from lung cancer and prostate cancer among workers with long-term cadmium exposure,¹³⁻¹⁶ although it has been difficult to control for confounding by concurrent occupational exposures to other lung carcinogens.

DIAGNOSIS, EVALUATION, AND TREATMENT

When evaluating persons with acute inhalation exposure to metal fumes, inquiry must be made concerning the possible presence of cadmium. Lack of awareness may be compounded by cadmium being present as only a trace component. The initial clinical picture can be confused with the benign condition, metal fume fever. Measurement of blood cadmium levels is considered a reasonable marker for recent cadmium exposure. However, with acute respiratory exposure blood cadmium may not be elevated and such test results might be delayed long after therapy may need to be initiated. Urinary cadmium levels, discussed below, can help assess cadmium body burden, but are not a good indicator of acute exposure. Therapy is primarily supportive. Chelation is risky since cadmium mobilized from pulmonary and other tissues is likely to be deposited in the kidneys, and thus precipitate or accelerate the development of renal dysfunction. Cadmium-induced chemical pneumonitis should be suspected in a welder who appears much more ill than would be typical in metal fume fever, or who fails to recover from apparent metal fume fever in the normal course.

Since the kidneys are the primary target organ with chronic cadmium exposure, and renal manifestations of cadmium toxicity are not reversible, the goal is to monitor workers to prevent the development of kidney dysfunction. The critical parameter for predicting toxicity is body burden or, more precisely, the renal burden of cadmium. Research methods for direct, in-vivo assessment of kidney burden of cadmium exist (e.g., neutron activation analysis), but are not practical clinical tools. The practical alternatives involve measurement of a variety of biologic parameters that reflect renal burden of cadmium or early nephrotoxicity.

On initiation of chronic exposure, cadmium levels in whole blood increase several-fold during the first few months, and then plateau. With cessation of exposure, cadmium in whole blood decreases following a two-compartment model, with an initial rapid clearance phase ($t_{1/2}$ of approximately 100 days), followed by a much slower phase ($t_{1/2}$ of about 10 years).¹⁷ Thus, measurement of cadmium in whole blood during ongoing exposure mostly reflects exposure during preceding months. However, increased blood cadmium can occur with relatively low body burden (e.g., after only a few months of exposure), and moderate cadmium levels in blood may be detected after prolonged absence of exposure, despite near critical body burden. In non-occupationally exposed persons, whole blood cadmium is usually well below 1 microgram Cd/100 ml whole blood, smokers have slightly higher levels than non-smokers.

Cadmium is excreted primarily via the urine. Among persons without occupational exposure, urine cadmium levels are generally below 2 micrograms Cd/g urinary creatinine. Smokers may have slightly higher levels than non-smokers. During ongoing exposure, and prior to saturation

of cadmium-binding sites within the kidneys, most filtered cadmium is reabsorbed in the proximal tubules, and so there may be only slight elevation of urinary cadmium. Urinary cadmium at this stage roughly reflects body burden. When binding sites within the kidney become saturated, urinary cadmium increases, and reflects 'overflow' of that which cannot be reabsorbed. At the onset of renal dysfunction, urinary cadmium increases dramatically, reflecting loss of cadmium that had been sequestered in proximal tubular cells. Even if exposure were to cease at this point, urinary cadmium would remain markedly elevated as more cadmium is lost from the kidney, and cadmium continues to be redistributed to the kidneys from non-renal tissue stores. The probability of renal dysfunction is increased when urinary cadmium exceeds 10–20 micrograms Cd/g urinary creatinine.^{8,17} Persons with cadmium-induced renal dysfunction generally have urine levels above this threshold.

The earliest sign of renal dysfunction is increased excretion of low molecular weight proteins that would normally be reabsorbed in the proximal tubule. Classically, this has been detected by measuring β -2 microglobulin in urine (normal: less than 200 micrograms/g urinary creatinine). Measurement of retinol binding protein or NAG are alternative choices; retinol binding protein has the advantage that it is more stable in urine in the range of physiological pH, but is not routinely available.

In persons with suspected renal dysfunction, a thorough evaluation should include measurement of serum electrolytes, BUN and creatinine, cadmium in blood and urine, full characterization of proteinuria, determination of whether renal calculi are present, a thorough screening for alternative or contributory factors to renal disease, and search for non-renal effects of cadmium exposure (e.g., pulmonary function tests, anosmia, liver dysfunction, yellowing of teeth). Renal histology is that of tubulointerstitial nephritis, as opposed to glomerular disease, and tissue cadmium content is elevated. Possible metabolic bone disease is prevented or treated with calcium and vitamin D supplementation. As suggested above, chelation therapy is probably risky since cadmium mobilized from non-renal body stores would tend to add to the kidney burden, and is not recommended. Also, removal of cadmium from renal sites would not help since kidney dysfunction is believed to be irreversible.

PREVENTION

Biologic monitoring of exposed workers, including urinary and blood cadmium, and urinary β -2 microglobulin, is recommended. The OSHA Cadmium Standard mandates reassessment of the worker's exposure and further medical evaluation at certain action levels (such as urine Cd > 3 micrograms/g creatinine or blood Cd > 5 micrograms/l), and removal from exposure at higher biologic monitoring levels (urine Cd > 7 micrograms/g creatinine, blood Cd > 10 micrograms/l). Chest x-ray and pulmonary function testing are also recommended for cadmium-exposed workers.

If possible, other materials should be substituted for cadmium. When this is not an option, exposures should be reduced through engineering controls, improved work practices, protective clothing, good housekeeping, and other standard approaches. Workers should be educated about cadmium, so that they can take appropriate steps when exposed to cadmium-containing materials.

39.5 Chromium

Alfred Franzblau, David H Garabrant

EXPOSURE SETTINGS

Metallic chromium was first isolated in 1797, and by the second decade of the 19th century chromium compounds had become important in industrial processes (e.g., potassium dichromate used as a mordant in textile dyeing). Following on soon after the discovery of their industrial utility were early descriptions of toxic effects of exposure to chromium compounds. Chromium and its compounds are widely used in industry.

The toxic effects of chromium are related primarily to exposure to the hexavalent [chromium(VI)] compounds, which are called chromates. Chrome alloys such as stainless steel [zero valence, chromium(0)] and trivalent chromium [chromium(III)] compounds have important and widespread industrial applications, but these compounds are generally less toxic than the hexavalent forms. NIOSH has estimated that over 305,000 workers in the United States are potentially exposed to chromium compounds, of which 196,000 are exposed to hexavalent chromium compounds.

In the occupational setting, exposure occurs by inhalation or skin contact with chromium-containing mist, dust, or fumes, or via direct contact with aqueous chromium solutions (e.g., in tannery workers). Ingestion of chromium salts or solutions can cause significant toxicity or death due to gastrointestinal irritation and renal failure, but this is not an important route of exposure in the industrial setting.

Chromium is derived from chromite ores (e.g., iron dichromate, FeOCr_2O_3), and exposure can occur among workers employed in the various roasting processes involved in the processing of ore and production of common commercially useful compounds (e.g., sodium or potassium chromate and dichromate, ammonium dichromate, and chromium oxide). Significant exposure also occurs during stainless steel production, stainless steel welding, and among users of chromium compounds. Chrome electroplating operations provide an opportunity for exposure to mist of plating bath solutions, which usually contain chromium trioxide (CrO_3), a potent irritant. Important exposure to chromium compounds also occurs in leather tanning (basic trivalent chromic sulfate, $\text{Cr}_2[\text{SO}_4]_3$, plus hexavalent forms), production and use of chromium-based paint pigments (yellow pigments based on lead chromate and zinc chromate), metallurgic operations (grinding or welding chrome alloy materials), use of cement (many cements contain trace amounts of various soluble hexavalent chromium compounds), textile dyeing (chromic oxide [Cr_2O_3] and chromic sulfate), manufacture of refractory products, and glassmaking (chromic oxide). Chrome compounds have produced toxicity among workers in a variety of smaller industries, including lithography, wood preserving, match production, paper pulp manufacture, and crayon making.¹

Total chromium exposures in US air are typically below 0.01 micrograms/ m^3 in rural areas and 0.01–0.03 micrograms/ m^3 in urban areas. Occasionally, levels above 0.5

micrograms/ m^3 have been measured. The proportion of total chromium comprising chromium(VI) varies but is often 20–30%. In the US, occupational permissible exposure limits are 1000 micrograms/ m^3 for chromium metal and insoluble salts, 500 micrograms/ m^3 for chromium(III) compounds, and 100 micrograms/ m^3 for chromic acid and chromates [carcinogenic chromium(VI) compounds]. Thus, ambient environmental exposures are typically at least two orders of magnitude below occupational exposures.²

CLINICAL EFFECTS

Chromium(III) and chromium(VI) are the oxidation states of chromium most commonly encountered by humans. Water-soluble chromium(III) compounds are not well absorbed into the body and enter cells poorly. Water-soluble chromium(VI) compounds (such as CrO_4^{2-}) are far more toxic because they are actively transported into cells in place of other structurally similar anions, such as phosphate (PO_4^{2-}). Inside the cell, chromium(VI) is reduced via reactive intermediates ultimately to chromium(III), which binds tightly to cellular ligands and is largely responsible for toxicity. Chromium(III) is an essential nutrient for humans and is involved in the metabolism of glucose. Average daily consumption of Cr(III) is 60 micrograms/day from food, with intake of 50–200 micrograms/day recommended.

Soluble hexavalent chromium compounds tend to be strong oxidizing agents. They also penetrate skin and mucous membranes more effectively than trivalent forms. These properties may explain, in part, the potent irritant properties of soluble hexavalent chromium compounds.

Cutaneous exposure to mist, dust, or chromium solutions can result in simple skin irritation. The classic cutaneous chromium lesion is the chrome ulcer, or chrome hole. This lesion was first described in 1827 and may be a relatively painless, although deep, punched-out wound that can penetrate into underlying tissue layers including cartilage, but usually not bone. Secondary bacterial infections are common. On removal of the affected individual from exposure, healing may require months and leave a residual scar. These lesions occur at sites of greatest exposure, such as over bony prominences of the hands and forearms, although they have been described on the lower extremities when work practices have been particularly poor. They also tend to occur at sites of skin trauma, such as incidental nicks or cuts. They are not related to chrome sensitization.³

The mucous membranes also suffer irritant consequences, including erythema of the throat, conjunctival irritation, nasal itching and soreness, edema of the uvula, coryza, epistaxis, ulceration of the nasal mucosa, and nasal septal perforation. With very high exposures, a high prevalence of nasal septal perforations may occur (greater than 50% in some settings) with rapid onset, in some cases less than 1 week, following initiation of employment. Because

the damaged cartilage is not the most anterior portion, there may not be any apparent external deformity of the nose. Sinusitis and nasal polyps also have been noted among exposed workers, and rare cases of perforation of the tympanic membranes have been described.

Inhalation of chromium mist, dust, or fumes can produce acute bronchoconstriction, probably through a direct irritant mechanism. Chronic bronchitis and persistent abnormalities in pulmonary function have not been described following cessation of exposure. Allergic asthma due to chromium is uncommon, with fewer than two dozen cases documented in the published literature. Immediate, late, and dual bronchoconstrictive responses may occur. The immunologic mechanisms that have been reported for asthma include chromium-specific IgE (in one case of an immediate reaction) and a cell-mediated response (in one case of a delayed reaction).⁴

In addition to their direct irritant effects, chrome compounds (usually dichromates or hexavalent forms) also are potent cutaneous sensitizers.⁵ Chromium allergic contact dermatitis is the most common occupational dermatosis among male patients. Exposure can be occult owing to the ubiquitous nature of chromium. Eczematous skin lesions usually are found in areas of greatest exposure, such as the hands and arms. Sensitization to chromium tends to persist for years, even after cessation of exposure, based on persistence of positive patch tests among workers who have been sensitized⁶ (see also Chapter 29.1).

A number of hexavalent chromium compounds are established human carcinogens, including calcium chromate, chromium trioxide, lead chromate, strontium chromate, and zinc chromate.⁷ Epidemiologic studies have documented increased rates of respiratory cancer (lung and nasal, primarily) among workers in the chromate production industry and the chromate pigment industry⁸ (see Chapter 30.2). Of interest, studies of stainless steel welders and in the ferrochromium alloy industry have given inconclusive results regarding cancer risks, even though exposure to chromium(VI) is appreciable in these settings.⁹ There is scant evidence that metallic chromium and chromium(III) compounds are carcinogenic in humans or animals and these materials are currently *not classifiable as to their carcinogenicity to humans* (IARC Group 3).¹ Lung cancers associated with exposure to hexavalent chromium compounds have prolonged latencies (delay from onset of exposure), generally lasting more than 20 years. There is no unique or predominant histology. Although some studies have indicated excesses of other cancers (such as gastrointestinal cancers) in the bichromate producing industry and the chromate pigment industry, these results are inconsistent. Chromium(VI) compounds generally are not regarded as causing cancers outside the respiratory tract.

Mild impairment of proximal renal tubular function, manifested by an increased excretion of β -2 microglobulin and retinol binding protein, has been documented among active chrome platers. There is no apparent effect on glomerular function, as reflected in the excretion of albumin. Tubular dysfunction appears to be reversible on cessa-

tion of exposure. Acute tubular necrosis with renal failure has been observed in rare cases following massive dermal absorption of chromium (e.g., falling into a vat of hot chromic acid). These observations of low molecular weight proteinuria and acute tubular necrosis raise the possibility that long-term exposure to chromates may be a risk factor for persistent renal injury.

DIAGNOSIS, EVALUATION, AND TREATMENT

The pharmacokinetics of chromium in humans are complex. Absorbed hexavalent chromium is mainly excreted in the urine. With ongoing exposure, the half-life in urine ranges from 15 to 41 hours. Detailed kinetic studies suggest a three-compartment model for chromates, with half-lives of about 7 hours, 15–30 days, and 3–5 years. Therefore, measurement of chromium in urine can be used to document recent exposure to chromates, although the concentration of chromium in urine is not correlated with toxicity.^{10,11} The correlation between chromium(III) exposure and urine chromium levels is poor and urine monitoring is not felt to be useful for these exposures. In non-occupationally exposed populations urinary chromium is usually less than 5 micrograms/g of creatinine.² Because of a lack of adequate data, blood, hair, and nail levels of chromium are not interpretable at present and should not be relied upon in assessing exposure.¹²

If not prevented, chrome ulcers should be identified early and workers with such lesions should be removed from exposure until complete healing has occurred. Treatment of other acute cutaneous and mucous membrane effects of chromium exposure also requires reduction of exposure. Patch testing can be used to distinguish between irritant dermatitis and allergic contact dermatitis. Topical steroid preparations may be beneficial in treatment of both entities. Because sensitization tends to be long lasting, affected workers may experience adverse social and economic consequences because of the need to find alternative employment.

The clinical approach to and prognosis of patients with lung cancer who have had occupational exposure to chromium compounds are the same as for other patients with lung cancer. There is evidence that the chromium content of pulmonary tissue from chromium-exposed workers with lung cancer is higher than among persons without lung cancer matched for smoking history, and also is higher than those with lung cancer but without any history of occupational chromium exposure. However, the diagnostic value of such measurements in an individual case is unclear. The histologic appearance and cell types of respiratory cancers related to carcinogenic chromium(VI) exposure do not have any defining characteristics.

PREVENTION

If alternative materials are not available, then engineering controls that minimize or eliminate chromium exposure must be applied. In addition, prevention of chrome ulcers

and other irritant effects of chromium compounds depends on the education of workers concerning the importance of industrial cleanliness and the use of personal protective equipment. Such measures should be supplemented with regular examinations of the skin and nose to detect early signs of irritant effects.

Assessment of pulmonary function and chest radiographs is recommended in workers with inhalational chromium exposure.

In some processes, substitution of trivalent chromium for hexavalent chromium, as in electroplating baths, can be beneficial in reducing the incidence of sensitization. Chromium sensitization among cement workers can be prevented by adding ferrous sulfate (FeSO_4) immediately before mixing, when most skin contact occurs. The quality of the cement is not impaired, but the hexavalent chromium present in the cement is reduced and precipitated as chromium sulfate, an insoluble trivalent species. This procedure is already in practice in Scandinavia.

39.6 Nickel

Alfred Franzblau, David H Garabrant

EXPOSURE

First isolated in 1751, nickel is abundant in the earth's crust (ranking 24th), and has multiple industrial applications. Current major industrial uses include stainless steel making, other alloys and superalloys, electroplating, plus lesser amounts used in cast iron, chemicals, batteries, ceramics and as industrial catalysts.¹ It is also a nutritionally important element, although a specific deficiency state has not yet been defined in man.

Most occupational nickel exposure occurs via inhalation of fume or dust, or skin contact with salts, alloys, or solutions. Diet is an important source of nickel exposure and is believed to be 100–800 micrograms/day (although less than 5% is typically absorbed), and contributes 80–94% of the total body burden of nickel among non-exposed populations.²

NIOSH has estimated that 250,000 persons in the United States have occupational exposure to inorganic nickel, and OSHA has estimated that 709,000 workers are possibly exposed to nickel and its compounds. Most exposed workers are involved in refining, smelting, machining, casting, welding, battery making, or grinding steel or other nickel alloys. Exposure to nickel salts is important in nickel plating operations. Release of air-borne nickel dusts from nickel refining and smelting operations has resulted in documented exposure to persons living downwind from such plants. Because of widespread use of nickel alloys in jewelry and other common consumer products, cutaneous exposure of the general population is prevalent. A small but significant problem is hypersensitivity of patients 'exposed' to implanted nickel-alloy bioprotheses; implanted prosthetic devices may employ alloys containing up to 35% nickel.

A small number of workers have potential exposure to nickel carbonyl ($\text{Ni}[\text{CO}]_4$). Formed by passing carbon monoxide over nickel-containing materials, it is a volatile, colorless liquid that boils at 43 degrees C. Sometimes described as 'musty', the gas lacks any strong or penetrating odor. This compound presents a considerable hazard in refining of nickel using the Mond process, gas plating, and also in synthesis of acrylates for paints and plastics. Exposure is usually via inhalation of the gas, although transcutaneous absorption of liquid presumably could be significant.

ABSORPTION, EXCRETION, AND BIOLOGIC MONITORING

Absorption of nickel compounds is related to their solubility, with nickel carbonyl being highly soluble, most nickel salts being soluble, and nickel oxides and sulfides being relatively insoluble. Gastrointestinal absorption of soluble nickel compounds is rapid, but only about 1–5% is absorbed. Absorption of metallic nickel and insoluble nickel compounds from the gastrointestinal tract is very small.

Absorption and clearance of inhaled insoluble nickel compounds (for example, nickel compounds in welding fumes) from the lungs is slow, occurring over months. Dermal absorption of nickel and nickel compounds is minimal.³

Absorbed nickel is rapidly excreted in the urine, with a half-life of 20–60 hours. Nickel concentrations in plasma and urine reflect recent exposure to soluble nickel compounds and therefore can be used to monitor such exposures. In contrast, concentrations of nickel in plasma and urine do not reflect exposures to insoluble nickel compounds, thus limiting the utility of biologic monitoring for most industrial nickel exposures. Among non-exposed populations, mean nickel concentrations in serum/plasma are in the range 0.14–0.63 micrograms/l, in blood < 0.05–3.8 micrograms/l, and in urine 0.9–3.2 micrograms/l and 1.5–1.6 micrograms/g creatinine.⁴ The use of hair and fingernail samples as indices of internal exposure is not reliable and has not been demonstrated to have any clinical utility.⁵

CLINICAL EFFECTS

Acute

Nickel carbonyl is the most acutely toxic nickel compound. Acute exposure to nickel carbonyl results in a two-phase illness that is dominated by pulmonary involvement. The first phase has almost immediate onset, and consists of multiple non-specific systemic complaints (fever, chills, nausea, lightheadedness, headache, dyspnea, and chest pain). These are easily confused with the 'flu' or acute bronchitis, and may resolve after a few hours. The second phase develops after 12–36 hours, but can be delayed up to five days. Acute chemical pneumonitis dominates the clinical picture, with cough, dyspnea, tachycardia, and cyanosis. Encephalopathy, due to cerebral edema and possibly hemorrhage, can also occur. Death may result from respiratory failure. Recovery from acute nickel carbonyl exposure can be prolonged because of slowly resolving pneumonitis.

Additional acute responses resulting from exposure to nickel compounds include irritation of mucous membranes, contact dermatitis, and/or asthma in sensitized individuals. Allergic dermatitis can result from exposure to either nickel salts, such as nickel sulfate among nickel platers, or metallic nickel or nickel alloys (see Chapter 29.1). The latter is exemplified by cutaneous reactions to jewelry, buttons, and other clothing items that contain nickel. Up to 15% of women in the general population, who have no history of occupational nickel exposure, are sensitized to nickel, based on patch testing.⁶ Dentists may also have a high prevalence (16%) of nickel sensitization.⁷ Industrial 'nickel itch' can present in a number of ways, including: itching or burning papular erythema in interdigital areas with spread to exposed areas on the upper extremities; or papular or papulovesicular dermatitis with some

lichenification, similar to atopic dermatitis or neurodermatitis. Eruptions distant from the site of metal contact have also been described.

Asthmatic reactions to nickel compounds, usually salts such as nickel sulfate, are unusual, but well documented.⁸ Reactions can involve immediate, delayed, and dual bronchospastic responses.

Chronic

Increased incidence of cancer of the lungs and nasal cavities has been documented among nickel refinery workers in numerous epidemiologic studies from different geographic locations (see Chapter 30.2).⁹ Other malignancies in humans are not established to be causally associated with exposure to nickel and its compounds. The precise agent(s) responsible for nickel carcinogenesis in man is uncertain, but insoluble dusts (nickel subsulfide – Ni_3S_2 ; nickel oxides – NiO and Ni_2O_3), soluble dusts (nickel sulfate, nitrate, or chloride – NiSO_4 , NiNO_3 , NiCl_2), nickel carbonyl, nickel pellets/dust, nickel acetate, nickel hydroxide, and nickel fluoride have been documented to be carcinogenic in various animal models.

The International Agency for Research on Cancer (IARC) classifies nickel compounds as carcinogenic to humans (Group 1), based on evidence of carcinogenicity of nickel sulfate and the combination of nickel sulfides and oxides encountered in the nickel refining industry. Metallic nickel and nickel alloys have also been evaluated, with inadequate evidence for carcinogenicity in humans for both metallic nickel and nickel alloys, but sufficient evidence in animals for metallic nickel and limited evidence in animals for nickel alloys and nickel carbonyl. Thus, metallic nickel is classified as possibly carcinogenic to humans (Group 2B).⁹ The US National Toxicology Program (NTP) classifies nickel and certain nickel compounds (nickel acetate, nickel carbonate, nickel carbonyl, nickel hydroxide, nickelocene, nickel oxide, and nickel subsulfide) as reasonably anticipated to be human carcinogens.¹⁰ It should be noted that this classification is different from the designation given by NTP to agents that are known to be carcinogenic to humans. Overall, it appears that insoluble nickel compounds (oxides and sulfides) are carcinogenic, while the carcinogenicity of soluble nickel compounds by inhalation cannot be determined because of conflicting data.¹¹

IARC has conducted a separate evaluation of the carcinogenicity of surgical implants and other foreign bodies, many of which contain nickel alloys. Implanted foreign bodies of metallic nickel and certain nickel alloys are classified as possibly carcinogenic to humans (Group 2B), while orthopedic implants of complex composition and dental materials are not classifiable as to their carcinogenicity (Group 3).¹²

As with most occupational malignancies, nickel-related tumors resemble those of non-occupational origin, but there are some features of nickel-related lung cancers and nasal cancers that are noteworthy. The sites of tumor occurrence appear related to airflow patterns and particle deposition in the nose and tracheobronchial tree.

Premalignant metaplastic changes in the nasal mucosa and nasal cancers typically originate at the anterior tips of the middle turbinates and spread along the lateral nasal walls and sinuses. The histology of sinus cancers among nickel workers is predominantly squamous cell. Nickel-related lung cancers tend to arise in the larger bronchi, and there may be a slight disproportionate increase in squamous cell histology.¹³

Despite numerous studies showing an increased risk of malignancy among nickel refinery workers, an increased risk of cancer among end-users of nickel compounds or products has not been documented unambiguously. Nevertheless, it is prudent to consider nickel dusts as potential human carcinogens, and to employ appropriate control measures.

Repeated or chronic exposure to nickel carbonyl may induce pulmonary fibrosis, even in the absence of a history of acute intoxication and ARDS.

Exposure to nickel aerosols (e.g., nickel sulfate – NiSO_4) has been associated with chronic rhinitis, sinusitis, perforation of the nasal septum, and anosmia. These effects are irritant reactions, and not immunologically mediated. Workers in electrolytic nickel refineries and those employed in nickel plating operations are at greatest risk.

Nickel alloys are frequently employed in various internally implanted medical devices, including orthopedic prostheses, cardiac pacemaker electrodes, replacement cardiac valves, and metal sutures. Such devices can induce cutaneous allergic reactions, including urticaria, eczematous changes, and pemphigoid lesions.

DIAGNOSIS, EVALUATION, AND TREATMENT

Nickel carbonyl is the only nickel compound that has caused acute inhalation poisoning. Nickel carbonyl poisoning must be suspected on the basis of the history because prevention of acute poisoning, including pneumonitis, and a favorable outcome depend on early diagnosis and treatment. Sodium diethyldithiocarbamate (dithiocarb, DDC) is an investigational drug that has been an effective antidote for nickel carbonyl poisoning in animal studies when administered parenterally soon after exposure. Although it has been used in several hundred patients, there are no adequately controlled studies to establish its clinical effectiveness in the treatment of human poisoning by nickel carbonyl.¹⁴ An adult oral dose of 35–45 mg DDC/kg in divided doses in the first 24 hours, then 400 mg every 8 hours until the urine nickel concentrations are near normal and the patient is symptom free has been recommended.¹⁵ Critically ill patients may be treated parenterally with 12.5 mg sodium DDC/kg. Patients with more than 100 micrograms Ni/liter of urine in the first 8 hours post-exposure, or in whom severe nickel carbonyl exposure is suspected, are candidates for treatment. Poisoning cases in which there is more than minor irritation of the upper respiratory tract should also undergo evaluation for acute chemical pneumonitis and carbon monoxide exposure.³

Because of chemical similarity to disulfiram, patients treated with dithiocarb must avoid alcohol so as not to experience an 'Antabuse' reaction. Studies provide no support for use of other common metal chelating agents, such as BAL, penicillamine, or EDTA. Otherwise, the therapy of acute nickel carbonyl exposure is supportive.

Patch testing with nickel sulfate can be used to distinguish irritant from allergic contact dermatitis due to nickel. Allergic reactions to nickel compounds generally mandate removal from exposure since even limited exposure of sensitized individuals will induce a response (i.e., asthma or contact allergic dermatitis). Enhanced in vitro lymphocyte proliferation using nickel acetate in lymphocytes obtained from sensitized individuals has been reported, but this test is an investigational tool and not widely available. Immediate response to skin prick testing may also be used to identify sensitized individuals. Routine screening of asymptomatic workers with patch tests to identify nickel sensitivity is not indicated. Cutaneous nickel hypersensitivity persists for years after cessation of exposure and ongoing dermatitis may persist because of contact with jewelry, buckles, and other apparel.

Treatment of nickel hypersensitivity among persons with implanted prostheses may require removal and replacement with non-nickel containing devices.

PREVENTION

Nickel and/or nickel compounds are carcinogens, therefore exposure to air-borne dust and fumes must be minimized. Nickel refinery workers should have regular medical examinations that include inspection of the nasal mucosa and chest radiography. Because of severe acute toxic potential, nickel carbonyl must be contained in enclosed systems to prevent human contact. Minimization of cutaneous exposure should reduce the likelihood of development of cutaneous sensitization or irritant effects.

39.7 Fluorine and Related Compounds

Stephanie Carter, Noah S Seixas

SOURCES OF EXPOSURE

Fluorine is a fairly ubiquitous element, forming 0.03% of the earth's crust, predominantly as the mineral fluor spar (calcium fluoride), as cryolite (sodium aluminum fluoride), and in phosphate rock.¹ Fluorine is the most electronegative of elements and is a powerful oxidizer, being able to form ionic or covalent fluoride compounds with all elements except helium, neon, and argon.² Fluorine gas (F_2) is a pale yellow gas used as a rocket fuel and in chemical processing to produce uranium hexafluoride, fluorocarbons, and other organic and inorganic fluoride compounds. Hydrogen fluoride (anhydrous, or in water as hydrofluoric acid), produced by the addition of sulfuric acid to calcium fluoride, is used as a catalyst in petroleum refining (alkylation), in etching glass, and metal cleaning in the electronics and semiconductor industries.

Simple salts of fluoride (including sodium, calcium, copper, stannous, and zinc fluorides) find a wide range of uses in steel making, pesticides, drinking water and toothpaste additives, in electroplating, lumber treatment, glass, enamel, ceramics manufacture, and as lubricants and fluxing agents for welding. Other fluoride compounds have specialized uses in industry: cryolite as a flux in aluminum reduction smelters; magnesium fluosilicate in concrete and waterproofing applications; polychlorofluorocarbons (e.g., Freon and Halon) as aerosol propellants and fire suppressors; and fluoropolymers (e.g., Teflon, Tedlar) have numerous specialized applications.

An estimated 183,000 US workers may be occupationally exposed to fluoride,³ while elevated community exposures may occur near aluminum smelters or phosphate fertilizer facilities, and during volcanic eruptions. Lower levels of exposure through toothpaste ingestion, fluoridated water supplies, and diet are almost ubiquitous in industrialized nations.⁴

ACUTE HEALTH EFFECTS

Both fluorine and hydrogen fluoride (HF) gas are severe irritants to the eyes, mucous membranes, and respiratory tract (see Chapters 19.5 and 29.1). Upon contact with skin or mucous membranes, HF quickly dissociates to form hydrofluoric acid. Chemical burns of the skin can also occur from contact with F_2 or HF. In the US, at least 1000 cases of exposure to liquid hydrofluoric acid and/or hydrogen fluoride occur each year.⁵ Fluorine concentrations between 100 and 200 ppm result in burns, which appear similar to a thermal burn, and heal relatively quickly. Skin contact with hydrofluoric acid produces deep burns, possibly contacting bone, which can be exceedingly slow to heal. Prompt medical treatment through water irrigation and neutralization is required to limit the severity of these burns. If the concentration and degree of exposure are sufficient, the fluoride ions can remove enough calcium and/or magnesium to induce cardiac arrhythmias, damage the liver and kidney,

and cause neuromuscular hyperirritability.⁵ Contact with hydrofluoric acid at concentrations greater than 50% produces immediate burning pain. At lower acid concentrations (especially below 20%), the symptoms may be unnoticed or delayed, thus delaying prompt treatment and allowing deep burns and systemic effects.⁶

Polymer fume fever is a flu-like acute response to the pyrolysis products of fluoropolymers, mold-release agents, and potentially other fluorocarbons (see Chapter 19.5). Symptoms of polymer fume fever include initial irritation followed 3–6 hours later by fever, chills, and general myalgia.⁷ The pyrolysis products thought to be responsible for the effects vary depending on the amount of oxygen available and the pyrolysis temperature. Of most importance is carbonyl fluoride, which converts to hydrogen fluoride upon contact with moisture in the respiratory tract. Smokers are at increased risk of polymer fume fever due to smoking fluoropolymer-contaminated cigarettes. Chemical pneumonitis and adult respiratory distress syndrome (ARDS) have also been reported after inhalation exposure from HF-containing consumer products.⁸

CHRONIC HEALTH EFFECTS

The most well-known effect of chronic exposure to fluoride is bony fluorosis, an increased bone density or, in severe cases, skeletal deformities and spinal rigidity. The occurrence of fluorosis was first described in an occupationally exposed cohort in 1932 in which 30 of 78 cryolite-exposed workers had radiologic findings ranging from increased bone density to hyperosteoses.⁹ Skeletal changes and possibly associated musculoskeletal complaints have continued to be observed among relatively highly exposed working populations. Kaltreider et al¹⁰ reported a high prevalence of fluorosis among aluminum smelter workers with more than 10 years of exposure to fluoride levels of 2.4–6.0 mg/m³. A follow-up of a small group ($n = 56$) of these workers 7–8 years later showed no further increase in bone density.¹¹ Possible and definite fluorosis was observed in 14% and 6.2%, respectively, of 2258 aluminum workers with relatively long exposure histories.¹² One study of aluminum workers suggests that musculoskeletal symptoms and increased rates of fracture may occur even in the absence of radiologic evidence of fluorosis.¹³

Fluorosis occurs as a result of the selective affinity of fluoride for bone and formation of fluorapatite. Despite the increased bone density associated with fluoride exposure, the possible benefits of fluoride in the treatment of osteoporosis are uncertain, with some studies indicating a higher risk of bone fracture, and animal studies indicating lower bone strength associated with fluoride exposure. The benefits of small amounts of fluoride in the prevention of dental caries have been well demonstrated. However, higher fluoride exposures during tooth formation in early childhood results in striation and mottling of teeth, while still higher levels may result in more severe dental

discoloration and pitting, with decreased tooth strength and an increase in cavities.⁴

Occupational asthma has frequently been observed among aluminum potroom workers exposed to fluorides.¹⁴ No specific causative agent has been identified in relation to asthma in this setting, though fluorides have been suspected. Current hypotheses are focusing on an irritant-induced mechanism with exposures to sulfur dioxide and HF as the primary suspected agents.

Other than bony fluorosis, there is no clear evidence of chronic systemic health effects of fluoride exposures. Gastrointestinal symptoms have been observed among groups with accidental high exposures or oral ingestion of fluoride compounds, probably due to irritation or erosion of the gastric mucosa.⁴ Several epidemiologic studies have considered the effect of various fluoride compound exposures on cancer mortality in occupational and community cohorts. Each of these studies, however, has had important potential confounding exposures that may have explained any increased cancer rates observed. For instance, elevated cancer rates among aluminum smelter or fluoride workers^{15,16} are more likely associated with carcinogens in coal tar pitch volatiles than fluoride exposures. The International Agency for Research on Cancer (IARC) has reviewed the available literature on fluoride exposure through drinking water, and concluded that there was no evidence of carcinogenicity from epidemiologic studies and insufficient evidence from animal studies.¹⁷

PREVENTION

Prevention of acute effects of fluorine or HF exposure is accomplished by preventing exposures, including short-term peak levels, from exceeding established guidelines (Table 39.7.1). The odor threshold for both HF and F₂ is approximately 0.1–0.2 ppm, exhibiting reasonable warning properties. In large part, the exposure limits are based

on the prevention of irritation of the eyes and upper respiratory tract, although fluorosis is also prevented at these concentrations.¹

The ACGIH¹ and OSHA PEL¹⁸ for fluorine differ substantially (1 ppm and 0.1 ppm, respectively). This difference is based largely on the importance placed by OSHA on animal studies. ACGIH relied more heavily on more recent workplace studies that suggested that exposures above 0.1 ppm did not result in significant health effects or irritation.

Hydrogen fluoride exposure limits are based on HF as a primary irritant of the eyes, skin, and respiratory tract. ACGIH recommends a more conservative ceiling limit (3 ppm) to prevent skin reddening and burning of the eyes and nose seen in human studies. The OSHA PEL and NIOSH REL designate both TWA and STEL limits based mainly on prevention of more severe respiratory irritation and fluorosis.

Emergency response planning guidelines developed by the American Industrial Hygiene Association (AIHA) for HF and F₂ indicate levels of exposure below which nearly all individuals can be exposed for 1 hour without experiencing mild or transient health effects, developing health effects that may impair ability to protect themselves, or experiencing life-threatening health effects. For HF, these limits are 2, 10, and 50 ppm, respectively; for F₂, the limits are 0.5, 5, and 20 ppm.¹⁹

Irritation is reported at fluoride particulate concentrations of 5–10 mg/m³. Changes in bone density appear to be prevented by maintaining exposures less than 2.6 mg/m³ (ACGIH). All major US exposure-setting organizations concur with the 2.5 mg/m³ limit for particulate fluoride including major international organizations. However, the German Maximum Allowable Concentration (MAK) includes a short-term level of 12.5 mg/m³ averaged over a period of 30 minutes.

Because respiratory protection is commonly used in areas of high fluoride particulate, biologic monitoring may be used to evaluate the body burden at a particular point in time. Table 39.7.2 provides a summary of the suggested biologic monitoring levels for fluoride. Urinary levels are corrected for concentration by adjustment either with creatinine concentration or specific gravity. Creatinine adjustment requires that the creatinine concentration be within specified limits. ACGIH recommends monitoring fluoride in urine and assuring that levels are maintained below 3 mg fluoride per gram creatinine for spot samples taken prior to a work shift, or 10 mg/g Cr at the end of the work shift. Background levels of fluoride in urine, related to food and water intake, rarely rise above 2 mg/l, with most below 1 mg/l.

Air-purifying respiratory protection should utilize acid gas cartridges. For exposures lower than the exposure

Exposure guideline source	Fluoride (mg/m ³)	Hydrogen fluoride (ppm)	Fluorine (ppm)
ACGIH – TLV	2.5 ^{TWA}	3 ^C	1 ^{TWA} , 2 ^{STEL}
NIOSH – REL	2.5 ^{TWA}	3 ^{TWA} , 6 ^{STEL}	0.1 ^{TWA}
NIOSH – IDLH	500	30	25
OSHA – PEL	2.5 ^{TWA}	3 ^{TWA} , 6 ^{STEL}	0.1 ^{TWA}

TWA: Time weighted average, over 8 hours.
 STEL: Short term exposure limit, over 15 minutes.
 C: Ceiling, concentration not to be exceeded.
 REL: Recommended exposure limit.
 IDLH: Immediately dangerous to life or health.

Table 39.7.1 Occupational exposure guidelines

Reference	Units	Pre-shift	Post-shift	Screening creat. (mg/l) or SG adjustment (g/ml)
(ACGIH 1996) ¹	(mg F/g creatinine)	3	10	Cr.: 300–3000
(DFG 1998) ²²	(mg F/g creatinine)	4	7	Cr.: 500–2500
(NIOSH 1975) ²³	(mg F/L)	4	7	SG: 1.024 g/ml

Table 39.7.3 Guidelines for HF burn treatment⁵

limits specially impregnated filters may also afford some protection. Use of full-face respirators has the advantage of providing protection from splashes and reducing eye irritation. Work areas where there is a potential for large gas releases of HF or F₂ should have fixed-point gas alarms or other exposure indicators, and firewater deluge systems to minimize cloud formation. Additional information on management systems for safe operations and maintenance of HF operations, including methods to identify surface contamination and leaks, is available.²⁰

EVALUATION AND TREATMENT

Immediate medical treatment is necessary for skin or significant inhalation exposure to hydrofluoric acid/hydrogen fluoride, with focus on irrigation with water followed by neutralization gels or solutions⁶ (see Chapters 19.5, 29.1, and 20.1). Brief treatment guidelines are given in Table 39.7.3.

Further assessment should include electrolyte levels (Ca, Mg, K), ECG if potential for cardiac arrhythmia is present, and chest x-rays for significant inhalation exposure or liquid contact with face/neck. HF can penetrate the fingernails without exhibiting external evidence, requiring advanced treatment through removal of the nails or calcium gluconate by IV. For further information on emergency treatment of HF burns, see Wilkes 2001.²¹

Workers chronically exposed to fluorides such as aluminum potroom workers who develop respiratory symptoms should undergo pulmonary evaluation for possible asthma, including spirometry and peak flow measurements (see Chapter 19.2). Evaluation and treatment are similar for other workers with non-sensitizing irritant induced asthma (see Chapter 19.2). Bony fluorosis should be considered in workers with prolonged higher exposures who develop musculoskeletal complaints (see Chapter 23.5). X-ray findings include sclerosis and exostoses. There is no specific treatment of fluorosis beyond removal from further exposure.

39.8 Lead

Jacqueline M Moline, Philip J Landrigan

Lead is an ancient metal. Because of its malleability and low melting point, humans have used lead since prehistoric times to make statues, jewelry, water pipes, and drinking vessels.¹ The salts of lead have long been valued for their brilliant colors. The quantity of lead used since 1940 surpasses the total used in all previous centuries. This heavy recent use reflects industrial applications as well as the use of lead as a fuel additive. In the mid-1970s, nearly 200,000 tons of lead were consumed annually in gasoline in the United States.² Virtually all of this lead was emitted into the environment from vehicles in a finely particulate form and caused widespread contamination of air, dust, soil, drinking water and food crops. In the United States and in many western European countries, the use of leaded gasoline has decreased sharply since 1976, and population mean blood lead levels have decreased by 90% as a result.³ Leaded gasoline continues, however, to be used widely in Eastern European and developing nations.⁴

OCCUPATIONAL LEAD EXPOSURE

A wide variety of industrial populations are at risk of occupational exposure to lead (Table 39.8.1). In the United States more than 3 million workers are estimated by NIOSH to be potentially exposed to lead in their work. Occupational exposure to lead is regulated in the United States by the OSHA lead standard, first promulgated in 1978. This standard sets limits on air-borne lead exposure as well as on permissible levels of lead in blood. It has been successful in reducing the most serious industrial exposures to lead. However, this standard is enforced inadequately and occupational exposure to lead remains widespread in the United States. Workers at highest risk are those in smaller industries such as secondary lead smelters and automobile radiator repair shops.

A major industrial group that previously had been exempted from the protection of the United States lead standard were construction workers. Major outbreaks of lead poisoning were observed among workers who cut lead-painted steel structures such as bridges with oxyacetylene torches and among renovation workers who remove lead paint from older homes. The heating and burning of lead paint by these workers can create a highly respirable fume consisting of air-borne lead particles less than 1 μm in diameter; inhalation of lead fumes can produce acute lead poisoning within days or even hours. In 1993, the OSHA lead standard was extended to cover the construction and demolition trades. A sharp decline in their exposures to lead and their blood lead levels resulted.^{5,6}

Occupational exposure to organic lead, principally tetraethyl lead (TEL), can occur in the manufacture of this compound for use as a fuel additive as well as in the cleaning of tanks and pipes that have contained TEL. Typically, in TEL manufacturing, exposures to organic and inorganic lead occur simultaneously.

Measurement of occupational exposure

Assessment of occupational exposure to inorganic lead requires measurement of lead levels in both air and blood. Air lead levels are measured by standard industrial hygiene techniques. The determination of lead in air provides direct information on sources and levels of exposure, information that is essential for controlling exposures to lead in the workplace. The OSHA standard (1993) for the permissible exposure level of lead in workplace air is 50 micrograms/ m^3 , expressed as an 8-hour time-weighted average.⁷ As is discussed below, this standard can no longer be considered adequately protective of workers' health, because lead toxicity has been observed in workers whose lead exposures do not exceed the current OSHA standard, and because fetal lead poisoning can occur in the offspring of female lead workers well below this level.⁸

Measurement of the blood lead level complements determination of lead levels in air. The finding of an elevated blood lead level identifies those workers who may have had uniquely high exposures that are not detected by air monitoring. For those workers in the United States covered by the OSHA lead standard, anyone found to have a blood lead level of 50 micrograms/dl or above must be removed from the high-exposure job (termed 'medical removal protection'). A worker is not allowed to return to a high-exposure job until the blood lead level has fallen to below 40 micrograms/dl. To prevent workers with elevated lead levels from being economically penalized during medical removal protection, the OSHA standard requires that these workers must continue to receive their full rate of pay (pay rate retention) while they are working in the less hazardous job.

ENVIRONMENTAL LEAD EXPOSURE

In the general population, children are the group most heavily exposed and most susceptible to the toxic effects of lead. The mean blood lead level of children in the United States is about 3 micrograms/dl.⁹ A decline of 90% in blood lead levels occurred among American children from 1976 to 1997 as a consequence of removal of lead from gasoline. In contrast, lead use in gasoline as well as in industry remains widespread in nations undergoing transition to industrialization; environmental contamination and blood lead levels of workers and residents of communities near polluting industries in these countries have been reported to be dangerously elevated.⁴

According to the Centers for Disease Control and Prevention (CDC), blood lead levels of 10 micrograms/dl and higher in children indicate excessive exposure.¹⁰ Blood lead levels of 10 mg/dl and above are associated with subclinical lead toxicity in children. More recently, consideration has been given to further decreasing the blood lead standard for children in light of recent data showing subclinical toxic-

ity at blood levels below 10 mg/dl.^{10a,10b} The CDC estimates that over 400,000 children in the United States have blood lead levels above 10mg/dl. The proportion of children with elevated blood lead levels is particularly high among minority inner-city populations, and among such children, the CDC estimates that as many as 35% of preschool children still have elevated blood lead levels.⁹

Lead-based paint is the major concentrated, high-dose source of lead for American children. Most cases of acute, symptomatic pediatric lead poisoning are caused by ingestion of dust derived from lead-based paint. Although new applications of interior lead-based paint are banned, an estimated 27.1 million housing units in the United States built before 1950 still contain lead-based paint. Since 1979, the maximum allowable concentration of lead in domestic paint has been regulated by the United States Consumer Product Agency at 0.06 parts per million.

Air, dust, soil, drinking water, cosmetics, dietary and herbal supplements, and soiled parental work clothing are additional potential sources of exposure to lead for children and for all members of the population. Children, because of their normal oral exploratory behavior, are at high risk of ingesting lead from dust and soil.^{11,12} In 2001 the US Environmental Protection Agency (EPA) developed standards for lead in dust and soil, which were now consistent with existing US Department of Housing and Urban Development guidance levels for home dust levels. This was critical, since Lanphear et al found that a strong relationship between interior dust level landing and children's blood lead levels exists below the levels in the prior guidelines of 100 micrograms/ft² for floors, 500 micrograms/ft² for interior window sills, and 800 micrograms/ft² for window troughs.¹³ The new dust standard is 40 micrograms/ft² for floors and 250 micrograms/ft² on window sills; soil levels must be below 400 parts per million (ppm) in play areas and 1200 ppm average for bare soil in the rest of the yard. Current lead in drinking water is due principally to the widespread use of lead solder to join pipe in water

service lines. Acidic drinking water can leach lead from solder and also from lead pipes.

An analysis of sources of lead poisoning in urban children found that in infants younger than 1 year of age the principal sources were household renovation with lead paint removal (40%), ingestion of lead paint chips (20%), preparation of infant formula with lead-contaminated drinking water (18%), exposure to lead-contaminated parental work clothing (2%), congenital poisoning (2%), and sources unknown (18%). By contrast, the same study found that sources of lead poisoning for older children (18 through 30 months) were home renovations (4%), paint chip ingestion (87%), and sources unknown (9%).¹⁴

Cases of lead poisoning through ingestion of contaminated herbal supplements or infant formula prepared in lead-contaminated vessels have been documented.¹⁵ The habit of sniffing leaded gasoline is an important source of lead poisoning for children in certain rural populations.¹⁶

Measurement of environmental exposure

Determination of lead levels in blood is the principal means of assessing the lead exposure of children. This assay should be conducted in a laboratory that has been licensed by the CDC or by comparable authorities and that participates satisfactorily in quality control and quality assurance programs. Hand-held portable blood lead instruments have been developed for use in the field. They complete the analysis in 2–3 minutes, appear highly reliable, and have been approved for use since 1997.⁹

Assessment of lead exposure in the general environment requires analysis by standard chemical and physical techniques. Lead levels in paint may be determined by portable, hand-held x-ray fluorescence (XRF) detectors. Determination of lead levels in air is undertaken under the requirements of the EPA's air lead standard; the community air lead standard in the United States is 1.5 micrograms/m³ of air, computed as a quarterly average. Lead in drinking water is most reliably determined in a first-draw morning sample, when water has had an opportunity to sit in contact overnight with any lead in pipes or in solder. The current EPA safe drinking water standard for lead in drinking water is 0.15 mg/l (15 parts per billion). Lead concentrations in dust and soil are determined by standard chemical techniques.

CLINICAL EFFECTS IN ADULTS

Acute inorganic lead toxicity

Intense occupational exposure to lead over a brief period of time can cause a syndrome of acute lead poisoning.¹⁷ Characteristics of this syndrome are abdominal colic, constipation, fatigue, hemolytic anemia, peripheral neuropathy, and in some cases, alteration of central nervous system function. A gingival lead line is occasionally seen. In profound cases, full-blown acute encephalopathy with coma, convulsions, and papilledema may occur; in milder cases,

only fatigue, headache or personality changes may be evident as manifestations of the neurologic toxicity of lead. Mild liver involvement, limited to modest elevations in serum glutamic-oxaloacetic transaminase (SGOT), and musculoskeletal pains and arthritic symptoms are common. Basophilic stippling may be seen in the red blood cells. Usually, these findings occur when the blood lead level is very high, 70 micrograms/dl or more.^{18,19}

Chronic inorganic lead toxicity

Chronic inorganic lead intoxication is an insidious illness that is highly prevalent among persons chronically overexposed to lead. Symptoms include arthralgias, myalgias, headache, weakness, depression, loss of libido, impotence, and vague gastrointestinal difficulties. The classic abdominal colic of acute lead poisoning is usually absent. Anemia may occur, accompanied in some cases by an increased reticulocyte count. Thyroid and adrenal function often are depressed. Hypertension may be present. Sperm counts can be depressed in men and fertility reduced in women. Measurement of renal function may reveal impairment of glomerular clearance; decreased tubular urate clearance resulting in hyperuricemia is common. Late effects of inorganic lead intoxication include chronic renal failure, gout, chronic encephalopathy, and hypertension.^{19,20}

The definition of chronic lead intoxication has, in recent years, been expanded by the recognition that lead can cause toxic injury at levels of exposure that only a decade ago were thought to be safe. The term *subclinical toxicity* denotes this concept that relatively low-dose exposure to lead may cause harmful effects to health in the absence of symptoms and signs that are evident on the standard clinical examination. The underlying premise is that there exists a spectrum of toxicity in which clinically apparent effects have their asymptomatic subclinical counterparts, which are detected through special testing.^{21,22}

The effects of lead on organ system function

Hematologic toxicity

Anemia is a classic clinical manifestation of acute lead toxicity (see also Chapter 21).¹⁷ The severity and prevalence of lead-induced anemia are correlated directly with the blood lead level in both adults and children.²³ It is important to note that the presence of anemia is not required for a diagnosis of lead poisoning; at lower levels of excessive lead exposure the hemoglobin concentration is most often within the normal range. Most patients with chronic and late-effects of lead poisoning also have normal blood hemoglobin levels.

Lead-induced anemia is the result of multiple mechanisms: impairment of heme biosynthesis, acceleration of red blood cell destruction, and an inhibition of erythropoietin production in the kidney.

Lead-induced inhibition of heme biosynthesis is due first to inhibition of the cytoplasmic enzyme, δ -aminole-

vulinic acid dehydratase (ALA-D). This effect is dose related. It is noted initially at blood lead levels of 10–20 micrograms/dl and is virtually complete at levels of 70–90 micrograms/dl. The mitochondrial enzyme ferrochelatase is the next most sensitive enzyme in the heme biosynthetic pathway inhibited by lead. Ferrochelatase catalyzes the transfer of iron from ferritin into protoporphyrin to form heme. Inhibition of ferrochelatase causes increased excretion of coproporphyrin in the urine and accumulation of protoporphyrin (a zinc-requiring enzyme, also called zinc protoporphyrin [ZPP]) in the erythrocytes.^{24,25}

Lead-induced acceleration of red blood cell destruction leading to hemolysis reflects toxicity to the red blood cell membranes and results probably from the inhibition of lead by the enzymes 5'-nucleotidase and ATPase. Erythropoietin, a glycoprotein hormone principally secreted by the proximal renal tubule, regulates red blood production. Chronic exposure to lead appears to inhibit secretion of erythropoietin, and may also act directly on erythrocyte progenitor cells in the bone marrow.²⁶

Neurologic toxicity

Neurologic toxicity of lead in adults In the peripheral nervous system, the myelin sheaths surrounding the motor axons are the principal target of lead (see also Chapter 28). Lead-induced pathologic changes in these fibers include segmental demyelination and axonal degeneration. Extensor muscle palsy with wrist drop or ankle drop has been recognized as the classic clinical manifestation of the peripheral motor neurologic toxicity of lead since the time of Hippocrates. Unlike other toxic neuropathies, this motor neuropathy may show left–right asymmetry. Mild to moderate sensory dysfunction also may be evident in lead neuropathy, and in such cases the clinical picture is one of mixed motor–sensory neuropathy, often with asymmetric features.

Recent studies of peripheral neurologic function in persons exposed to lead have used electrophysiologic probes to determine whether exposures insufficient to produce clinically evident signs and symptoms can cause covert abnormalities.²⁷ With the development of increasingly sensitive test methodologies, these studies have been able to detect peripheral neurologic toxicity at progressively lower blood lead levels. For example, Seppalainen et al, in a prospective study of new entrants to the lead industry, reported slowing of motor conduction velocity in the ulnar nerve at blood lead levels as low as 30–40 micrograms/dl.²⁸ In the central nervous system, high-dose acute exposure to lead causes encephalopathy characterized clinically by obtundation, coma, and convulsions. Among persons who recover from acute lead encephalopathy, a high proportion are left with significant neuropsychologic deficits, including reduced intelligence, shortened attention span, and instability of mood.²³

The question of whether lead causes asymptomatic impairment in central neurologic function in adults at doses insufficient to produce clinical encephalopathy has been the subject of extensive research. Early investigations of this issue have shown a correlation between lead exposure and diminished neuropsychologic performance in a

group of asymptomatic adult workers, all of whom had blood lead levels below 70 micrograms/dl.²⁹ The functions most severely impaired were those dependent on visual intelligence and visual-motor co-ordination. An increased prevalence of fatigue and short-term memory loss was observed in lead smelter workers that increased as blood lead levels rose. Other studies also found evidence of depressed mood and other central neurologic deficits in lead workers with blood lead levels in the range 40–70 micrograms/dl.²³ Stewart et al reported that past exposure to lead, assessed by elevated bone lead content, was associated with persistent decrements in neurobehavioral test results in a group of organolead workers.³⁰ Additional studies are required to confirm this finding, to elucidate toxic mechanisms, and to ascertain whether or not toxic effects occur at lower blood lead levels. A further implication of the finding that lead may cause insidious injury to the central nervous system is the possibility that some as yet unknown proportion of cases of presenile dementia, motorneuron disease (amyotrophic lateral sclerosis [ALS]),^{30a} and other chronic neurologic and psychiatric conditions in adults may be the result of chronic exposure to lead. Such exposure may result in an accelerated attrition of neurons that becomes clinically evident with age.³⁰ These possible associations are currently the focus of research efforts.

Pediatric neurologic toxicity of lead Lead is now recognized to cause subclinical neurologic toxicity in children at much lower levels of exposure than in adults (see also Chapter 28). The earliest suggestion of this toxicity came from studies by Byers and Lord in the 1940s of the survivors of acute lead poisoning. These early investigations demonstrated the presence of permanent neuropsychologic sequelae, including learning disabilities and shortening of attention span as well as highly aggressive behavior in children who had recovered from acute lead encephalopathy.³¹

The existence of subclinical lead neuropathy in asymptomatic children was then confirmed in a series of cross-sectional neuroepidemiologic studies undertaken by Needleman and colleagues in the mid-1970s.³² These landmark investigations found an association between asymptomatic increased exposure to lead and decreased intelligence. Children with elevated body lead burdens, corresponding to blood lead levels of 25–55 micrograms/dl, were found to have mean verbal IQ scores 4.5 points lower than similar children with lower lead burdens. This deficit remained evident when results were adjusted for parental education, childhood illness, socioeconomic status, and other biologic and social variables. Subsequent long-term follow-up studies have shown that these deficits in IQ are associated with learning difficulties, reading problems, an increased rate of failure to graduate from secondary school and an increase in violent behavior. Needleman has noted that a 4.5 point downward shift in mean IQ produces a 50% reduction in the number of gifted children (IQ above 120) in a population, and a 50% increase in the number of retarded children (IQ below 80).^{32,33}

The data from these cross-sectional studies have been further corroborated by data from a series of prospective epidemiologic studies of newborn children, followed from birth through the first several years of life. Each of these studies found that cord blood lead levels at birth as low as 15–20 micrograms/dl were associated with decrements in childhood intelligence.^{34–37} Lead poisoning has also been associated with decreased hearing. An inverse relationship between blood lead levels and height has also been noted. Most recently, an analysis of data from the US National Health and Nutrition Evaluation Survey (NHANES) suggests that a negative association between lead and neurobehavioral function is evident in children at blood lead levels as low as 5–10 micrograms/dl.³⁸

In recognition of the extreme sensitivity of the developing nervous system to low levels of lead, the CDC has periodically revised the definition of childhood lead poisoning. Currently, the CDC considers a blood lead level of 10 micrograms/dl or higher as evidence of excess lead burden.¹⁰ (The previous definition of lead toxicity, prior to 1992, was a blood lead level of 25 micrograms/dl or above.) Children with blood lead levels of 10 micrograms/dl or above must be provided medical follow-up and environmental monitoring, as is described in the section on clinical management. The therapeutic goal is to identify and reduce the child's environmental exposures to lead, so as to reduce the threat of subclinical neurotoxicity and to prevent re-exposure. In the near future, CDC may further reduce the blood lead standard for children.^{10a,10b}

Renal toxicity

The cells lining the proximal tubules of the nephron appear to be the tissue in the kidney that is most highly sensitive to lead (see also Chapter 25).²⁰ In children with acute, high-dose lead poisoning, injury to these cells occasionally results in the development of acute Fanconi syndrome, in which glucose, amino acids, and phosphates are spilled in the urine in large quantities. This syndrome typically is reversible, and it is not known whether or not it predisposes the individual to long-term sequelae. Fanconi syndrome is not commonly seen in adults exposed to lead.

At blood lead levels below 25 micrograms/dl, lead inhibits the metabolic activation (hydroxylation) of vitamin D, a transformation that takes place in the cells lining the proximal tubules.³⁹ Also in these cells, at blood lead levels of 40–80 micrograms/dl, lead induces the formation of dense intranuclear inclusion bodies consisting of a lead protein complex.²⁰ These inclusion bodies persist for approximately 1 year. Hyperuremic gout, apparently resulting from increased reabsorption of uric acid by the tubular cells, is a third metabolic consequence of lead-induced renal impairment.

Chronic nephropathy, which may progress to kidney failure, is the classic late manifestation of chronic lead toxicity in the kidneys. It appears to result from long-term, relatively high-dose exposure to lead, but dose-response relationships have not been well defined. Individuals with chronic low-level lead exposure have abnormal urinary excretion of

n-acetyl glucosaminidase (NAG) compared to controls, suggesting renal tubular dysfunction may occur after chronic low-level lead exposure. Population-based studies, such as the Normative Aging Study, also demonstrated a deleterious effect of lead in kidney function when body burdens of lead were assessed.^{40–42}

The evolution of lead nephropathy usually is silent. The central event appears to be the progressive destruction of tubular cells and their replacement by fibrosis. Clinically obvious manifestations of impairment, such as elevations in BUN and serum creatinine, do not ordinarily become evident until 50–70% of the nephrons have been destroyed. Pathologically, chronic lead nephropathy is characterized by interstitial fibrosis with atrophy and dilation of the tubules and relative sparing of the glomeruli; intranuclear inclusions are infrequent, and the kidneys are small and shrunken. The pathologic picture may be indistinguishable from changes of chronic hypertension, which usually coexists (see later).²⁰

Excess mortality from renal disease has been observed in several epidemiologic studies of lead workers. In each of these investigations, a two- to threefold increase has been noted in deaths from chronic nephritis, and in one of the investigations a positive association was observed between duration of employment in a lead smelter and mortality from chronic nephritis.^{43,44}

Lead and hypertension

Hypertension has long been associated with lead toxicity, in both animal and epidemiologic studies. Early in the last century, long-term, high-dose exposure to lead was reported to be associated with an increased incidence of hypertension and cerebrovascular disease.¹⁷ With the reduction in lead exposure that has occurred in most industries, these overt associations are now noted less commonly. Also, these exposures may have occurred many years prior to the development of hypertension, making this causal association less obvious.

However, population studies have investigated the effect of blood lead, even relatively low blood lead levels, on hypertension. An analysis of the NHANES II survey data revealed that lead was a significant contributor to hypertension in the US population.⁴⁵ Hypertension has also been associated with elevated bone lead levels.^{45a} In addition, Schwartz et al found left ventricular hypertrophy was correlated with blood lead levels, demonstrating that lead was not merely raising blood pressure but also contributing to end-organ damage.⁴⁶ An analysis of the data from the Normative Aging Study also found an association between body burdens of lead and hypertension.⁴¹

Different mechanisms for lead-induced hypertension and renal failure have been proposed, including an increased responsiveness to α -2 adrenoreceptor stimulation after lead ingestion, and alterations in cAMP-dependent availability of calcium for contractile processes in vascular and cardiac myocytes. Other potential mechanisms of action include increases in endothelin-3 concentration, decreases in endothelium-derived relaxing factor, and alterations in renin activity.^{47,48}

From the perspective of disease prevention, it is most important to prevent hypertension in lead workers. Elevations in blood pressure, even at low levels, are associated with significantly increased rates of mortality from heart disease and stroke. A biomedical surveillance program of workers exposed to lead, therefore, should incorporate as a specific aim the prevention of elevated blood pressure. Periodic determination of blood pressure should be a routine component of the biomedical monitoring of workers exposed to lead.

Reproductive toxicity of lead

Male lead workers, especially those newly exposed to lead, can have evidence of decreased fertility (see also Chapter 27.2). Decreased sperm counts, abnormal sperm morphology, and decreased sperm motility have been noted in several studies when lead levels were above 40 micrograms/dl.^{18,49} Animal studies indicate that blood lead concentrations greater than 30–40 micrograms/dl are associated with impairment of spermatogenesis and reduced concentrations of androgens. Changes in endocrine profiles have been noted in men with lead levels over 60 micrograms/dl. Men currently employed in lead trades may have reduced fertility, as measured by increased time to conception in their wives.⁵⁰ The effects of lead on male reproductive function at lower levels are more uncertain.

In women, lead at high doses can also be toxic to reproductive function (see also Chapter 27.2). Clinical reports, most of them from the first half of the 20th century, describe an increased incidence in spontaneous abortion among female lead workers as well as in the wives of male lead workers.⁵¹ Low-level maternal lead exposure may increase the risk of spontaneous abortion.⁵²

A difficult problem in the prevention and clinical management of the reproductive toxicity of lead is the finding that lead may cause neurologic damage to the fetus at blood levels as low as 5–10 micrograms/dl, substantially below the current OSHA standard for blood levels of lead in workers. Lead passes virtually unimpeded across the placental barrier, and the neurologic impairment that it produces in the fetus appears to be irreversible.^{34,35} This problem is further compounded by the fact that under the metabolic stress of pregnancy, lead may be mobilized from bony stores of the mother to enter her blood and thus the blood of the fetus.^{52a} Thus, if a woman who has previously had chronic lead exposure or who has suffered lead poisoning becomes pregnant, there may be mobilization of skeletal lead with resultant fetal exposure.

It is not known whether or not exposure of the father to lead before conception results in fetal injury.

The prevention of fetal lead encephalopathy requires that blood lead levels of prospective mothers be kept below 10 micrograms/dl, not only during pregnancy but also in the years preceding conception.²¹ If this principle is followed, exposure of the fetus to currently absorbed lead, as well as to lead released from previously accumulated bony stores, should be prevented. If a woman who has previously had elevated blood lead levels wishes to become pregnant, it may be reasonable to recommend either an x-

ray fluorescence examination of bone to determine the body burden of lead or to perform a chelation mobilization challenge test prior to conception (see below). If extensive bony lead stores are demonstrated by either of these tests, delay in conception may be indicated. In women with a history of exposure to lead, blood lead levels should be monitored frequently throughout pregnancy.

Carcinogenicity

Lead has been found to produce renal cancers in experimental studies in mice, rats, and hamsters. Positive dose-response relationships were observed between lead dose and tumor incidence. Also, brain tumors have been noted in rats exposed to lead.⁴ Lead is currently considered by the International Agency for Research on Cancer (IARC) to be a probable human carcinogen (group 2A) based on 'Sufficient' animal data and 'limited' human data.⁵³

Experimentally, lead exposure inhibits DNA repair and appears to interact with zinc binding sites on human protamine, an important DNA-associated protein, and lead may also cause changes in the conformational structure of P53, a tumor suppressor gene. These findings suggest that rather than altering DNA directly, lead may increase the carcinogenicity of other mutagens.

Epidemiologic studies of lead workers have shown excess kidney cancer in 5 of 6 published cohort mortality studies. Also 4 of these 6 studies have shown excess numbers of tumors of the brain and central nervous system.^{54,55}

Most of the epidemiologic studies on the carcinogenicity of lead do not present adequate data in dose-response relationships. At present, there have been insufficient reported cases in humans to enable a definite conclusion to be reached as to whether or not lead causes human cancer.

Organic lead

One organic compound of lead, TEL, was widely used in the United States as an antiknock agent in gasoline and is still used extensively in developing nations. While overall exposure to TEL has declined significantly, individuals who work as producers, blenders, and persons who clean and maintain tanks are at risk of poisoning by TEL. It is a volatile liquid which, unlike inorganic lead, is absorbed readily through the skin.

Exposure to TEL produces a syndrome that is different from inorganic lead poisoning. TEL poisoning is limited largely to acute or subacute central nervous system signs and symptoms. Early symptoms of insomnia and anorexia are followed by muscle irritability. Agitated encephalopathy resembling delirium tremens occurs in cases of severe poisoning. Increased deep tendon reflexes and cerebellar signs (tremors and ataxia) are characteristic in severe cases.⁵⁶

CLINICAL EVALUATION

Clinical evaluation strategy for adults

The diagnosis of inorganic lead intoxication in adults requires (1) demonstration of excess lead absorption, (2)

Rights were not granted to include this figure in electronic media.
Please refer to the printed publication.

Figure 39.8.1: The three-compartment model for distribution of lead in the body. Estimates of half-life are given for each compartment. In the steady state almost all lead is stored in bone, so only very small amounts are excretable by other compartments. (From: Rabinowitz MB, Wetherill GW, Kobbie JD. Kinetic analysis of lead metabolism in healthy humans. *J Clin Invest* 1977; 58:260-70.)

documentation of impairment in an organ system consistent with the effects of lead, and (3) exclusion of other causes of impairment. An assessment of increased lead absorption requires an understanding of the distribution and kinetics of lead. Lead is not distributed homogeneously in the human body. Instead, it is dispersed among several physiologically distinct compartments that differ from one another in their size and in the bioavailability of their lead (Fig. 39.8.1).⁵⁷

Lead in blood comprises approximately 1% of the body lead burden; most of the lead in blood is red cell bound. The half-life of lead in blood is about 36 days. Elevation of the level of lead in blood provides the single best indicator of recent, acutely increased lead absorption. Thus, the blood lead level provides good information on lead absorption in persons with relatively brief exposure, such as construction workers or new entrants to the lead industry. The blood lead level rises rapidly within hours after an acute exposure episode and remains elevated for several weeks.

Normal adult blood lead levels in the United States are below 10 micrograms/dl. Clinical symptoms generally appear at blood lead levels of 30-40 micrograms/dl and become more frequent and severe as levels rise further.²³ Under the OSHA lead standard, as was noted earlier, workers with blood lead levels above 50 micrograms/dl must be immediately removed from lead exposure, and they cannot return to work with lead until their levels have fallen below 40 micrograms/dl.

Ninety to ninety-nine percent of absorbed lead is contained within the calcified tissue of skeleton and teeth in adults. In children, the portion is approximately 70%. There is evidence that the half-life of lead in bone is different for cortical and trabecular bone sites, but both half-lives are in the range of 15-25 years.⁵⁷

In persons with long-term exposure to lead and substantially elevated bony lead stores, the blood level correlates poorly with current exposure. Under these conditions, the blood lead level appears principally to reflect release of stored lead from deep tissue compartments, principally the skeleton, and the influence on the blood lead level on release of lead from those compartments is proportional to

the amount of stored lead. For this reason, the blood lead level is of only limited value in assessing dose–response relationships for the long-term consequences of lead exposure such as renal disease, hypertension, and chronic neurologic impairment. Also, the storage and later release of large amounts of lead in bone account for the long persistence of elevated blood lead levels in older retired lead workers who have ceased exposure to lead.

K-shell x-ray fluorescence (XRF) analysis is now a well-established technique for accurate, non-invasive and relatively rapid assessment of chronic lead exposure. It directly measures levels of lead in bone.^{58,59} The radiation dose delivered is de minimus (approximately 1/500th of the average dental x-ray effective dose for a tibia lead measurement of an adult, and approximately 1/20th for a 1-year old).⁵⁸

Zinc protoporphyrin (ZPP) or free erythrocyte protoporphyrin (FEP) levels reflect the toxic effect of lead on the erythrocytic enzyme ferrochelatase. FEP levels begin to rise in adults when blood lead levels exceed 30–40 micrograms/dl. Once elevated, FEP levels tend to stay above background for several months, which is substantially longer than acutely elevated blood lead levels.

A combination of normal FEP value and high blood lead level indicates very recent exposure that has not yet had opportunity to poison heme metabolism. The long persistence of elevations in ZPP creates a problem in the use of this test as a screening tool for lead exposure in occupationally exposed adults. Because the ZPP level remains elevated long after the blood lead level has fallen, this test does not discriminate between recent and past exposure. Therefore, it is of only ancillary value in evaluating occupational lead exposure.

In the past, the gold standard for determination of total body lead burden was the measurement of urinary lead excretion after intramuscular injection of 1 g of calcium EDTA (given mixed with lidocaine). Several studies have now shown that chelatable lead in general, and EDTA-chelatable lead in particular, bear little relation to bone lead stores.^{30,60} Bone lead measurements using the x-ray fluorescence technique^{60a} have therefore become the de facto standard for assessing body lead burden, because they sample the overwhelmingly largest pool of lead in the body. Chelatable lead remains the clinical gold standard but may be better viewed as an indicator of soft tissue bioavailable lead burden.

No other standard clinical test or laboratory finding is either very sensitive or specific for lead poisoning. Clinically evident anemia occurs only in relatively far-advanced cases of lead poisoning; thus, the diagnosis of lead poisoning cannot await the appearance of anemia. Basophilic stippling in the red blood cells is seen in most patients with acute hemolysis and occasionally in patients with chronic hemolytic syndromes; it is not specific to lead poisoning. Lead lines on the gums are uncommon except in cases of severe poisoning and may be difficult to recognize in patients with poor dental hygiene.

Complete blood counts and routine blood chemistry determinations should be performed as baseline measure-

ments in asymptomatic workers exposed to lead. Other baseline tests that may be of value include creatinine clearance, BUN, and uric acid. Blood pressure should be measured regularly. Blood lead levels should be obtained on a periodic basis in lead workers. If the whole blood lead level exceeds 40 micrograms/dl, these tests should be repeated monthly; blood lead levels over 50 micrograms/dl require immediate removal of workers from lead-exposure, and they may not return to work in a lead-exposed job until there have been two lead-levels below 40 micrograms/dl.

Measurement of the urine lead level is of little value in monitoring populations exposed to inorganic lead; the test is too highly variable to be reliable. Similarly, hair lead analysis is not considered reliable for monitoring purposes.⁶¹

Clinical evaluation strategy for children

Preschool children in the United States should be screened routinely for lead poisoning according to guidelines developed by the CDC and the American Academy of Pediatrics.^{62,63} These guidelines replace universal screening for all children, and target screening to geographic areas with older housing stock, and to communities where a substantial proportion of 1 and 2 years olds have elevated blood lead levels. Determination of the blood lead level is the principal technique for assessing increased lead absorption in children. Recent evidence suggests this can be accomplished safely and accurately using a capillary tube sample obtained by needlestick. In some areas, an alternative is measurement on a filter paper. Elevated levels must be confirmed on a venous sample and tested in an accredited laboratory.

Guidelines for the interpretation of blood lead levels in children were developed by the CDC. Because recent data suggest that adverse health effects may occur in children at blood lead levels as low as 5–10 micrograms/dl, the CDC guideline of 10 micrograms/dl may need to be revised.^{10a,10b} Currently, the CDC guidelines define a level above 10 micrograms/dl as excessive.¹⁰

A multi-tier approach for the evaluation of childhood blood lead levels has been developed by CDC and is reproduced in Table 39.8.2; this table also indicates the follow-up activities appropriate for each level of exposure.¹⁰

Provocative or challenge chelation with EDTA can be used to determine whether a child with an initial blood lead level of 25–44 micrograms/dl will respond to chelation therapy with a brisk lead diuresis. A dose of 500 mg EDTA/m² is administered intravenously over 1 hour. Urine is then collected for 8 hours, and the test is considered positive if the ratio of lead excreted (in micrograms) to the amount of EDTA infused (in milligrams) is greater than 0.6.⁶⁴ This test is recommended for use only in centers where large numbers of lead-exposed children are routinely evaluated. Children whose blood lead levels are 45 micrograms/dl and above should not receive a provocative chelation test; instead, they should be referred immediately to a pediatric center for appropriate chelation therapy. The use of XRF to assess bone lead stores is beginning to replace challenge chelation as a tool for assessing body lead burden in children.²²

BLL* ($\mu\text{g}/\text{dl}$)	Action
<10	Reassess or rescreen in 1 year. No additional action necessary unless exposure sources change.
10–14	Obtain confirmatory blood lead levels, provide family lead education. Provide follow-up testing, within 3 months Refer for social services, if necessary.
15–19	Provide family lead education. Provide follow-up testing, with confirmatory blood lead level within 1 week. Refer to social services, if necessary. If BLLs persist (i.e., 2 venous BLLs in this range at least 3 months apart) or worsen, proceed according to actions for BLLs 20–44.
20–44	Provide co-ordination of care (case management). Confirm blood lead level within 1 week. Provide clinical management. Provide environmental investigation. Provide lead hazard control.
45–69	Within 48 hours, begin co-ordination of care (case management), including chelation with clinicians experienced in lead toxicity therapy. Environmental investigation, and lead hazard control.
70 or higher	Hospitalize child and begin medical treatment immediately. Begin co-ordination of care (case management), environmental investigation, and lead hazard control immediately.

* A diagnostic BLL is the first venous BLL obtained within 6 months of an elevated screening BLL.

Table 39.8.2 Interpretation of blood lead test results and follow-up activities: class of child based on blood lead concentration

Clinical evaluation strategy: organic lead

Organic lead (TEL) intoxication is difficult to diagnose without a history of exposure. Blood or urine lead levels and FEP levels are not predictably elevated in TEL poisoning; increased values are useful, but normal or borderline values may be seen in mild poisoning. Cerebrospinal fluid examination usually is normal.

MANAGEMENT

Management of lead poisoning in adults: acute intoxication

In all cases, the most important first step is the immediate removal from exposure to lead. Decisions to chelate should be based on several factors, including the blood lead level, current symptoms, and signs of lead-associated toxicity and duration of exposure. Chelation should be considered for blood levels greater than 80 micrograms/dl, especially when there are central or peripheral nervous system effects. For blood lead levels of 60–80 micrograms/dl, decisions regarding chelation should be made on a case-by-case basis, depending on clinical signs and symptoms. For individuals with blood lead levels less than 60 micrograms/dl, chelation is usually not required unless they have significant symptoms or unusual circumstances (such as a desire to conceive in a short time frame).

There are multiple chelating agents available. The best established agent is intravenous calcium EDTA. This treatment requires hospitalization, and should be supervised by an experienced physician. The usual dose is 1 g of calcium EDTA (in 250 ml of 5% dextrose in water) infused slowly over 1–2 hours once or twice a day for 5 successive days. The patient should also receive intravenous hydration during the chelation. Daily determinations of kidney function, potassium levels and a urinalysis should be obtained; treatment should be discontinued if there is evidence of renal dysfunction or hematuria. Blood lead levels should be determined before treatment and after treatment ceases. It is common for a ‘rebound’ in blood lead levels to occur after chelation, and treatment of this rebound may require subsequent courses of chelation.

Oral chelation with DMSA (2,3 dimercaptosuccinic acid) has become widely used in adults as an alternative to intravenous EDTA, although the FDA approved DMSA only for children with lead levels over 45 micrograms/dl.^{64,65} In adults, chelation with DMSA has been well tolerated and results in drops in blood lead levels similar to EDTA therapy. Dosages have varied, but treatment regimens of 10 mg/kg in three divided doses for 5 days have been used with success.^{65a} Individuals with higher lead levels may require longer treatment; dosages of 10 mg/kg three times a day for 5 days followed by 10 mg/kg twice a day for 14 days (a total of 19 days) can be used. Hepatic and kidney function should be checked along with platelet counts. As with chelation with EDTA, a rebound in blood lead levels may occur, necessitating subsequent course of chelation. Oral chelation should never be used prophylactically during ongoing lead exposure as it enhances systemic absorption of lead.

Management of chronic lead intoxication

Patients with chronic manifestations of lead toxicity and high body burdens have been treated similarly to those with acute exposure, although the efficacy of treatment in such patients has not been proved. Studies are needed to confirm whether chelation therapy of adults with chronic lead intoxication results in amelioration of long-term effects such as gout, hypertension or renal insufficiency, as has been suggested.⁴² The administration of chelating agents to persons with chronic lead intoxication must be approached with great care, because they often have impairment of renal function.

Chronic administration of oral chelation agents to workers who continue to be exposed to unacceptably high levels of lead in their work has been used by some unscrupulous employers as a means of reducing blood lead levels while not reducing levels of lead in air in the workplace. The practice is unethical and represents medical malpractice.²³ Moreover, the chronic administration of chelating agents may itself cause renal impairment or aggravate lead nephropathy, particularly in persons with continuing lead exposure.

Management of organic lead poisoning

The treatment for TEL poisoning is primarily support; chelation with calcium EDTA has been tried with variable efficacy. Sedation and careful observation are required in severe cases, often for prolonged periods.

Management of pediatric lead poisoning

Lead poisoning in children should be managed according to the detailed guidelines issued in 1991 by the CDC.¹⁰ This approach is summarized in Table 39.8.2. Heavy emphasis is placed at every level on screening children and preventing further exposure.

All children with blood lead levels of 45 micrograms/dl and above require therapeutic chelation plus immediate removal from all sources of exposure to lead. Symptomatic lead poisoning in a child constitutes a medical emergency, and the child should be hospitalized immediately in a pediatric referral center.

DMSA, a chelating agent licensed by the Food and Drug Administration in 1991, has become the therapeutic agent most widely used for the treatment of childhood lead poisoning. It is available in 100-mg capsules. The recommended initial daily dose is 10 mg/kg or 350 mg/m² every 8 hours for 5 days, followed by 10 mg/kg or 350 mg/m² every 12 hours for 14 days.⁶⁵ A course of treatment, therefore, lasts 19 days. If additional courses of treatment are needed, a minimum of 2 weeks of rest between courses is recommended, unless blood lead levels indicate the need for immediate retreatment. In extreme cases of lead poisoning, intravenous CaNa₂EDTA is recommended.

When EDTA is used alone, it may aggravate symptoms in patients with very high blood levels. Therefore, EDTA always should be used in conjunction with BAL when the blood lead level is greater than 70 micrograms/dl or when overt symptoms of clinical lead poisoning are present in children. In such cases, the first dose of BAL always should precede the first dose of EDTA by at least 4 hours. (BAL is not used in adults.)

Doses of BAL are administered by deep intramuscular injection. The initial dose is 75 mg/m² of body surface area. The total daily dose of BAL is 450 mg/m²/day in divided doses of 75 mg/m² every 4 hours. Once the initial dose of BAL is given and an adequate urine flow is established, EDTA is given in a dose of 1500 mg/m²/day. EDTA is given as a continuous intravenous infusion in dextrose and water or in a 0.9% saline solution.

It is important to use only CaNa₂EDTA in treating children with lead poisoning. Na₂EDTA (disodium edetate) should never be used for treating children with lead poisoning because it can induce tetany and possibly fatal hypocalcemia.

Clinical management of asymptomatic lead-poisoned children with blood lead levels high enough to require chelation is similar to the management of symptomatic children. If the blood lead level is between 45 and 69 micrograms/dl, chelation treatment should be limited to DMSA only. If the level is 70 micrograms/dl or above, EDTA and BAL should be used, as described above. Patients

who have received therapeutic courses of EDTA, with or without BAL, may use DMSA for subsequent treatment after an interval of 4 weeks.

Because lead can cause neurologic impairment at levels below 45 micrograms/dl, children with elevated lead levels between 22–44 micrograms/dl have been chelated in the past.⁶⁶ However, a recent multicenter study of chelation in children with lead levels in this range found no long-term improvement in cognitive function after chelation, and thus found no evidence to support the use of DMSA at levels below 45 micrograms/dl.⁶⁷

It is most important that blood lead levels be rechecked frequently after treatment in all children who have been chelated. There is danger (1) of rebound blood lead levels subsequent to mobilization of lead from bony lead stores and (2) of re-exposure of a child to an unabated environmental source. Both of these possibilities should be strictly guarded against.

PREVENTION

Prevention of occupational lead poisoning

Air-borne exposure to both organic and inorganic lead in the workplace must be strictly limited by enclosure of hazardous processes, ventilation, and other engineering controls. At the present time, the OSHA lead standard mandates that occupational exposures to lead be held below 50 micrograms/m³ of air, expressed as an 8-hour, time-weighted average. However, studies have shown clearly that toxic adverse effects can occur in lead workers at levels of exposure below this standard. An additional component of the current occupational lead standard is the existence of a biologic exposure limit regulating the permissible amount of lead in the blood. Recent research has demonstrated that clinical or subclinical toxic effects can occur at and below the current biologic exposure limit of 50 micrograms/dl of whole blood. A physician may remove a worker with a lower blood level if lead poisoning is diagnosed and restrict the worker from return to exposure until approved by the physician.

If the lead standard is reduced in the future, increasing reliance will need to be placed on the use of respirators in the workplace. In the hierarchy of industrial controls, process enclosure and ventilation take precedence over the use of respirators. However, respirators must be used when engineering approaches are not adequate to fully protect workers.

Prevention of childhood lead poisoning

The key to preventing childhood lead poisoning is prevention of exposure to lead.^{62,68} The most urgent need in preventing children's environmental exposure to lead is to reduce exposure to lead-based paint. Whenever a child is found to have an elevated blood lead level, a vigorous search should be instituted for sources of all lead-based

paint, as well as for other lead sources in the child's home and in other locations where the child may spend any significant part of the day. The child should not be allowed to return to a contaminated home or other contaminated environment until removal of lead-based paint has been completed. Moreover, no child and no pregnant woman should be allowed to be present in a home while abatement is occurring because of the high risk of their sustaining heavy lead exposure during abatement. In addition, special care must be taken for children undergoing chelation treatment, since they are at risk for further lead absorption if exposed to lead during treatment.

Control of lead in drinking water is most easily achieved by running the water for 3–5 minutes in the morning to flush the line before obtaining water for morning drinks or infant formula. System-wide alkalization of drinking water systems will be required to prevent leaching of lead from pipes by acidic water.

Lead from interior house dust is best removed by first removing the lead-based paint that is the usual source of lead in dust. The contaminated dust is then removed by wet mopping.

Lead in soil is most effectively managed in most areas by leaving it in place and covering it with fresh topsoil and vegetation. In some cases, however, when contamination is intense and prospects for establishing plant cover are low, removal of topsoil may be required, followed by replacement with clean fill.

Prevention of lead poisoning in the community requires frequent screening of children for lead and community-wide surveys to identify lead hazards. Also, outreach and educational programs are necessary.

Screening of children for lead poisoning requires obtaining a brief history to ascertain a child's exposure to lead followed by measurement of blood lead level.

In 1991, the CDC recommended that all preschool children in the United States be screened for lead.¹⁰ Subsequently, the CDC issued guidelines for state and local health authorities to enable them to decide on an appropriate lead screening policy, based on the housing stock and the prevalence of elevated lead levels in the community.⁶³ For communities with 27% or more of the housing stock built before 1950, or more than 12% of all 1–2 year olds with elevated lead levels, universal screening is recommended. For communities without a defined program for lead screening, universal screening is also advised. Priority groups for screening have been established, as shown in Table 39.8.3. Children in high-priority groups should be screened more frequently.

CONCLUSION

Ultimate control of lead poisoning in both adults and children will be achieved by eliminating all unnecessary uses of lead and by replacing lead with safer substitute materials whenever possible. It may be anticipated in the years ahead that the use of lead as an industrial material will diminish in developed countries; use in developing countries seems likely to continue for the foreseeable future.

- Children living in or regularly visiting a house or childcare facility built before 1950
- Children living in poverty
- Children with siblings or playmates who have or had lead poisoning
- Children of parents with occupational or environmental lead exposure
- Children with developmental delays whose oral behaviors put them at risk
- Immigrant children, including adoptees
- Children who may be exposed to lead-containing folk remedies

Table 39.8.3 Priority groups for screening of young children

39.9 Mercury

Alfred Franzblau, Mary Carol Fromes

EXPOSURE

According to NIOSH, over 150,000 people in the United States have potential occupational exposure to mercury or its compounds, including elemental mercury, inorganic mercury salts, and organic mercurials.¹ The largest fraction of this group is employed in jobs that entail low-level chronic or intermittent exposure to elemental mercury, such as chemical and science technicians, nurses and dental technicians, and machine operators. Those workplaces that have greatest potential for clinically significant mercury exposure are more directly involved with industrial production and use of elemental mercury, such as chloralkali plants, cinnabar mining and processing, and manufacture and use of instrumentation containing elemental mercury.

The absorption and toxicity of mercury are largely a function of the form of mercury and route of exposure. The term 'organic mercury' may be confusing in this context, since it includes short-chain alkyl compounds and also long-chain alkyl and non-alkyl organic compounds (e.g., phenyl mercury). The latter tend to be rapidly metabolized *in vivo*, with splitting of mercury from the organic moiety, and thus have toxic profiles similar to elemental mercury or the inorganic salts. In short-chain alkyl mercury compounds (e.g., methyl mercury salts and dimethyl mercury), mercury remains covalently bound to carbon for a prolonged period *in vivo*, which in part explains the different pharmacokinetics and toxic profile of the short-chain alkyl mercury compounds.²

Elemental mercury is a liquid at room temperature with a substantial vapor pressure. Most occupational mercury exposure results from inhalation of elemental mercury vapor; pulmonary retention is more than 80%. Dermal absorption/exposure can also be significant, particularly for organic mercury compounds. Ingestion of mercury compounds is not a major route of exposure in the work setting, in part because gastrointestinal absorption of elemental mercury is poor (approximately 0.10%).

Gastrointestinal absorption is the major route of mercury exposure among the general population, and is implicated in a number of tragic toxic episodes (e.g., Minimata, Japan (see Chapter 53)). The distinguishing feature is that mercury species associated with exposure in the general population are primarily short-chain alkyl mercury compounds (organic mercury or methyl mercury) derived from food, particularly large fish such as tuna and swordfish. Inorganic mercury discharged from industrial sources is metabolized to short-chain alkyl compounds by microorganisms, which are consumed by higher organisms. The alkyl mercury compounds have a prolonged half-time in animal tissues, and become concentrated in the food chain. More than 95% of ingested alkyl mercury is absorbed in humans. The average daily absorbed dose of mercury among persons without occupational exposure is estimated to be 10–20 micrograms, largely from mercury in the food chain.¹

Some forms of mercury exposure which were previously important are now only of historical significance. Mercury and mercury compounds were used widely as medicinal agents. In the Middle Ages mercurial compounds were employed in treatment of syphilitic sores; until just after World War II, mercury compounds were an important constituent of teething powders given to infants; and mercurial diuretics were the mainstay of diuretic therapy until displaced by furosemide and ethacrynic acid in the 1960s.³ The classic description of 'mad hatters' resulted from exposure to mercuric nitrate used as a carotting agent in preparation of animal skins for production of hats. Mercury compounds employed in the production of hats were replaced with less toxic agents during the late 19th and early 20th centuries. Certain organic mercury compounds once were used widely as fungicidal agents in paints (e.g., phenylmercuric acetate and phenylmercuric propionate). This use stopped in the United States in the early 1990s.¹

Mercury exposure related to dental amalgam deserves special mention. Such exposure must be divided into two distinct categories: mercury exposure of dentists and dental technicians (a form of occupational exposure mentioned previously), and exposure of patients who have tooth fillings consisting of mercury amalgam. Dental amalgam, which has been in use for approximately 150 years, typically consists of (by weight) 50% mercury, 35% silver, 9% tin, 6% copper, and a trace amount of zinc.¹ A single filling (involving the multi-surface grinding portion of a molar) contains between 750 and 1000 milligrams of elemental mercury. Millions of mercury amalgam tooth fillings are put in place each year in the United States.

Occupational exposure of dental personnel to mercury has been well documented. In surveys conducted between 1975 and 1983, average urinary mercury among dentists in the United States was 14.2 micrograms per liter, well above the mean of the general population.⁴ Following an educational campaign on mercury hygiene sponsored by the American Dental Association, similar surveys in 1985 and 1986 documented that mean mercury levels in urine among dentists had dropped to 5.8 and 6.7 micrograms per liter, respectively.⁵ In 1995, the mean level had fallen to 4.94 micrograms per liter.⁶

Characterization of mercury exposure to patients with amalgam tooth fillings has been somewhat confused. In the early 1970s, technologic advances made it possible to measure mercury in intraoral air, leading to a flurry of publications that applied this technique. It was documented that in patients with amalgam tooth fillings, various routine activities (e.g., tooth brushing, chewing gum, and professional manipulations such as cleaning or polishing) resulted in marked transient elevations of intraoral mercury concentrations. Unfortunately, many of the assumptions and modeling procedures employed initially to estimate an overall absorbed dose of mercury related to amalgam fillings were flawed. More recent measurements

and analyses have shown that among subjects with multiple amalgam tooth surfaces (13–48 surfaces), the average daily absorbed dose of mercury is 1.7 micrograms (range: 0.4–4.4 micrograms), which is small in comparison to the usual daily dose of non-occupationally exposed persons (10–20 micrograms per day).⁷ The influence of such 'internal exposure' on urinary mercury concentration (a more universal standard of inorganic mercury exposure) was correlated with the number of amalgam tooth surfaces, but was small⁸ when compared with the major source of environmental mercury, dietary intake.

CLINICAL EFFECTS

Acute

Acute high-level exposure to elemental mercury vapor primarily affects the respiratory system. Clinical effects include metal fume fever, bronchial irritation, and acute chemical pneumonitis. Within hours of exposure (which need last only a few minutes), subjects begin to experience dyspnea, chest pains, cough, chills, weakness, and possibly hemoptysis. These can be accompanied by lightheadedness, nausea, and vomiting. Tachypnea and rales may be noted, and laboratory studies can demonstrate leukocytosis, hypoxemia, diffuse infiltrates on chest radiographs, and impaired diffusion capacity. Respiratory failure and death can occur. Gingivitis and mercurial stomatitis can develop in the weeks following recovery from the acute event. Patients may have residual restrictive impairment of pulmonary function and reduced diffusing capacity.⁹

Some mercury compounds are direct cutaneous irritants. However, it is likely that the frequency of true hypersensitivity to mercury compounds has been overestimated in the past due to use of mercuric chloride (HgCl_2) as a patch test reagent at concentrations which were frankly corrosive. Elemental mercury is only rarely a cause of allergic contact dermatitis. Documented cases of allergic dermatitis usually result from sustained exposure to organic mercurial compounds. Fewer than 50 cases of mercury hypersensitivity (e.g., stomatitis and/or dermatitis) related to dental amalgam are reported in the literature published in the 20th century. It adds some perspective to recall that dental amalgam contains other metals which are potential sensitizers (e.g., copper), and that other metals commonly used in dental appliances (e.g., gold, nickel, cobalt, and chromium) are well-documented sensitizers.

Ingestion of mercuric chloride (HgCl_2 , corrosive sublimate) may be lethal, making it a common method of suicide in the past. Clinical manifestations include direct gastrointestinal irritation with fluid loss and shock, as well as acute renal failure. The latter results from accumulation of mercury in proximal renal tubules with consequent acute tubular necrosis.³

Chronic

Classic mercurialism usually results from exposure to elemental mercury vapor or inorganic salts, and the

primary target organs are the nervous system, oral cavity, and kidneys. The neurologic expressions include: fine intention tremor of the extremities, tongue and lips; psychologic disturbances consisting of nervousness, irritability, and pathologic shyness (erethism); mental confusion; and peripheral polyneuropathy (sensorimotor axonopathy) affecting the lower extremities more than the upper. Oral cavity disorders can include gingivitis, stomatitis, salivary gland swelling, and excessive salivation. Unless severe, the clinical manifestations tend to abate following cessation of exposure. Only minor neurologic abnormalities were documented in a recent study of chloralkali workers examined an average of six years after their exposure to mercury ended.¹⁰ Remote (in time) occupational mercury exposure appears to interact with normal aging processes (i.e., natural neuronal attrition) so as to unmask prior exposure-related subclinical effects, particularly peripheral polyneuropathy and tremor, among workers with high past exposures.¹¹

Absorbed inorganic mercury is preferentially concentrated in the renal proximal tubules, but tubular dysfunction is unusual in the occupational setting. Glomerular disease with nephrosis is the most common, though infrequent, manifestation of renal dysfunction among occupationally exposed individuals. Interestingly, pathologic findings include interstitial and/or glomerular immune-complex nephritis, suggesting that mercury-related glomerular disease may have an immunologic mechanism. Proteinuria usually abates following removal from exposure.³

Short-chain alkyl mercury compounds (organic mercury) are a potential exposure hazard in the general environment in addition to the work setting, and have distinct pharmacokinetic and toxic profiles. With chronic exposure the clinical manifestations usually have a gradual onset. Following a single, massive exposure, there is usually a latency of several weeks before the appearance of clinical abnormalities. The spectrum of effects is similar regardless of the time course of exposure, and the primary target is the nervous system.¹²

The clinical effects of short-chain alkyl mercury compounds are distinct from classic mercurialism; salivation, stomatitis, and erethism do not occur. The effects include: neurasthenia (weakness, fatigue, headache, poor recall and concentration, emotional instability, and intellectual deterioration in severe cases); numbness and tingling in fingers, toes, mouth, lips, and tongue; global ataxia involving impairment of speech, swallowing, gait, writing, and truncal movements; spasticity and intention tremor; impairment of hearing; concentric constriction of visual fields; and possible seizures. If exposure occurs prenatally, the clinical expression may be cerebral palsy in the newborn or a less severe presentation, such as psychomotor retardation. There appears to be increased susceptibility to, and preferential concentration of, alkyl mercury in the fetus, since mothers of affected infants may have lower tissue levels, and not demonstrate clinical effects.¹²

A rare form of inorganic mercury poisoning which has been described only in children is acrodynia. The mechanism of acrodynia is poorly understood, but is best described

as an uncharacterized form of 'hypersensitivity' to mercury. The syndrome usually begins weeks or months after onset of exposure to mercury. It consists of: severe pain and cramps in the extremities; muscle weakness in the pectoral and pelvic regions; nerve dysfunction in the lower extremities; characteristic cutaneous manifestations (pink or red macular rash on the hands and/or feet, with desquamation); pruritus; irritability and mood swings; intermittent low-grade fevers; abdominal cramps; photophobia; increased perspiration; hypertension; hypotonia; and tachycardia. The diagnosis is confirmed by documentation of elevated urine mercury in a 24-hour specimen, but the concentration is frequently below the usual range associated with typical, chronic mercury poisoning.

Allegations of mercury exposure being associated with various immunologically mediated diseases (e.g., multiple sclerosis related to mercury dental amalgam) are without foundation.

DIAGNOSIS, EVALUATION, AND TREATMENT

Acute inhalational exposure to a high concentration of elemental mercury vapor (greater than 1–3 mg/m³ for a few hours) is a life-threatening medical emergency. With development of acute pneumonitis, subjects require aggressive supportive respiratory care. Chelation with penicillamine, dimercaprol, or dimercaptosuccinic acid (DMSA) can help to accelerate the urinary excretion of mercury following acute high exposure. Although it is necessary to rely on the history and clinical picture to make the initial diagnosis and begin therapy, measurement of mercury in 24-hour urine specimens (frequently in the thousands of micrograms per liter of urine) confirms exposure.

Acute ingestion of mercuric chloride, usually with suicidal intent, is also a medical emergency. Chelation can mobilize mercury from tissue, specifically the kidneys. Hemodialysis, possibly with cysteine infusion, can remove mercury from the body.¹

The early clinical manifestations of chronic mercury poisoning are non-specific, and therefore confirmatory laboratory tests, specifically biologic monitoring, are important. Appropriate biologic monitoring techniques are predicated on the pharmacokinetics of different mercury compounds. Elemental mercury, inorganic mercury salts, and organic (non-short-chain alkyl) compounds of mercury are rapidly cleared from blood and metabolized *in vivo* to the mercuric form (Hg⁺⁺), primarily excreted via the urine. The half-life of the total body burden is about 30–60 days, although there is great variability among the different organs (e.g., retention in brain tissue may be of the order of years).¹ Short-chain alkyl mercury compounds are not metabolized quickly, and are more evenly distributed to all body tissues due to their lipid solubility. Ninety percent of short-chain alkyl mercury in blood is bound within red blood cells. Excretion of alkyl compounds is primarily via feces due to excretion in bile. There is

efficient enterohepatic circulation, and the half-time in the body is about 70 days.¹³

In light of the preceding observations, recent or chronic ongoing exposure to elemental mercury, mercuric salts, and non-short-chain alkyl compounds is assessed best via measurement of mercury in urine, preferably 24-hour specimens. Measurement of mercury in blood can also be used for this purpose during the first few days following cessation of exposure. However, dietary habits can confound the interpretation of blood measurements since short-chain alkyl compounds found in certain foods also appear in blood, but not in urine. Clinical abnormalities of classic mercurialism are usually not found among chronically exposed workers with urine levels maintained below 300 micrograms Hg/l,¹ and the World Health Organization endorses 50 micrograms Hg/g of creatinine as an appropriate biologic threshold value for persons exposed to inorganic and elemental mercury. Persons without occupational exposure to mercury usually have urine levels below 5 micrograms Hg/g creatinine. The correlation of urine or blood levels of mercury with toxicity is poor.

Measurement of mercury in whole blood or hair appears to reflect body burden of the short-chain alkyl compounds (predominantly methyl mercury). For reasons outlined previously, urinary levels are not useful in assessing exposure to short-chain alkyl mercury compounds. Levels in blood or hair that exceed 20 micrograms Hg/100 ml or 50 micrograms Hg/g, respectively, may be associated with early toxicity. WHO endorses a threshold value of 10 micrograms Hg/100 ml in blood. The validity of hair analysis for trace elements has been questioned. Analysis of hair from one individual by multiple commercial laboratories may yield significantly different results.¹⁴

With documentation of exposure and findings consistent with chronic (classic) mercury poisoning, the primary therapeutic maneuver is removal from exposure. In most cases, the natural elimination of mercury coincides with gradual clinical improvement of neurologic, oral cavity, and renal abnormalities. Although chelation may accelerate urinary excretion of mercury, such aggressive therapy may result in worsening of patients' clinical conditions, since mobilization of mercury from body stores may increase toxicity in the kidney and cause greater deposition in the brain. Penicillamine may present less of a hazard in this regard, and may also be more effective in ameliorating the nervous system effects of mercury.¹³ Because of the potential for renal damage due to mercury, assessment of tubular and glomerular proteinuria should be considered.

Removal from exposure is also the primary therapeutic approach for persons exposed to short-chain alkyl mercury compounds, commonly a reduction in fish consumption or other potential dietary sources. Chelation is not effective in accelerating the excretion of organic mercury or improving clinical outcome. However, there is promise in approaches directed at interrupting enterohepatic circulation of alkyl mercury compounds excreted in bile, such as ingestion of non-absorbable mercury-binding substances (e.g., polythiol resins).¹³

PREVENTION

Process substitution, appropriate engineering controls, good industrial hygiene and housekeeping practices, worker education, and, when necessary, use of personal protective equipment should reduce or prevent occupational exposure to mercury. Workers with potential exposure to elemental, inorganic, or non-short-chain alkyl mercury compounds should be monitored via measurement of mercury in 24-hour urine specimens. Periodic assessment of mercury in whole blood should be used to monitor workers with exposure to short-chain alkyl mercury compounds. Pregnant women, or women intending to become pregnant in the near future, should limit their intake of foods known to contain elevated levels of mercury (e.g., swordfish, tuna, etc.).¹ Hypersensitivity reactions to mercury in dental amalgam are exceedingly rare and usually self-limited; removal of amalgam tooth fillings for this reason is almost never justified.

39.10 Copper, Manganese, Thallium, Vanadium, Zinc

Alfred Franzblau, Mary Carol Fromes

COPPER

Exposure

Copper was one of the earliest metals utilized by man. The word was derived from the Greek for Cyprus ('Kyprios'), which was known for its rich deposits of this reddish-brown metal. Romans referred to the metal as 'aes cyprium' (ore of Cyprus) and later as 'cuprum'. The English word evolved from this latter term.¹

The toxicity of copper is dependent on its chemical form and mode of exposure. Copper salts tend to be more toxic than metallic copper, although the latter is more widespread in industrial settings. Copper is also an essential trace metal, and humans have evolved homeostatic mechanisms for control of copper balance. Derangements of these mechanisms, as occurs rarely in certain dietary circumstances or inherited diseases, leads to severe illness (Indian childhood cirrhosis, Menkes' syndrome, or Wilson's disease), but these will not be discussed further.²

Copper is extremely malleable, and possesses high thermal and electrical conductivity. Industrial exposure to copper occurs primarily via inhalation of fume in the setting of welding on copper-containing metal objects, or formation of copper alloys (e.g., bronze or brass). Grinding or polishing of copper-coated materials can release very fine metallic copper dust that is respirable. Copper sulfate is used widely as a fungicide and algicide. Skin contact with copper salts or metal dust can result in cutaneous reactions, but these are rare. Copper salts, particularly the sulfate, are most toxic when ingested. Copper can leach out of copper-containing beverage containers or pipes when the pH is acidic, and result in clinically significant soluble copper exposure.²

Clinical effects

The most prominent consequence of industrial copper exposure is metal fume fever (MFF) resulting from inhalation of copper fume while welding or brazing (see Chapter 19.5). Finely divided metallic copper dust may cause the same condition. The clinical syndrome is identical to MFF caused by other metal fumes (e.g., zinc, nickel, etc.). Symptoms consist of delayed onset (up to 24 hours) of fever, chills, headache, nausea, vomiting, myalgia, malaise, shortness of breath, non-productive cough, and sometimes a metallic taste. These symptoms usually abate within 24–48 hours, and resolve without specific therapy in a few days.³ Transient infiltrates may be noted on chest radiographs.

However, the association of copper inhalation with MFF has recently been called into question.⁴ A critical review of published reports on this topic has revealed only a small number of original case reports, and that copper exposures were not always measured properly in these studies. This

has led to speculation that the workers described as having MFF related to copper may actually have inhaled fumes or dusts contaminated with other metals known to be associated with this syndrome.

Air-borne copper sulfate exposure is associated with mucous membrane irritation, rhinitis, and cough. Cutaneous sensitization to copper or copper salts is probably rare.¹

An uncommon occupational pulmonary problem associated with copper exposure is 'vineyard sprayer's lung,' which has only been described among agricultural workers in Portugal. It is related to inhalation of 'Bordeaux mixture', a 1–2.5% solution of copper sulfate neutralized by hydrated lime. Bordeaux mixture is applied manually to combat mildew on grape vines. Typically, patients can present with restrictive lung disease after many years of exposure. Chest radiographs can reveal diffuse reticulonodular or miliary changes. Pathologic findings of interstitial lung fibrosis, granulomas, and pigmentation with copper deposition have been reported. Granulomas may also be found in other organs, such as the liver, indicating that this entity can mimic sarcoidosis. There is suggestive evidence that there may be an increased incidence of lung cancer among patients with this disorder, but no population-based or cohort studies have been performed.⁵

Although first described in the 17th century among coppersmiths, green hair (due to exogenous deposition of copper) among copper workers has all but disappeared. Occasional reports of green hair continue to appear, but are usually related to showering or swimming in water with a high copper content.⁶ When the copper content of water exceeds 5 mg/l, a mild blue-green tint may be visible.² In these circumstances the metal is leached from copper pipes by acidic water, or is derived from copper salts used as algicides in swimming pools. Discoloration from copper is a sign of external exposure and not systemic toxicity.⁶

Systemic toxicity of copper or its salts is seen almost exclusively in association with ingestion. Copper sulfate solution is inexpensive, so at one time ingesting it was a preferred method of suicide in some regions of India. Multiple system effects may be seen among victims. Copper is a direct irritant of the gastrointestinal mucosa, causing nausea, vomiting, and burning in the epigastrium. A metallic taste is frequently noted after ingestion.⁷ Once copper is absorbed, it is deposited in the liver, where accumulation can lead to centrilobular necrosis. If enough copper is absorbed, the patient is at risk of massive hemolytic anemia, with subsequent development of acute renal failure and attendant complications. Copper leached from copper-containing water pipes or beverage containers can also produce gastrointestinal irritation.²

Diagnosis, evaluation, treatment, and prevention

Clinically, the most useful approach for assessing occupational exposure to copper is to obtain a good history and documentation of the industrial process. Indices for biologic monitoring for copper are not well established, although there are a few reports in which blood concentration or urinary excretion of copper have been employed. The primary difficulties are that there are wide normal ranges for copper levels in blood and urine, and these can vary substantially due to intercurrent medical illnesses.³

Following removal from exposure, therapy for copper-related illness is usually supportive. Chelation therapy is only employed in the setting of Wilson's disease, which causes copper to accumulate in the liver and other organs. Zinc acetate has also been used to treat Wilson's disease because zinc induces production of intestinal metallothionein, which binds copper and prevents its movement into the blood by forming complexes with the metal in intestinal cells.² Metal fume fever is self-limited and generally has no long-term consequences. Engineering controls, worker education, and personal protective equipment are the primary measures to prevent copper-related illness in the occupational setting.

MANGANESE

Exposure

Manganese is an essential trace element with a typical intake of 1–5 mg/day. Under normal circumstances manganese can be identified in small quantities in most human tissues. It is the second most abundant heavy metal in the earth's crust (0.1%), after iron. Although there are thousands of facilities in the United States that manufacture, process, or produce manganese, almost no manganese ore has been mined in the US since the late 1970s. Manganese ore is imported from Australia, Brazil, Mexico, Morocco, and South Africa.⁸ Industrially, it is used primarily in production of steel (85–90% of all tonnage). Other significant applications include dry-cell batteries, matches, fireworks, chemicals, glass, ceramics, paints, inks, dyes, animal feed supplements, antiknock compounds, welding rods, drugs, fungicides, fertilizers, as an intravenous contrast agent (i.e., mangafodipir) for magnetic resonance imaging (MRI), purification of water, and as a preservative of rubber and wood products.⁸

Industrial (inorganic) manganese exposure typically occurs via inhalation of dust or fume. Cutaneous and gastrointestinal absorption are negligible (except in the setting of iron deficiency), which, in part, explains why almost all reported cases of chronic manganism have occurred in an occupational setting rather than in relation to environmental contamination. Manganese-associated illness has been described primarily among workers in dusty operations associated with mining, transportation, crushing, and sieving of manganese-bearing ore.⁹ Historical

dust levels of 250 mg Mn/m³, and higher, have been reported with these processes. Cases of disease have also been reported among industrial end-users of manganese, such as workers employed in smelters producing ferromanganese alloys, foundry men, ceramics workers, welders using manganese-coated welding rods, and those who perform burning or grinding of ferromanganese alloy steel.^{10,11} Cutaneous absorption of (organic) manganese can be significant among agricultural workers who spray manganese-containing fungicides, such as Maneb (manganese ethylenebisdithiocarbamate) or Mancozeb (zinc manganese ethylenebisdithiocarbamate).¹² Patients on total parenteral nutrition and/or with severe liver dysfunction can demonstrate increased manganese in blood and characteristic changes on brain MRI, and may have signs consistent with manganese toxicity.^{13–16}

Considerable controversy has developed over the potential for human exposure and adverse health effects related to use of methylcyclopentadienyl manganese tricarbonyl (MMT) as an octane booster in gasoline.¹⁷ The concern is that widespread use of MMT in gasoline with consequent dispersion of manganese salts via tailpipe emissions could parallel the environmental impact related to decades of use of tetraethyl lead in automotive fuel. However, recent data and environmental models suggest that the contribution of MMT in gasoline to air-borne respirable manganese particulate, and the absorbed daily dose of manganese, is low in relation to existing background levels.¹⁸ Nevertheless, further research is needed to better characterize the potential for adverse health effects, particularly among more susceptible subpopulations.¹⁹

Clinical effects

Acute

Manganese salts can act as minor irritants to skin, eyes, and mucous membranes. Inhalation of fume of manganese oxide can cause metal fume fever (see Chapter 19.5). Potassium permanganate (KMnO₄) is corrosive to tissue due to its potent oxidizing capability.

Pulmonary function deficits, bronchitis, asthma, and/or an increased incidence of pneumonia (but not pneumoconiosis) have been reported among manganese-exposed workers, and also persons living in the vicinity of manganese-emitting plants (e.g., smelters). Some of these reports are from the early to middle part of the 20th century, prior to the availability of antibiotics, and the clinical and epidemiologic descriptions are limited.²⁰ In some cases, 'manganese pneumonia' has been noted to be resistant to antibiotic therapy, and there is some animal evidence to suggest that manganese exposure may increase susceptibility to bacterial infections. Manganese may directly cause inflammation of pulmonary tissue, and may also serve to increase susceptibility to bacterial infection. However, in an epidemiologic study of non-malignant respiratory disease mortality among ferroalloy plant workers, Hobbesland et al²¹ did not find any consistent relationship between manganese exposure and pneumonia.

Nevertheless, manganese dusts and fumes may be possible aggravating factors in the development of the pulmonary effects noted above, but additional causes should not be overlooked if evaluating possible pulmonary disease among manganese-exposed industrial workers, or those living adjacent to manganese-emitting plants.

Chronic

The primary health concern related to manganese exposure is development of a neurologic syndrome, termed manganism, which was first described by Couper in 1837.²² He reported on five men employed grinding manganese dioxide for the manufacture of bleach. Subsequently, hundreds of cases from a variety of industrial circumstances have appeared in the medical literature.

Clinical manifestations of manganism can occur after a variable length of time, depending upon intensity of exposure, individual susceptibility, and possibly the type of ore (a mixture of $\text{Mn}_2\text{O}_3/\text{MnSiO}_3$ may be more damaging than MnO_2 , although data are limited). The mechanism by which manganese produces neurotoxicity has not been clearly established. Rare cases have developed after just one or two months of exposure, while others have become recognized only following more than 20 years of employment. The crude 'length of exposure' may be a misleading parameter, as illustrated by cases involving industrial workers with longstanding manganese exposure who develop manganism within months following breakdown of ventilation equipment and consequent increase in manganese exposure.¹¹

More recently, neuropsychologic screening of exposed workers has uncovered subclinical or mild impairments that might otherwise not have come to clinical attention, and at levels of exposure that had been considered 'acceptable'.²³⁻²⁷ Based in part on these findings, the American Conference of Governmental and Industrial Hygienists (ACGIH) lowered the 8-hour time-weighted average threshold limit value (TLV) from 5.0 mg Mn/m³ to 0.2 mg Mn/m³.²⁸

The earliest effects of manganism are non-specific and usually subjective, such as anorexia, asthenia, apathy, somnolence, headaches, and reduction in spontaneous social interaction. Patients can appear depressed or excited. A minority may experience a brief period of aggressiveness, increased sexual activity, hallucinations, and at times pressured or incoherent speech. These manifestations of excitement are termed 'manganese psychosis'. Patients with both depressive and excitatory effects mistakenly have been referred to psychiatrists for evaluation.

With continued exposure speech can be affected, with loss of variation of pitch. Diction is slowed and inarticulate, often with stuttering. In advanced manganism, there can be almost complete muteness. The facies become fixed in expression ('masque manganique'), although it is possible to make voluntary facial movements. Episodes of inappropriate laughter or weeping can occur. Patients are noted to develop clumsiness, especially of the upper limbs. On examination, one finds an increase in reflexes, particularly in the lower extremities, and adiadochokinesia.

Patients in the advanced stages are notable for aggravation of the above signs and symptoms, the development of disturbances of gait (e.g., the 'cock walk'), and possibly resting tremor. Micrographia can be apparent on samples of writing.

Manganism appears to be a progressive condition even after cessation of exposure, particularly once it has advanced to clinically overt stages.²⁹ Long-term follow-up of manganese-exposed industrial workers with subclinical impairments is variable; the neurologic findings typically do not progress, but they may or may not improve after reduction or elimination of exposure.^{30,31}

Although many similarities with idiopathic Parkinson's disease (PD) have been noted, important clinical and pathologic distinctions have been described more recently. Patients with manganism tend to have more psychiatric disturbances early in their history, less frequent resting tremor, more frequent dystonia, and are less likely to be responsive to PD drugs such as levodopa.^{32,33} A distinguishing gait disturbance found among patients with manganism, but not those with PD, is the 'cock walk'.³² In humans (and animal models) the pathologic lesions of manganism are more diffuse (i.e., in the pallidum, caudate nucleus, putamen, and possibly cortex) than among persons with idiopathic PD (i.e., primarily in pigmented areas such as the substantia nigra). Lewy bodies are usually present in the substantia nigra in patients with PD, but usually not among patients with manganism.³² MRI scans of patients with manganism can demonstrate characteristic changes thought to represent the accumulation of manganese in brain tissue.^{13-16,32} Patients with idiopathic PD usually have normal MRI scans. Fluorodopa positron emission tomography (PET) scanning is reported to be abnormal in PD, but normal in manganism.³⁴

Diagnosis, evaluation, and treatment

Diagnosis of manganism requires a history of exposure, and typical findings on medical examination. As noted above, the early effects can be subtle and non-specific. Unfortunately, valid and accurate methods of biologic monitoring for assessing exposure to, or body burden of, manganese are not well established. Manganese is excreted primarily in bile and feces, and only a small percentage in urine.⁸ The total body half-life varies from 15 to 35 days. In the blood, most manganese is bound within red blood cells. Individual manganese levels in blood and urine are not well correlated with recent or past exposure, and thus should not be relied upon as definitive evidence in assessing exposure. In contrast, group mean concentrations of manganese in blood or urine correlate with recent exposure in epidemiologic studies.²⁷ Challenge tests with EDTA to determine if the body burden is increased are not helpful. As noted above, MRI scans may show increased manganese uptake in the brain.^{14,32} In spite of numerous reports of successful application of hair analyses, these are difficult to interpret for the usual reasons: there is no standard method for washing, and external contamination can be difficult to distinguish from internal deposition.

Treatment of manganism is primarily removal from exposure. Chelation has not been shown to have any consistent benefit. Treatment with drugs used for idiopathic PD, such as levodopa and 5-hydroxytryptophan, has been advocated in the past,^{35,36} but less success has been noted more recently.³² A small double-blind study of levodopa among patients with chronic manganism did not show any positive effects.³³

Prevention

Engineering control of exposures is the mainstay of prevention of manganese-related occupational disease. Pre-employment and periodic medical examinations of exposed workers should include attention to personality changes and movement disorders in order to detect early manganism, when it will have the highest potential for reversal with removal from exposure. Most human health studies on MMT in gasoline have been based on healthy adult males, with a focus on neurotoxicity. Human data pertaining to possible reproductive, developmental or other effects, especially at low levels of exposure, are limited, and further studies are needed to address these issues.

THALLIUM Exposure

Thallium was discovered in 1861, and within two years it was known to be highly toxic. Despite such knowledge, thallium compounds were employed as medicinal agents for almost 60 years. Uses during the late 19th and early 20th centuries included the treatment of syphilis, tuberculosis, and ringworm. It was also employed as a depilatory.³⁷ Numerous instances of iatrogenic toxicity were documented.³⁸

In 1920, thallium compounds were first used as pesticides in Germany. Subsequently, ingestion of thallium-containing rodenticides, usually thallium sulfate, was a common cause of thallium poisoning, particularly among children. These compounds, and many other thallium formulations, have excellent transcutaneous, gastrointestinal, and pulmonary absorption. In 1972, thallium rodenticides were banned in the United States, with a consequent decrease in the incidence of such episodes. However, the problem of ingestion of thallium rodenticides continues elsewhere in the world.

Industrial exposures to thallium compounds can result in acute and chronic disease, but now are rare. Thallium is a byproduct of the combustion of flue dust, the smelting or refining of zinc and lead, and cadmium production, but it has not been produced in the United States since 1981. Thallium has limited industrial applications, with only small amounts currently utilized, of the order of a few thousand pounds per year in the United States. Thallium is a component of crystals employed in equipment for detection and signaling of long wavelength radiation and spectrometers, and photoelectric cells. Solutions of organic thallium salts are used to perform gravimetric separation of

minerals. Thallium compounds are also used in certain low temperature thermometers, as an additive to cement, in pigments, and in other specialized products. Grinding or machining of thallium alloys has resulted in occupational exposure.³⁹

Environmental exposure to thallium has been documented in a number of instances. Soil and water contain minute quantities of thallium. In the past, episodes of environmental exposure involved ingestion of foods, such as bread, in which grain had been treated excessively with thallium-containing pesticides. More recently, persons living in the vicinity of a cement plant in Germany that emitted thallium were reported to have excessive absorption and toxicity. Toxicokinetic analyses revealed that thallium absorption in this population was correlated with consumption of locally grown vegetables.⁴⁰

Radioactive thallium isotopes (thallium-201) are used in nuclear medicine, but the quantities injected are small. Thallium toxicity has not been reported in this setting.

Clinical effects

Acute

Thallium has high acute toxicity. The minimum lethal dose for an adult is 1g or less. Neuropathy, gastrointestinal irritation, and hair loss form the classic triad of acute thallium intoxication. Gastrointestinal upset (abdominal pain, nausea, vomiting, diarrhea or constipation, and hemorrhagic gastritis) can occur within hours of ingestion of large doses. Peripheral neurologic changes, initially painful parasthesias, can appear within a few days, followed by motor neuropathy. Multiple levels of the nervous system can suffer injury, including cranial nerves (particularly the optic and vagus nerves), autonomic function, spinal cord, and areas of the cortex and basal ganglia. Convulsions have been described. Alopecia is delayed for two or three weeks, and can become total. Other organ systems can also be affected. Liver enzymes (ALT, AST, alkaline phosphatase) can become elevated, and centrilobular necrosis has been reported. Renal function may deteriorate due to tubular necrosis. In fatal cases, focal necrosis of skeletal and myocardial muscle has been documented at autopsy. The latter probably plays a role in refractory arrhythmias, although vagal neuropathy may also be responsible.⁴¹ Thallium is teratogenic in a number of animal species.

Histopathologic studies of nerves following thallium poisoning disclose axonal degeneration.⁴¹ As with many toxic axonopathies, recovery is slow, inversely related to severity of injury and duration of exposure, and may be incomplete.

Mees' lines can be seen two to three weeks following an acute ingestion. In some cases a blue line appears in the gingiva within two or three days.⁴²

Chronic

Effects of chronic thallium exposure represent a subset of the acute effects noted previously, but with slower and more insidious onset. In this setting, gastrointestinal symp-

toms are less prominent or absent, and alopecia is the most classic finding. The pattern of hair loss is unusual in that it can be complete on the head, but axillary and facial hair (e.g., eyebrows) are spared. Sensorimotor peripheral neuropathy completes the clinical picture. Patients may also experience a variety of non-specific symptoms, such as disordered sleep, headache, fatigue, and emotional disturbances.⁴³

Diagnosis, evaluation, and treatment

Aside from an accurate history, the best test for documenting thallium exposure is measurement of thallium in urine, preferably a 24-hour sample. The concentration of thallium in urine of unexposed persons is less than 1.5 micrograms per liter, or 1.0 microgram per gram of creatinine. Determination of blood concentration of thallium is not useful since the metal tends to be rapidly cleared and to reside intracellularly. In this respect ionic thallium tends to behave like potassium. Hair analyses are also unreliable for the usual reason: external deposition cannot be distinguished from internal incorporation of the metal. Thallium is excreted predominantly via the kidneys with a half-life in urine of approximately 30 days. Unfortunately, aside from documenting exposure, the thallium concentration in urine cannot be used to predict clinical effects or outcome.

Cessation of exposure and general supportive measures are the primary therapeutic modalities for acute intoxication. Most signs of toxicity resolve with cessation of exposure, but effects on the nervous system may be permanent. Attempts at specific treatment of acute thallium poisoning are aimed at displacing thallium from tissues and increasing excretion. Although there may be increased excretion of the metal, no therapeutic approach has demonstrated significant or unequivocal improvement in clinical outcome, and some approaches are associated with clinical deterioration, at least initially (e.g., potassium supplementation). Potassium supplements may displace thallium from its intracellular compartment and may also enhance the renal excretion of thallium by competing with it for resorption at the distal tubule. Potassium ferricyano-ferrate II, or Prussian Blue, is another potential therapy for thallium poisoning. This dye is given because thallium is concentrated in stomach acid and bile, and the alkaline pH of the small intestine allows the metal to be exchanged for potassium in Prussian Blue, which may facilitate fecal excretion of thallium and end its enterohepatic circulation. Chelation with a variety of agents is another possible approach. Peritoneal and hemodialysis are of limited usefulness because thallium is primarily an intracellular toxin.⁴²

Prevention

Thallium is no longer applied as a medicinal agent, and its use as a rodenticide has been banned in most countries. Care must be exercised to prevent thallium from entering the human food chain, either from inadvertent human consumption of thallium-treated grain or vegetable products, or environmental contamination of farm areas with

thallium, as occurred near the German cement plant noted above. Because of its extreme toxicity, workers with potential exposure should be educated about its effects, and industrial exposure prevented by appropriate work practices and engineering controls. Measurement of thallium in urine is helpful to assess whether occupational exposure has occurred.

VANADIUM Exposure

Vanadium usually is recovered as a byproduct of mining of other metals, such as uranium, iron, copper, zinc, and lead. The largest fraction of vanadium use is for various alloys of iron, molybdenum, bronze, brass, and aluminum. Smaller amounts are employed in chemical processes as catalysts (ammonium vanadate and vanadium pentoxide), in ceramics, dyeing processes, inks, insecticides, photographic developer, color phosphors for television, and glass production. Most foods contain minute amounts of vanadium. Vanadium may be an essential trace element, although a deficiency state is not recognized.⁴⁴ It is known to have insulin-mimetic properties in humans and other mammals.

Inhalation of vanadium dust or fume, particularly the pentoxide, is the most common route of industrial exposure. Vanadium is poorly absorbed from the gastrointestinal tract or transcutaneously. It can cause a local irritant or hypersensitivity reaction when in contact with skin, mucous membranes, or upper respiratory tract. Industrial exposure (inhalation) can occur whenever there is release of vanadium dust or fume, such as mining, milling, and refining, although such exposures are usually minor.⁴⁵

Shellfish have a relatively high content of vanadium, which explains why it is a trace constituent of crude oil and coal. The concentrations in crude petroleum vary considerably, from 0.1 ppm (certain domestic crudes) up to 1400 ppm (crude from western Venezuela).⁴⁶ Combustion results in deposition of vanadium in bottom ash (as high as 15.3%) and crusted deposits, or clinker, on the inside of boilers (up to 35%).⁴⁷ Numerous reports have documented vanadium dust and fume exposure (in the form of pentoxide) among workers involved in cleaning and refurbishing of oil- and coal-fired boilers.⁴⁸

Clinical effects

The most significant pattern of illness observed among workers exposed to vanadium dust is that of irritation of the upper respiratory tract. Depending on the concentration in air, workers can begin to experience symptoms within hours of onset of exposure, including: cough; wheezing; irritation of the eyes, nose, and throat; hemorrhagic bronchitis; and, rarely, chemical pneumonitis. Pulmonary function tests have been variable among symptomatic subjects, but have included reductions in forced vital capacity (FVC), forced expiratory volume in one second (FEV₁), peak expiratory flow, and mean mid-expiratory flow (FEF₂₅₋₇₅). Symptoms and decrements in

pulmonary function usually resolve within one or two weeks following cessation of exposure, although bronchial hyper-responsiveness may persist for several months.⁴⁹

The potential for rapid onset of symptoms with a first exposure suggests that the mechanism is irritant and not immunologic, although some reports have noted an apparent increase in sensitivity on subsequent exposures, which would suggest the possibility of an immunologic response, as would high levels of IgE documented in some individuals with bronchial hyper-responsiveness following vanadium exposure.⁴⁹

Vanadium skin rashes are usually of an irritant nature. However, positive patch tests have been noted in some cases. With particularly heavy exposure a green discoloration of the tongue has been described, which is due to oral deposition of inhaled vanadium dust, and is not a sign of systemic toxicity. There is no evidence to suggest that chronic pulmonary dysfunction or emphysema results from vanadium exposure. In addition, vanadium has not been implicated as a human carcinogen.

Diagnosis, evaluation, and treatment

There is no specific treatment for vanadium-induced illness. Symptomatic individuals should be removed from exposure, and therapy is supportive.

Biologic monitoring of vanadium in urine and blood are possible approaches to documenting recent exposure. The concentration of vanadium in whole blood is normally below 0.1 microgram per deciliter, and less than 1.0 microgram per gram of creatinine in urine. The half-life in urine is 20–40 hours following cessation of exposure. Although documentation of exposure is feasible, it has been difficult to correlate vanadium levels in air with urinary excretion.⁵⁰

Prevention

Industrial operations that have the potential for creating vanadium dust or fumes should employ appropriate engineering controls, such as wet drilling in mining operations. Persons involved in cleaning or refurbishing of coal- or oil-fired furnaces, particularly boilermakers and others who might work inside the firebox, should use appropriate respiratory protection. The occurrence of a case of vanadium-related pulmonary disease mandates an investigation and implementation of control measures. At present there is insufficient evidence to justify routine biologic monitoring of workers potentially exposed to vanadium.

ZINC Exposure

Zinc is ubiquitous in the environment. It is a trace component of many foods and an essential nutrient. It is also one of the oldest metals used by humans. Despite its long history of use, its most prevalent industrial toxicity, metal fume fever, was not described until the early part of the 19th century. Zinc exposure can occur in a variety of

industries. However, it is the inhalation of freshly formed zinc oxide fume that is of primary concern. Such exposure occurs in processes where volatilization of zinc is possible (e.g., welding on galvanized materials, in brass foundries, etc.).⁵¹

Zinc vaporizes at 907 degrees C. The vapor reacts with ambient oxygen to form zinc oxide, which then precipitates to form a fume. Particle size is critical, and the freshly formed particles of zinc oxide are respirable, typically in the range of 0.2–1.0 microns. With passage of time, the small particles may flocculate, resulting in larger particles that deposit in upper airways when inhaled, thus making them less hazardous. Transcutaneous absorption of zinc oxide is insignificant, and oral toxicity is minimal.

Other salts of zinc, particularly zinc chloride, are irritating to skin and mucous membranes. Zinc chloride is used in smoke generators and in certain soldering fluxes, and can therefore become volatilized.⁵¹

Zinc-bearing ores usually contain at least trace amounts of arsenic, cadmium, and other potentially toxic metals. Processes that result in volatilization of zinc can therefore also cause exposure to these other metals. The toxicities of these other metals can be overlapping, as in the acute effects of cadmium on the lungs (i.e., metal fume fever and chemical pneumonitis), or distinct (e.g., release of arsenic and hydrogen with formation of arsine gas during the process of acid-stripping and galvanizing of steel products).

Clinical effects

Acute

Metal fume fever (MFF) has appeared under a variety of titles including brass founder's ague, brass chills, zinc fever or chills, spelter's shakes, glavo, metal shakes, brazier's disease, foundry fever, and 'the smothers'. Almost all cases have been reported in association with processes that include vaporization of zinc; a few have been reported in association with grinding, buffing, or sanding of zinc-coated surfaces. Tolerance may be a factor in the development of this condition, as reflected in the additional eponym 'Monday morning fever'; an absence from exposure may increase one's susceptibility. Seasonal variation, with increased incidence during winter, has been reported, although this probably reflects greater exposure resulting from reduced natural ventilation during colder months.

The clinical syndrome of MFF is well described. Usually within 2–10 hours following inhalational exposure to zinc oxide fume, workers begin to experience dryness and soreness in the throat with cough, followed by fever (sometimes over 103 degrees F), chills, malaise, hoarseness, chest tightness, and myalgias. There can also be profuse sweating, rigors, thirst, nausea, vomiting, and a metallic taste in the mouth. Findings are quite variable, depending on the severity of the episode. Rales and/or wheezes may be present during the acute phase. Laboratory test results are also variable, and can include: elevation of the white blood count (reported over 30,000/mm³ in some cases) with

left shift; impairment of pulmonary function (decreased FVC, FEV₁, and diffusion capacity); scattered infiltrates on chest radiographs; and mild hypoxemia on blood gas analysis.⁵²

There is evidence that MFF results when respirable particles of zinc oxide elicit an inflammatory response in the lungs. Bronchoalveolar lavage performed 20 hours after volunteers were exposed to zinc oxide fume or air demonstrated increased levels of polymorphonuclear leukocytes and inflammatory mediators (such as tumor necrosis factor- α and interleukin-8) in the lavage supernatant after exposure to zinc oxide compared to air.⁵³

Zinc chloride is also a direct irritant of mucous membranes, and exposure can result in the usual constellation of clinical effects of the eyes, nose, and throat. Because of its marked hygroscopicity, zinc chloride can cause direct irritation to exposed skin. Inhalation of zinc chloride fume is a cause of occupational asthma.⁵⁴ Massive inhalational exposure has resulted in chemical burns of bronchial mucosa, chemical pneumonitis, and adult respiratory distress syndrome, which may occur weeks after exposure and may be fatal.⁵⁵

Diagnosis, evaluation, and treatment

Diagnosis of MFF depends primarily on the symptoms, and the clinical and occupational histories. Zinc levels in blood and urine are not correlated with disease severity and therefore are not useful.⁵¹ The differential diagnosis typically includes flu, acute bronchitis, bacterial pneumonia, or hypersensitivity pneumonitis. Distinction of MFF due to zinc oxide exposure from MFF related to exposure to other metals that can cause MFF is not possible clinically, although the presence of additional toxic effects related to other metals should be sought as these may require specific therapies. The syndrome usually resolves completely within 24–48 hours. Chronic consequences are not well documented. Treatment is supportive, including fluids, and use of antipyretics/analgesics.

Common 'folk remedies' for MFF employed by workers include drinking warm milk to treat the acute illness and to prevent illness. Drinking of peppermint oil derivatives has also been reported. These treatments have no documented value, but they are also not believed to be harmful.

Prevention

As with many conditions, the key to prevention is to avoid exposure. Employer and worker awareness of the presence of a potential hazard is critical. Engineering controls should be employed to prevent inhalation of zinc oxide fume or to reduce exposure to acceptable levels. These measures can be supplemented with personal respiratory protection where needed.

Chapter 40

Organic Solvents and Related Compounds

Ingvar Lundberg, Christer Hogstedt, Carola Lidén, Gun Nise

Organic solvents constitute a chemically diverse group of liquids characterized by their ability to dissolve oils, fats, resins, rubber, and plastics. Organic chemistry emerged in the early 1800s, and expanded during the second half of that century, with the development of large-scale distillation of coal tar. It thus became possible to obtain specific hydrocarbon compounds such as the aromatic solvents, with a wide variety of applications in the chemical industry. Later, coal tar was largely substituted by petroleum as the raw material for production of these solvents, including aliphatic hydrocarbons, alcohols, and petroleum distillates such as naphtha or white spirit.

Chlorine is a byproduct in the alkali industry, and the commercial exploitation of this byproduct for the chlorination of the aliphatic hydrocarbons led to the introduction of the chlorinated solvents during the 1920s. Reports on the toxicity of these solvents to exposed workers appeared soon after their introduction on to the market.

CHEMICAL STRUCTURE, USE AND EXPOSURE

Solvents may be divided into a number of categories based on their chemical structures. These categories are described in Tables 40.1 and 40.2, together with some physicochemical properties and the main areas of use of common solvents.

The National Institute for Occupational Safety and Health estimated that 9.8 million workers were exposed to solvents in the United States in the first half of the 1970s. In the 1980s, around 400,000 workers in Denmark, or approximately 15% of the Danish labor force, were estimated to be occupationally exposed to solvents on a daily basis. In 1984 over 49 million tons of organic solvents were produced in the United States. Thus, exposure to organic solvents is common and constitutes one of the most important occupational chemical hazards. However, in the industrialized world the exposure level has decreased in many occupations during recent decades. In Sweden only about 6% of the workforce report solvent exposure during at least one-quarter of the work shift in the early 1990s. Table 40.3 lists several occupations that continue to involve significant solvent exposure.

ENVIRONMENTAL MEASUREMENTS

Measurements of solvent vapor concentrations are performed for different reasons, e.g., to compare workers'

exposure with hygienic standards, to control the effect of different interventions, to evaluate the exposure levels associated with complaints, or to assess exposure in cross-sectional or retrospective studies.

The exposure measurements are performed in different ways, depending on the aim of the investigation. When a possible adverse effect from solvent exposure is studied, the concentration of the solvent itself or its metabolites in the target organ is of interest. This concentration depends not only on the air concentration, but also on the skin uptake, workload, and other factors. However, on most occasions, the solvent dose to the relevant tissue cannot be obtained, and only the air concentration in the breathing zone can be measured. The measurements have to be planned and performed in cooperation with an experienced industrial hygienist to ensure reliable and representative results. Use of biologic sampling, including measurement in blood and metabolites in urine, is available for some solvents (see Biologic monitoring).

Sampling methods

When the individual worker's exposure is measured, a portable sampling device is used. A small battery-operated membrane pump, which draws the air through a small glass tube packed with some adsorbent, is commonly used. Activated charcoal, a coconut-based carbon, is the most common adsorbent for solvent sampling. This adsorbent can be used for the collection of the most commonly used solvents. However, methanol and ethanol cannot be sampled on activated charcoal, as desorption may result in underestimation of the exposure.

Modified polystyrene polymers, including XAD, Tenax, Chromosorb, and Porapak, are adsorbents with a lower capacity. They are primarily used to sample high molecular weight non-volatile solvents. Most adsorption tubes consist of two separate sections, one for sampling and one for backup. If solvents are found in the backup section during analysis, the sample has been overloaded and will not give a reliable result.

Progress in vapor sampling has been achieved by the use of continuously collecting passive monitors. The exposed worker carries a small badge with an adsorbent. No sampling pump is needed because the sampling is controlled by diffusion. According to Fick's first law of diffusion, the mass uptake is a direct function of the badge sampling rate, the ambient concentration, and the sampling time. The manufacturers distribute lists of sampling rates for various solvents. The adsorbent used in the passive monitors is usually activated charcoal. The sampling area of most

Chemical class of hydrocarbon	Solvent	Boiling point at 101.3 kPa (°C)	Vapor pressure at 25°C (kPa)	Flash point	(°C)Water solubility (weight %)	Partition coefficients w/a	Partition coefficients b/a	Partition coefficients o/a	Odor threshold (ppm)

Table 40.1 Physicochemical properties, partition coefficients and odor thresholds of commonly used solvents

Solvent (World production in metric tons 10 ³ 1996)	Main uses
<i>n</i> -Hexane	Component in gasoline and solvent in production of plastic and rubber, in printing of laminated products, in extraction of vegetable oil (use of the pure solvent has diminished because of toxicity).
Benzene (20,124)	In chemical syntheses (of nitrobenzenes, halogenated derivatives, aromatic amines, styrene, phenols and others). In unleaded gasoline for antiknock properties. Solvent for paints, inks, rubber, plastics (although uncommon in industrialized countries because of toxicity).
Toluene (7881)	In the production of benzene and toluene diisocyanate and solvent in paints, coatings, inks, adhesives, and in the leather and pharmaceutical industries. In gasoline to improve octane rating.
Xylenes (12,802)	Solvent in paints, lacquers, and varnishes; in rubber manufacturing; in plastics and leather industries; in the manufacture of insecticides and pharmaceuticals. In gasoline to improve octane rating.
Styrene (15,415)	Solvent in polyester resins, particularly in the manufacturing of glass fiber-reinforced plastics.
Methylene chloride	Aerosol propellant, paint stripper, degreasing. Solvent for oils, fats, bitumen. Extraction at low temperatures, such as decaffeination of coffee. Manufacturing of photographic films.
Chloroform	Production of fluorocarbons (use limited because of toxicity).
Carbon tetrachloride	Production of fluorocarbons and solvent in rubber and chemical industries (use limited because of toxicity).
Trichloroethylene (113)	Vapor degreasing and cleaning of metallic and electronic parts.
Tetrachloroethylene	Dry cleaning and vapor degreasing.
Methyl chloroform	In vapor degreasing and cleaning of metallic parts and solvent in printing trades, in office machinery, in electrical industries, insecticides. Extractant for oils, fats, and resins. As an aerosol propellant.
Ethyl acetate	Solvent in paints, varnishes, lacquers, inks, and synthetic rubbers. Used in the manufacturing of photographic films, linoleum, plastic wood, artificial silk, and leather. In the cleaning of textiles.
Acetone (2104)	Solvent for resins, fats, lacquers, oils, cotton, cellulose acetate, acetylene. Employed in paint, varnish, lacquer, rubber, plastics, and chemical manufacturing industries.
Methyl ethyl ketone	Solvent in manufacturing of paints, varnishes, and lacquers; in the electronics industry; and in the manufacturing of synthetic resins.
Methyl- <i>n</i> -butyl ketone	In glues and cleaning fluids (current use is limited because of toxicity).
Methyl-isobutyl ketone	Solvent in paints, varnishes, and lacquers.
Methanol (13,438)	In production of formaldehyde. Used in shellac, lacquers, and other surface coatings. Used as a cleaner for surface coatings, metal, and resins. Solvent in rubber industry, for rotogravure inks, and duplicator fluids.
Ethanol	Extractant in chemical processes. Intermediate in syntheses of methylated chemicals. Denaturant in ethanol. Solvent in paints, varnishes, and lacquers and in the manufacture of plastics, drugs, plasticizers, and cosmetics. Used in chemical synthesis of acetaldehyde, ethyl ether, chloroethane, butadiene, and others.
Iso-propanol	Solvent for oils, gums, and resins. Deicing agent for liquid fuels, defogging, and antifreeze products. Used in the manufacture of many cleaning and degreasing agents, including packet products for antiseptic wiping. It is used in several chemical syntheses and as an extractant.
<i>n</i> -Butanol (3000)	Solvent in paints and lacquers and for synthetic and natural polymers. Used for extraction and dehydration in the pharmaceutical industry.
Butanols (2494)	Used as a deicer and as an antifreeze formulation in heating and cooling systems. As a solvent in lacquers, inks, adhesives, and resins.
Ethylene glycol (5075)	Solvent in paints, lacquers, car painting, and silk screen printing.
2-Ethoxyethanol	Solvent in paints, lacquers, car painting, and silk screen printing.
2-Ethoxyethyl acetate	Used in the production of rayon fibers. Used in the manufacture of optical glass and in semiconductors.
Carbon disulfide (205)	Solvent for vinyl-based polymers in the manufacture of films, fibers, and coatings; for making polyurethane lacquers for clothing and accessories made of synthetic leather; and for fibers and films based on polyacrylonitrile.
Dimethylformamide (100)	Solvent in glues, paints, varnishes, inks, and wetting and dispersing agents in textile processing.
Tetrahydrofuran	Degreasing operations.
Limonene	Intermediate in production of various chemicals, for example 1,2-ethane and glycol ethers. Antimicrobial sterilant.
Ethylene oxide (4830)	Solvents in paints, lacquers, varnishes, agrochemicals, industrial cleaning, and others.
Naphthas (143,757)	Solvent in paints, lacquers, varnishes, agrochemicals, and industrial cleaning.
White spirit (3495)

passive monitors is large compared with that of the tubes, explaining why the risk of contamination through splashing has to be considered. Furthermore, knowledge of the influence on each solvent's sampling rate from different solvents in a mixed exposure is still limited, and should be considered when mixed solvents are present.

Direct-reading instruments, usually portable, which continuously take samples from the air, may be used to follow changes in the solvent concentration during different work operations. The detectors in such portable instruments are often of an infrared or photoionization type. The solvent concentration might be recorded on a printer or

collected into a data logger for later evaluation. The calibration of these instruments is important, and this procedure is rather complicated for many instruments. When a solvent mixture (like painter's naphtha) is measured, the instrument must be calibrated with the mixture used in the process, otherwise, there is a risk of under- or overestimating exposure. Some direct-reading instruments are also sensitive to changes in temperature and humidity.

The indicator tube, a glass tube filled with chemical material that changes color on contact with the sampled solvent, is the simplest direct-reading sampling device. The solvent air concentration is obtained by comparing the

Painting with solvent-based paints, particularly spray painting and painting large areas (mixed solvents)
Paint manufacturing, particularly manual cleaning of equipment with solvents (mixed solvents)
Production of glass fiber-reinforced polyester plastics, particularly lamination of large areas as in the production of boats (styrene)
Floor laying (mixed solvents)
Rotogravure printing and screen printing (toluene, mixed solvents)
Metal degreasing (commonly 1,1,1-trichloroethane)
Dry cleaning (commonly perchloroethylene)

Table 40.3 Occupations that may involve heavy solvent exposure

colors produced to a set of standard colors or by measuring the length of the stain produced. Grab samples with indicator tubes describe the conditions at the moment of sampling, and give a rough estimate of the exposure level. However, the results can be misleading due to the effects of variable factors, such as temperature and humidity, inexperience in interpreting the results, and lack of specificity of detection methods.

Sampling strategy

When measurements are performed to compare the solvent exposure level with hygienic standards, a personal sampling device should be used, e.g., a portable pump with adsorption tube or a passive monitor. Air from the worker's breathing zone is monitored during the whole shift, usually 8 hours. It is important that cleaning operations are included in the sampling time because such work often involves heavy exposures. The shift may be covered by only one sample, but it is advisable to divide it into at least two sampling periods. If there is a great variation in the exposure, several continuous samples during the shift will give more information about the conditions, which is valuable for determining intervention approaches.

The direct-reading instruments are often small enough to be used for personal monitoring. Such instruments are also suitable to investigate vapor leakage from different operations and the distribution of the solvents in the workplace from the emitting area. Furthermore, they give an immediate picture of the air concentration; alternatively, the adsorption tubes and the passive monitors have to be sent to a laboratory for analysis. However, used together with personal sampling devices, a good picture of both the time-weighted average exposure and the variation of the air level is obtained. Such information is of importance when efforts are made to lower the worker's exposure.

The distribution of solvent vapors might be visualized by sampling with a direct-reading instrument at several locations in the working area within a short period, so-called map sampling. Such a map is valuable during the discussion of the most suitable interventions. In addition, a direct-reading instrument together with a video camera provides educational information on the exposure levels associated with different working habits.¹

Grab samples randomly monitored during the shift will depict the variation of the exposure level. The geometric mean of these samples will roughly illustrate the average

exposure level during the shift. The larger the variation in exposure, the more grab samples are needed.

All measurements have to be well documented. The report should contain information on the reason for sampling, the sampling method, the sampling periods, and the production conditions. The reader of a measurement report needs such information to interpret the results correctly. When retrospective exposure assessment is performed for epidemiologic studies of health effects from long-term solvent exposure, well-documented measurement reports are of particular importance. A further discussion of sampling principles is provided on Chapter 4.2.

DECREASING EXPOSURE LEVELS IN INDUSTRY

The preventive measures taken against solvent-related health hazards are manifest in the lists of hygienic standards that are published in most industrialized countries. During the last 20 years there has been a substantial reduction of regulatory standard levels in most countries. In some countries, such as those in Scandinavia, the hygienic standard level reductions have been more pronounced than those of the American Conference of Governmental Industrial Hygienists (ACGIH).

Among the common solvents, the reduction of standard levels is substantial for methylene chloride. The finding that this solvent was metabolized to carbon monoxide caused a dramatic reduction between 1970 and 1980. The potential carcinogenicity of the compound, as shown in animal experiments, led to a further reduction (in 1990) to less than one-fifth of the 1970 standards. The low standard for benzene in most countries is related to its hematotoxicity and carcinogenicity. The reproductive effects of 2-methoxyethanol have led to a substantially decreased exposure limit. For most other solvents, the hygienic standards are commonly based on neurotoxic and irritant effects, and the differences between those of the Scandinavian countries and those of the ACGIH probably reflect different assessments of the importance of such effects.

It is likely that improved standards have resulted in a reduction in the number of heavily exposed workers in the industrial branches of larger operations. This is particularly true in the case of automation, which reduces the number of workers and moves the remaining workers away from the production process. The decrease of toluene exposure among rotogravure printers in Sweden is shown in Figure 40.1. However, in small and medium sized enterprises the exposure level may still be high or even increase due to lack of knowledge and resources.

REDUCING EXPOSURE BY DIMINISHING SOLVENT CONTENT IN PAINTS

In trades involving end-use of solvents (e.g., painters), the possibilities of reducing the exposure by closed systems

Figure 40.1: The decrease of the average toluene exposure level in rotogravure printing. During the period 1948–1985 five factories are included in the estimation (further development of data presented in Svensson et al³⁷).

Figure 40.2: The time spent painting with solvent-based and water-based paints among Swedish house painters.

and exhaust ventilation are much smaller than in industry. In fact, among painters, efforts to reduce exposure to solvents have followed another route, namely, reducing the solvent content in paints by replacing the solvent-soluble binders with water-soluble alternatives. This tendency is obvious in all industrialized countries, although the pace of substitution may vary. The use of solvent-based paints and water-based paints among Swedish house painters can be seen in Figure 40.2. The replacement of solvent-based paints has continued and in 1995 as many as 97% of the paints used indoors were water based.

PHARMACOKINETICS

Uptake and distribution

Uptake through the lungs

During occupational exposure, solvents may be taken up through the lungs or through the skin; uptake through the gastrointestinal tract is negligible. Generally, the lungs provide the most important absorption route. The most important determinant of pulmonary uptake is the solubility of the solvent in the blood. Even for solvents that are readily absorbed through the lungs, the uptake cannot exceed approximately 80%, with the remainder exhaled because of dead-space ventilation. The uptake at rest for methylene chloride, trichloroethylene, toluene, xylene, and styrene is between 50% and 70% of the amount inhaled.

Physical activity is the major important modifying factor on the toxicokinetics of organic solvents. The amount of

Figure 40.3 Solvent uptake at different workloads. (Data from Strand I. Effect of physical exercise on uptake, distribution, and elimination of vapors in man. In: Fiserova-Bergerova V, ed. Modeling of inhalation exposure to vapors: uptake, distribution, and elimination. Vol II. Boca Raton: CRC Press, 1983;107–30.)

solvent taken up per time unit increases during exercise. Figure 40.3 shows the uptake of some common solvents during rest and exercise. Male volunteers were exposed to different solvents during 30 minutes of rest followed by 30 minutes of exercise at 50 W (light work), 100 W (medium work load), and 150 W (heavy work), respectively. The solvents in the figure may be divided into two groups. Those in the first group, i.e., styrene, xylene, acetone, and butyl alcohol, are more soluble in the blood and tissues than the solvents in the second group, i.e., methylene

chloride, trichloroethylene, and toluene. This is shown by the fact that, in the first group, there was a linear increase of solvent uptake with increasing workload that was caused by increasing ventilation. In the second group, the uptake increased at 50 W, but remained fairly constant when the workload was further increased, indicating that an equilibrium had been reached. Thus, it is important to determine the workload when considering the potential health effects of, particularly, the solvents in the first group.²

The amount of solvent taken up by a body tissue depends mainly on the solubility of the solvent in that tissue, but the blood flow through the tissue is also of importance. The change in adipose tissue blood flow during exercise increases uptake. Thus the toluene concentration in adipose tissue was ten times higher after light physical exercise compared to rest, although the respiratory uptake and the blood toluene only doubled.³ The effects that most solvents have in common, i.e., on the nervous system and the skin, are to a large extent dependent on their lipophilicity. In experiments with human volunteers, the distribution of different organic solvents to the subcutaneous fat has been investigated. Obese subjects, compared with thin ones, retained more solvents. It was also observed that, on average, 5% of xylene, 8% of styrene, 9% of methylene chloride, and 17% of the total amount of toluene taken up by the body was retained in fat deposits. These figures are influenced not only by the fat solubility of the solvent, but also to a large extent by the degree of biotransformation of each solvent. The half-life of methylene chloride in fat tissue was around 8 hours, compared to 3–5 days for toluene, styrene and xylene.

In studies on occupationally exposed workers, it has been shown that the body fat accumulates a significant amount of some solvents, implying a residual continuous low-dose solvent exposure during work-free periods.

Uptake through the skin

Solvent compounds may be absorbed through the skin in considerable amounts, and may thus contribute to the total body burden. Skin absorption may occur in settings of single solvent compounds or to products containing solvent mixtures, such as cleansing and greasing agents, and in some cases to vapors.

The uptake of a solvent through the skin varies widely between different solvents. Factors of importance are water solubility, lipid solubility and volatility. Most readily absorbed are solvents that are easily soluble in water and in lipophilic compounds, i.e., having amphiphilic properties. Risk assessments of skin absorption of solvents have benefited from calculations of permeability coefficients, based on the logarithm of the partitioning coefficient between octanol and water ($\log P_{o/w}$). Other factors influencing the rate of skin absorption of solvents are environmental factors such as humidity, temperature, air velocity, vehicle, occlusion and exposure time.

Skin exposures to glycolethers and dimethylformamide are hazardous as they contain a lipophilic and a hydrophilic portion. Skin absorption from vapors is also significant. The absorption of glycolethers is enhanced by

their relatively low volatility and high boiling point, which allows them to remain on the skin surface for long periods. For most common solvents, significant skin exposures are needed before the skin absorption reaches the level of lung uptake. For example, if both hands are kept in a xylene bath for 15 minutes, uptake will be equal to the respiratory uptake from air exposure to 100 ppm during the same period. This does not apply to dimethylformamide, for which the skin uptake may be substantially higher than the respiratory uptake during normal industrial working conditions.

Lists of hygienic standards often contain a special notation, skin, to mark whether a substance is efficiently absorbed through this route. The notations are, in general, based on limited data, and the absence of the notation should not be interpreted to mean that dermal exposure is negligible. The number of solvents with a skin notation has, in recent years, been much extended in the US and several European countries. Benzene, carbon disulfide, carbon tetrachloride, dimethylformamide, 2-ethoxyethanol, methanol, methylene chloride, methyl-n-butyl ketone, n-butanol, styrene, toluene and xylene are some of the solvents with a designation of significant skin absorption.

Biotransformation and elimination

Absorbed solvents are usually biotransformed to more water-soluble metabolites that may be excreted in the urine. The main site for metabolism is the liver. Up to 95% of the xylene and styrene absorbed, and up to 80% of the total amount of trichloroethylene and toluene absorbed, is biotransformed. However, some common solvents like methylchloroform and perchloroethylene are metabolized to a small extent and largely excreted unchanged by exhalation. Excretion of unchanged solvent by exhalation increases during physical activity. The exhalation of toluene, styrene and trichloroethylene were approximately doubled at light physical work compared with rest.⁴

Biotransformation has important implications in the evaluation of solvent toxicity and in the assessment of solvent exposure.⁵ Solvents may be biotransformed into reactive metabolites that are more toxic than the mother compound. For example, the trichloromethyl radical obtained from carbon tetrachloride is responsible for the hepatotoxicity of this solvent. In fact, solvents that show acute, dose-related hepatotoxicity, such as chloroform and dimethylformamide, are often hepatotoxic through reactive metabolites. Similarly, the peripheral neurotoxicity of n-hexane and methyl-n-butyl ketone is caused by the metabolites of these solvents. Metabolites from other solvents, including the epoxides produced from trichloroethylene and styrene, may result in carcinogenic effects.

Non-toxic metabolites from other solvents may be used to estimate the dose of the solvent that has been absorbed (see section on biologic monitoring later in this chapter).

Biotransformation and individual susceptibility

The rates of oxidative metabolism vary substantially among different individuals, sometimes reflecting genetic poly-

morphisms, leading to potential differences in susceptibility to solvent effects. The metabolism of specific solvents may be altered through a variety of factors. Solvents have been shown to interact with each other; for example toluene and xylene seem to inhibit competitively the metabolic degradation of each other because they compete for the same enzymes for side-chain hydroxylation.⁶ Toluene and xylene inhibit the biotransformation of benzene, thus protecting experimental animals from the hematotoxicity of benzene. Ingested ethyl alcohol inhibits the metabolic degradation of toluene and xylene, increasing blood levels and decreasing the rate of elimination from the blood of these solvents, thus enhancing central nervous system effects. Drugs (e.g., acetaminophen) and smoking may also decrease the elimination of toluene from the blood. Dietary factors may play a role, and a diet with a low carbohydrate intake probably enhances the metabolism of several solvents. Tobacco smoking enhances the metabolism of numerous organic solvents.

HEALTH EFFECTS

This section focuses on the effects common to all organic solvents or to large groups of solvents, namely, mucous membrane irritant effects, and effects on the skin and central nervous system. It also provides information on potential common effects involving other tissues. Specific effects on other tissues will be addressed in the following section.

We differentiate between short- and long-term exposures, denoting exposures of hours to days and months to years, respectively. We also distinguish among acute, subchronic, and chronic effects. Acute effects are readily reversible after the discontinuation of exposure. Subchronic effects are most often reversible within 6 months and always within 1 year. Chronic effects are not reversible, only partly reversible, or reversible after more than 1 year.

As a caveat, it should be noted that practically all studies on which our knowledge is based have been performed in developed countries. We cannot exclude the possibility that the effects may be different when undernourished workers with other diseases, particularly liver diseases, are exposed. All comments on safe levels for different solvents and various effects should be understood to have this limitation.

Irritant effects

Most solvents produce irritant effects on the mucous membranes of the eyes, nose, and throat. A burning sensation is induced from the stimulation of trigeminal afferent nerve endings of the eyes and nose; cough is produced from the stimulation of laryngeal nerve endings in the pharynx, hypopharynx, and laryngeal regions. However, all common solvents have weak irritant properties in comparison with intense irritants, such as toluene diisocyanate, acrolein or formaldehyde. The eyes are often sensitive. Heavy exposures are commonly associated with bronchitic symptoms of cough, as well as chest tightness, and a feeling of breathlessness. At very high exposures, a number of common solvents, such as toluene, xylene, and methylene chloride,

can induce pulmonary edema or chemical pneumonitis (see Chapter 19.6).

Different solvents have varying potentials to irritate mucous membranes. It is probable that irritation is mediated through an interaction between the solvent and receptor proteins located in the lipid bilayer of the cell membrane. Animal experiments and practical experience suggest that butanol, styrene, toluene, xylene and methyl ethyl ketone are irritating at comparatively low concentrations, while higher concentrations are needed for irritant effects from ethyl acetate, isopropanol, methanol, acetone, and ethanol.⁷ The reason for the differences in potency between these solvents is unclear. It is a common experience that, when entering, for example, a paint factory, most visitors feel some irritation, particularly of the eyes. Mild irritant effects may occur at exposure levels below current hygienic standards; however, this irritation disappears within minutes. Adaptation to the irritant effects seems to occur for many solvents, but the mechanism behind this adaptation is not known.

Skin

Contact dermatitis represents 90% of occupational skin diseases (see Chapter 29.1). The most common localization of contact dermatitis is the hands. Hand eczema is most frequently an irritant contact dermatitis caused by skin irritation, but may on occasion represent allergic contact dermatitis resulting from a contact allergy. Dermal exposure to organic solvents has been estimated to be responsible for up to 20% of occupationally induced dermatitis.⁸ The main effects of organic solvents on the skin are irritant, including contact dermatitis and acute burns. Dermal sensitization rarely occurs. Other effects are subjective irritation, whitening, contact urticaria, generalized dermatitis, and systemic toxicity due to percutaneous absorption. The skin may be exposed to organic solvents when cleaning the hands with solvents or cleaners containing solvents, by spills, lack of proper protective equipment, or poor hygienic practice, and lack of appropriate cleaning facilities at work.

Skin irritation

The mechanism and nature of skin-related solvent injuries differ.⁹ Organic solvents have a defatting action on the skin. Repeated exposure may easily develop into an irritant contact dermatitis with dryness, erythema, edema, scaling and fissures. Prolonged exposure and occlusion may cause chemical burns. The irritation results in increased water loss and facilitated uptake of other substances.

Low-boiling-range (<250 degrees C) petroleum solvents have the greatest defatting action and potential to cause dermatitis. Aromatic solvents are more potent irritants than aliphatic solvents. Skin contact with perchloroethylene and several other halogenated solvents may cause erythema, blistering, burns, or exfoliation of the skin. This may occur if clothes have not been properly dried after dry cleaning with perchloroethylene or trichloroethylene.

Alcohols are claimed to be less irritating than the aldehydes or ketones. The potential to cause irritation decreases as

the molecular size increases. The alcohols act as drying agents, resulting in xerosis and subsequent irritant contact dermatitis. Ketones are mild skin irritants. Esters are, in general, more potent skin irritants than the corresponding alcohols.

Carbon disulfide is one of the most irritating solvents. Dimethyl sulfoxide (DMSO) is used as an industrial solvent and also in veterinary medicine. DMSO is readily absorbed through the skin. Its systemic toxicity, however, is low but it may facilitate the percutaneous absorption of other substances.

Sensitization

Because organic solvents often cause irritant contact dermatitis, they may facilitate dermal sensitization to workplace allergens. Contact allergy to organic solvents themselves, however, is rare.⁸

Turpentine was previously a common solvent for paints, but its use has declined. It is still added to oil-based paints and varnishes and is used as an ingredient in other industrial and commercial products. Turpentine of Swedish and Finnish origin was previously a common cause of allergic contact dermatitis among painters. American, French, and Portuguese turpentines are less potent sensitizers. 2,3-Carene is regarded as the main allergen in turpentine. Turpentine contains several mono-terpenes, and their oxidation products are sensitizers.

d-Limonene, a citrus solvent, is an organic solvent increasingly used in metal cleaning, and it has many other uses. It is a major fragrance component and is used as a perfume ingredient in various products. Allergenic oxidation products are created with air exposure of d-limonene. The main allergens are limonene oxide, l-carvone and limonene hydroperoxides. In addition to allergic reactions, irritant effects can occur. The oxidation of d-limonene can be prevented by avoidance of air exposure and by the addition of antioxidant.¹⁰ Case reports exist of contact allergy to the alcohols methanol, ethanol, ethylene, glycol and propylene glycol, and there are a few reports of contact allergy to styrene and dioxane. Contact urticaria has been caused by xylenes, alcohols, DMSO and, in single cases, by other solvents.

Protective equipment

Protective gloves should be used to prevent dermal exposure to organic solvents. Gloves are manufactured in different types, according to their use and thickness, by different methods, and from several polymeric materials, with variable resistance to chemicals. Commonly used latex gloves are permeable to a number of solvent compounds. When selecting protective gloves, permeation test data must be considered, as well as the risk of contamination and adverse effects related to gloves (e.g. allergy related to glove material).¹¹ Barrier creams are far less efficient than protective gloves in reducing percutaneous absorption of organic solvents.¹²

Diagnosis

Skin lesions caused by organic solvents do not have a specific clinical picture. The diagnosis is based on dermatologic examination and the history of dermatitis, exposure

to organic solvents, other chemicals, and skin irritants. Hand eczema is the most common solvent-induced dermatologic lesion. Dermatitis on the face and other contact distributions are also caused by organic solvents, whether by aerosol or through hand contamination. Dermatitis on the neck and flexures may be caused by solvents in working clothes, including those that have been dry cleaned and not properly dried. Hand eczema is often caused by a combination of several factors, such as exposure to solvents, water, detergents, other skin irritants, and contact allergens. Atopic dermatitis and hand eczema in atopic patients are often aggravated by exposure to organic solvents. Patch testing should be carried out in the case of persistent dermatitis. The contact allergens that often cause hand eczema in association with solvent exposure are rubber chemicals in protective gloves, preservatives in creams, soaps, paints, perfumes, nickel, chromate, and colophony. Contact allergy to oxidized d-limonene should also be considered.

Treatment and prognosis

Clinical management of dermatitis caused by organic solvents should emphasize the avoidance of dermal exposure to solvents and exposure to other skin irritants. Solvent-induced dermatitis should be treated similarly to other forms of dermatitis with topical corticosteroids and emollients. Systemic corticosteroids are indicated only in severe cases (see Chapter 29.1). Mild hand eczema may clear spontaneously. Hand eczema, however, often becomes chronic or recurrent, as a result of repeated exposure to skin irritants and contact allergens. Hand eczema in persons with atopic dermatitis often becomes more chronic than in others. Contact allergies are frequently persistent. In the case of contact allergy to a solvent (i.e., to d-limonene or turpentine), contact must be avoided in the future. Hand eczema caused by exposure to solvents may necessitate a change of job, especially in cases where exposure cannot be avoided.

Central nervous system

In the middle of the 19th century, the process of vulcanization of rubber was developed, and carbon disulfide was found to be a suitable solvent to use in the process. Soon after its introduction, the French physician August-Louis Delpech described severe neuropsychiatric effects among rubber workers, and was able to identify carbon disulfide as the causative agent. The exposure to carbon disulfide was extremely high in a large number of small workshops in Paris, and many workers became ill.

Delpech discerned two phases in the development of carbon disulfide poisoning. The first appeared rapidly, sometimes after only a few hours of exposure. It was characterized by an excitatory phase followed by collapse. The other phase developed much more slowly and was frequently chronic. It was associated with fluctuations in mood, insomnia, memory problems, loss of sensation in different parts of the body, and impotence. A few of the workers became clinically psychotic. The symptoms described by Delpech seem approximately to fit with modern concepts of the acute and

chronic effects of solvents on the central nervous system¹³ (see Chapter 28.1).

Acute effects

Short-term high-level exposures to organic solvents produce narcotic effects. In fact, several solvents (e.g., trichloroethylene and chloroform) have been used medically as general anesthetics. The narcotic effect of a solvent is directly related to its solubility in fat, and associated bioavailability in lipid-rich cerebral tissues. Acute symptoms include headache, dizziness, confusion, a feeling of inebriation, and, if the exposure continues, unconsciousness and death. Such symptoms have been common in several heavily exposed occupations. The acute symptoms are reversible after the discontinuation of exposure, but may increase sensitivity to future exposures.

A vast number of laboratory investigations have been carried out to elucidate the relationships between acute solvent exposures and neuropsychiatric symptoms and neurobehavioral test results. In general, these studies have confirmed that irritant and prenarcotic symptoms occur in a dose-related manner. It is apparent that current solvent hygienic standards in some countries are too high to protect workers completely from these acute central nervous system effects.

Subchronic and chronic effects

Most workers are exposed to mixtures of aromatic and aliphatic solvents, and the majority of these workers are exposed to solvents in paints and lacquers. The most important occupational groups include different kinds of painters (e.g., house painters and car painters) and paint manufacturing workers. The solvent mixtures often contain painter's naphtha (brush painting), xylene, or toluene (industrial painting) as main components.

Exposure to mixed solvents has for a long time been associated with long-lasting central nervous system symptoms and case reports have appeared throughout the previous century. The interest in these complaints grew in the 1970s and 1980s when Scandinavian investigators reported excesses of disability pensions caused by neuropsychiatric disorders in solvent-exposed occupational groups. At the same time, several cross-sectional studies, also from Scandinavian countries, reported excess neuropsychiatric symptoms and impaired neuropsychologic performance in house painters, car painters, and workers exposed to jet fuel. Studies from Switzerland, Holland, the USA and other countries have later verified similar excesses of disability pensions caused by neuropsychiatric conditions.

Several cross-sectional studies from different countries have reproduced the findings of excess neuropsychiatric symptoms and impaired neuropsychologic performance among workers with long-term exposure to solvents, but some studies have been unable to reproduce the findings. There are compelling reasons for the discrepancies in some cases. These include very low solvent exposures or exposure mainly to water-soluble solvents with a low potential to induce neurologic damage. In other cases, the reasons for the discrepancies remain unclear.

The studies cited show that long-term solvent exposure has been consistently associated with similar symptoms related to the central nervous system. Most of the early studies were performed in Scandinavian countries, and the existence of a clinical syndrome caused by solvents was first accepted in those countries. During the 1980s, the concept gained wider acceptance, and two international workshops with participation of most researchers in the field reached consensus on the potential association and refined the classification of neurobehavioral disorders caused by solvents.

Three studies¹⁴⁻¹⁶ published between 1988 and 1999 were designed to minimize bias related to the healthy worker effect. In two,^{14,15} painters were examined who had been union members for more than 10 years before the data collection started, and regardless of trade or activity at the time of examination. Symptoms compatible with functional or structural brain damage were observed in excess among painters compared with comparison groups. However, there were very mild effects on psychometric test scores when painters were compared as a group with referent groups. In both studies there was evidence of exposure-response relationships, such that painters with lower cumulative exposure often performed better, painters with intermediate exposure often equal to, and painters with higher exposure often worse than the comparison group. Mikkelsen et al¹⁴ attribute this mainly to a less fortunate choice of the referent group, while Lundberg et al¹⁵ suggest that it may be a selection effect among painters, resulting in lower exposure among painters with greater potential for upward social mobility.

In the study by Daniell et al¹⁶ abnormal psychometric test scores were more common among previously exposed than previously non-exposed retired workers. Hence there is still some debate as to what extent long-term occupational solvent exposure may contribute to chronic effects on the central nervous system. Further research is needed to study whether there is a selection out of solvent-exposed work related to neuropsychologic performance, to clarify the association, to gain information on which types of solvent exposures are most likely to cause effects, on potentially toxic concentrations, and on the reversibility of the syndromes. However, there is currently sufficient support for the association of high long-term solvent exposure with long-lasting psycho-organic symptoms to consider this a clinical reality.

The central nervous system effects of specific solvents are discussed in the section on effects from specific agents. However, all solvents seem to elicit similar central nervous system symptoms.

Symptoms and signs

The symptoms described in case reports and cross-sectional studies of solvent-exposed workers include memory problems, concentration difficulties, affective changes (such as aggressiveness, irritability and depression), fatigue, vertigo, decreased libido, sleeping problems, and hyperautonomic symptoms (such as palpitations and increased sweating). The frequent headaches described among those with acute symptoms related to heavy exposures are also common after long-term exposure. The time of appearance of the symptoms and their severity is believed to depend

on the previous exposure level. At least some years of exposure are typically required for the symptoms to become chronic, even in heavily exposed occupations.

Diagnosis of solvent-induced CNS effects

The diagnosis of solvent-induced neuropsychiatric dysfunction mainly rests on the clinical evaluation of the previously mentioned symptoms and exposure history. The development of the symptoms is often insidious. Initially, the symptoms may disappear over weekends and holidays, but over a period encompassing years they will become chronic. In the end, they will typically be perceived by the individual and their relatives as a fundamental change in mental status and personality.

Patients will complain about changes in their ability to work, to participate in social activities, to function sexually, and to manage relationships. They do not remember what to bring or where to go; they stop participating in organized activities and playing music or cards or doing other hobbies which they used to enjoy and in which they may have been skilful. They may be accompanied to the physician by a spouse because they have severe memory deficiencies and because they are afraid.

It is vital that the examining physician inquires about such functional changes, professionally and socially, to elucidate the cognitive and personality changes that have occurred, often over a period of years. The diagnosis of a solvent syndrome is clinical, and is based on a thorough exploration of the intellectual, memory, and affective changes, from the premorbid personality, that has caused the patient to seek medical advice.

Some of the symptoms, such as memory problems and concentration difficulties, may also be demonstrated as an impairment in the corresponding functions assessed in neuropsychologic tests. Such tests were originally developed to measure mild forms of brain damage, and have been widely used in the diagnosis of early stages of dementia. The neuropsychologic test batteries in common use measure several functions thought to be sensitive to neurotoxic exposures (non-hold tests) and some functions that are considered insensitive or less sensitive (hold tests). The latter type of tests are used to evaluate premorbid neurobehavioral function, assuming that the original level was the same in all functions. The assumption is based on dementia testing, but may be highly variable on an individual basis. There has been a fair correlation between the results in tests measuring different types of intellectual functioning. The use of different test batteries in epidemiologic studies has created some difficulties in the interpretation of results. Therefore, the World Health Organization has developed a test battery suitable for the detection of group differences in working populations, as well as development of entirely computerized test batteries.¹⁷

The demands put on a test battery for clinical purposes may be different than those on a battery used for assessing group differences. The test battery in clinical use should not only discriminate exposed and non-exposed individuals, but should also assess as many functions as

possible to provide a profile of the abilities and deficits of a given individual. A basic requirement for tests used in clinical practice is the existence of reference data to enable the comparison with a healthy population without neurotoxic exposures of the same age, social class, and gender. The tests used in Scandinavian countries cover at least the verbal ability (hold tests), cognitive non-verbal functions (often unchanged by exposure), psychomotor function (non-hold test), perceptual speed (non-hold tests), and short-term memory (non-hold tests). A number of tests that are used in Scandinavia and the United States in the clinical evaluation of individuals with suspected solvent-induced neuropsychiatric disorders are listed in Table 40.4.

It is important that the tests are performed and interpreted by an appropriate trained neuropsychologist or psychologist. The evaluation of the premorbid functioning in relation to the present, within the different functions measured and between hold tests and non-hold tests, may be subtle and requires experience (see Chapter 28.1).

The ability of several other methods to predict the diagnosis of solvent-induced changes has been assessed in different studies; the results are in general discouraging. Although differences have been detected between exposed and non-exposed groups, and between persons with and without the diagnosis, this diverse group of tests, including electroencephalographic studies, computed tomographic scans, magnetic resonance tomography of the brain, liquor proteins, regional cerebral blood flow, and evoked potentials, have been difficult to interpret. The group differences are too small and the interindividual differences too large for these methods to be of value in an individual case.

The vertigo experienced by many long-term solvent-exposed workers is a feeling of unsteadiness and movement. Solvent-induced disturbances in the vestibulo-oculomotor system may often be the origin of such symptoms. Solvent-

Test types	Examples of tests
Hold tests	Verbal comprehension vocabulary (WAIS) Similarities (WAIS) Synonyms
Semi-hold tests	Cognitive non-verbal function. Block design (WAIS) Picture completion (WAIS) Figure classification
Non-hold tests	Psychomotor function simple reaction time (WHO) Santa Ana (WHO) Purdue peg board Pursuit aiming (WHO) Perceptual speed Digit symbol (WAIS, WHO) Trail making Short-term memory Benton visual retention (WHO) Digit span (WAIS WHO)
WAIS denotes that the test is included in the Wechsler Adult Intelligence Scale. WHO denotes that the test is included in the WHO neurobehavioral core test battery

exposed workers, particularly those with toxic encephalopathy, have shown rather pronounced disturbances in vestibulo-oculomotor functioning. However, methods to measure vestibulo-oculomotor malfunction seem also to provide little help in the diagnosis of individuals.

Exposure evaluation

Exposure evaluation is crucial in the diagnosis of solvent-related central neurologic syndromes. Solvent exposure may occur in many occupations, but there are large quantitative and qualitative differences between the exposure conditions in different jobs, companies, and countries. Lipid-soluble solvents, such as the common aromatic, aliphatic, and chlorinated hydrocarbons, are much more likely to cause chronic central nervous system effects than are the more water-soluble solvents, such as the common alcohols, ketones and esters.

A thorough evaluation of lifetime solvent exposure is crucial in the assessment of a patient with possible solvent-induced changes. The evaluation should concern all exposed employment, as well as specific work hygiene conditions, and all hobby-related exposures (see Chapter 3). Jobs that are associated with high solvent exposures are listed in Table 40.3.

Even in heavily exposed jobs, the worker is usually solvent exposed during only part of the workday, and may not be exposed during some periods. Others have large amounts of overtime, or an additional job where they are heavily exposed. The exposure level is usually dependent on the size of the area from which the solvent may evaporate and the temperature. Solvent uptake is modified by the workload and respiratory rate, the use of respirators and gloves, and the availability of engineering and ventilation controls. To evaluate particularly heavy exposures, it is useful to ask about the occurrence and frequency of symptoms of acute intoxication, including light-headedness and feelings of inebriation. Many painters, floor layers, and paint manufacturing workers have fainted on their jobs because of intoxication. In some instances, the exposure evaluation may be challenging, and collaboration with a trained industrial hygienist may be warranted.

Syndromes associated with solvent exposure

The following is a classification of solvents syndromes, with some modifications, agreed on in two international meetings in 1985.¹⁸

1. Type I: Symptoms only. The patients have non-specific symptoms of fatigue, memory and concentration disturbances, affective changes, and sleeping problems. Psychometric tests show no impairment. The symptoms are most often reversible within 6 months and always within 1 year after discontinuation of exposure.
2. Type IIa: Personality or mood change. There is a marked and sustained alteration in personality with obvious affective changes such as increased depressivity or aggressivity, fatigue, diminished impulse control, and decreased motivation. Psychometric test results are usually normal. It is unclear to what degree these symptoms are reversible.

3. Type IIb: Impairment in intellectual function. There is difficulty in concentration, impairment in memory, and decreased learning capacity. There may also be minor neurologic signs. Psychometric test results are affected. After the discontinuation of exposure, this syndrome may remain stationary or improve. Progression should not be expected.
4. Type III: Dementia. This condition involves global deterioration in intellect and memory and is often accompanied by neurologic signs. Psychometric test results are severely affected. This syndrome is caused by repeated, severe overexposure and is not reversible after discontinuation of exposure. Non-occupational etiologies include glue sniffing.

It is assumed that progressively higher exposure levels are required to elicit the syndromes from types I to III, but the relative importance of peak exposures versus cumulative exposure, the importance of age when the exposure occurs, and other factors are not well characterized. However, the cumulative exposure, as summed up in exposure months, is often related to the severity of the changes and may be used in the clinical evaluation. Clinical experience indicates that heavier exposures may have a relatively greater influence on brain function than lower exposures.

In the authors' experience, the Type IIa syndrome is not well delineated from Type IIb. The patients usually have complaints concerning intellectual functions and personality and mood changes, but only some of the patients show changes in neuropsychologic test results. In Scandinavia, the Type IIb syndrome, which requires changes in neuropsychologic test findings, has been labeled a chronic toxic encephalopathy. To diagnose a type IIb syndrome, a significant impairment, compared with the appropriate reference values, in at least two functions (e.g., memory, perceptual speed and accuracy, and psychomotor performance) is required, together with smaller differences in verbal ability.

In Sweden there is consensus on some diagnostic requirements concerning a chronic toxic encephalopathy (Type IIb syndrome) elicited by solvents; these are (1) long and/or intense exposure to solvents (often of many years duration), (2) relevant symptoms as described above, and (3) consistent changes on neuropsychologic testing in settings where exposure data are available. Long and intense exposure may be assumed to have occurred if average 8-hour exposure over at least 10 years has corresponded to more than 250 mg/m³ of painters' naphtha (or equivalent exposure to other lipophilic solvents). In Sweden, such exposures were common among painters until the mid 1970s.

Time course and prognosis

The symptoms and neuropsychologic impairment seem to progress as long as the solvent exposure continues. After discontinuation of solvent exposure, symptoms of psychological distress are often alleviated, although full recovery is seldom achieved. The impairment in neuropsychologic tests commonly remains stationary. Progress is not to be expected, either for symptoms or for neuropsychologic test results.¹⁹

Differential etiologies and differential diagnoses

The symptoms produced by long-term solvent exposure are common in everyday life. They may be elicited by a wide variety of psychologic and psychosocial factors and by different neurotoxic exposures. They may also occur without any immediately apparent reason. The time of occurrence is crucial in determining whether or not the symptoms are the result of solvent exposure. The chronic symptoms associated with solvent-induced CNS injury may develop with a concomitant feeling of change in the perception of oneself and the environment after a prolonged exposure to solvents for several years.

Symptoms and neuropsychologic impairment may occur as a consequence of excessive alcohol consumption. In settings of concurrent solvent hepatotoxicity, the pattern of hepatic enzymes may be useful, AST/ALT ratio is atypically less than in alcohol-related hepatitis (see chapter 26.1). Moreover, alcoholism will usually be apparent if the patient is followed over some period. Depression may result in a clinical syndrome similar to solvent-induced encephalopathy; it may be differentiated from the solvent-induced syndrome by its rather sudden reversibility within a certain period. Depression associated with chronic encephalopathy is usually more severe, and less responsive to antidepressant therapy. Evidence of cognitive impairment disproportionate to that which occurs in depression is also helpful in diagnosing a solvent-induced effect.

It is reasonable to presume interactive effects. The presence of these conditions does not, by itself, exclude solvents as a contributing cause of the disorder. Previous meningitis or encephalitis and previous head trauma with loss of consciousness may also produce chronic encephalopathy. It is thus important that the patient interview covers such causes. Other differential diagnoses involve ischemic brain disease, brain tumors, and presenile and senile dementia. These causes may be identified by laboratory evaluations such as electroencephalography, computed tomographic scans, evoked potentials and magnetic resonance imaging (MRI). The time course of presenile and senile dementia is also different from that of solvent-induced encephalopathy, with a progressive and often rapid, deterioration of intellectual functions. If the diagnosis is uncertain, neurologists and psychiatrists with experience in psycho-organic syndromes and their differential diagnoses should be consulted.

Treatment

Cognitive therapy may be useful in selected individuals though results are often disappointing. Patients with chronic toxic encephalopathy offered a 10-week rehabilitation program involving intellectual training, with particular emphasis on memory and group discussions, experienced an initial significant improvement in symptoms and neuropsychologic test results measuring memory. While a continuing improvement in emotional symptoms was still present at 6 months, cognitive and somatic symptoms had returned to the original level. Only tests associated with verbal memory continued to show improvement. In a recent follow-up 7 years after the rehabilitation program, substantial improvement was found with respect to social functioning and

stress-related symptoms among patients who had participated, as well as not participated, in the program. In neither of the groups was there any improvement in neuropsychologic tests. Thus this particular program did not show a sustainable effect.¹⁹

However, too little effort has been devoted to the treatment of chronic toxic encephalopathy. Although the identification of neurotoxic hazards implies that primary prevention is achievable, and thus is the most important aim of occupational health studies, it is important not to ignore the potential for rehabilitation for those with a chronic work-related disease. Methods obviously need to be developed to improve the rehabilitation of patients with central nervous dysfunction related to solvent exposure, and there is a need for further studies to evaluate the effect of rehabilitation programs. Early retirement should be the last option and should only be considered when work rehabilitation has failed, or in very severe cases.

Additional CNS effects

Solvent exposure may decrease olfactory function at exposure levels below current hygienic standards in industrialized countries. The specific site of the action is unknown, although it has been speculated that the olfactory neuron is the target. It has also been shown in experimental studies that aromatic solvents may induce hearing loss. It is unclear whether these findings have clinical relevance at current exposure levels in industry; however, interaction with noise-induced hearing loss is a concern. It also seems likely that solvent exposure may impair color vision. Various studies have suggested that solvent exposure may contribute to many other disorders such as multiple sclerosis, Parkinson's disease, Alzheimer's disease and epilepsy, but several studies have failed to confirm these results.

Some studies have suggested an excess of alcoholism diagnoses in solvent-exposed occupations, and studies of toluene-exposed printers and animal experiments indicate that solvent exposure may contribute to excess alcohol consumption, possibly through a desire either to avoid withdrawal from or to prolong the acute central nervous system effects of occupational solvent exposure.

Peripheral nervous system

Some studies performed on groups exposed to mixed solvents have indicated impaired peripheral nerve functioning, as evidenced by group differences in some electrophysiologic variables. Jet fuel may be particularly prone to induce a mild neuropathy. However, the effects of mixed solvents seem to be subclinical in the large majority of exposed workers, and some studies have been unable to demonstrate such an effect. The effects of n-hexane, methyl-n-butyl ketone, styrene, and toluene on the peripheral nervous system are discussed in the section on the effects of specific agents.

Liver

A number of halogenated solvents are classic hepatotoxins (see Chapter 26.1). The 1,1,2,2-tetrachloroethane used in

the aeronautics industry during World War I caused employees to develop jaundice with subacute hepatic necrosis developing over a period of weeks. Carbon tetrachloride and chloroform will be discussed in the section on the effects of specific agents.

Several epidemiologic studies have been performed to determine the hepatotoxicity of long-term exposure to such solvents. Most of these studies are cross-sectional and use routine hepatic enzymes as the outcome. These studies have reported variable results with mixed solvent exposure; a number of studies have demonstrated elevations in serum bile acids. Some recent studies suggest that fatty liver disease, not reflected by liver enzymes, may occur as an effect of solvent exposure,^{20,21} but further confirmation is needed. The interaction between common solvents and other agents that may render these solvents hepatotoxic has not been well characterized.

As a rule, hepatic effects from solvents are avoided if the hygienic standards are respected, and hepatic effects should not readily be anticipated if neuropsychiatric effects are absent. Among patients with raised hepatic enzymes, suspected to be caused by solvents, removal from exposure for a 2–4-week period may play a useful diagnostic and therapeutic role (see Chapter 26.1).

Kidney

For many decades, it has been known that certain solvents, particularly chlorinated compounds like carbon tetrachloride, as well as ethylene glycol, may induce renal failure in humans after acute exposures through a mechanism of acute tubular necrosis. Acute solvent intoxication from a number of common solvents has been associated with renal failure in case reports. Several cross-sectional studies have found increases in the excretion of glomerular or tubular proteins, erythrocytes, and enzymes in groups exposed to common solvents and solvent mixtures. In aggregate, these studies have not localized a unique anatomic lesion. In recent years, most of the interest concerning solvent nephrotoxicity has been devoted to the possible induction of glomerulonephritis (see Chapter 25). Case referent studies have demonstrated a significant association between solvent exposure and glomerulonephritis, while some epidemiologic studies have not demonstrated an association. A low power to detect small increases in the relative risk associated with this uncommon condition has likely contributed to this discrepancy.

In patients in whom occupational causes of proteinuria have been ruled out, it is important to interview them concerning their solvent exposure.

Circulatory system

Among those who abuse solvents for their inebriating properties, there has been an excess of sudden deaths during the intoxication. Experiments in dogs have shown that the likely reasons for these deaths are disturbances in the cardiac rhythm, which are mediated by norepinephrine. The solvents may make the myocardium more sensitive

toward endogenous norepinephrine or increase the amount of norepinephrine reaching the heart by decreasing its uptake and degradation. The effects have been seen only at very high exposure levels, and should not be expected in occupational settings unless significant intoxication is present. Carbon disulfide and methylene chloride have effects related to the function of the heart. These are discussed in the section on the effects of specific agents.

Blood

Benzene is a bone marrow toxin that may cause pancytopenia (see the following section on effects of specific agents). Ethylene glycol ethers have also been implicated in hypoplastic syndromes (see Chapter 21). Several studies have indicated that exposures to mixed solvents may induce some lymphocytosis in exposed compared with non-exposed populations, possibly as an effect of irritative effects and associated inflammation. The clinical relevance of this has not been characterized.

Carcinogenicity and mutagenicity

Benzene is a potent leukemogen. Several studies have demonstrated an excess risk of lung cancer and cancer of the bladder among painters. Based on an evaluation of these studies, the International Agency for Research on Cancer has considered painting an occupation at increased risk of cancer. A number of studies have also shown increases of non-Hodgkin's lymphomas and myelomas in occupational groups exposed to mixed solvents, though this association has not been well characterized. The risk for carcinogenicity associated with styrene, methylene chloride, trichloroethylene, perchloroethylene, carbon tetrachloride, and chloroform is discussed in the section on the effects of specific agents.

Reproductive effects

General information on reproductive and developmental effects is found in Chapter 27.2. Glycol ethers with short alkyl groups, 2-methoxy- and 2-ethoxyethanol are teratogenic and testicular toxins at rather low doses in experimental animals. This observation has entailed a shift to glycol ethers with longer alkyl chains in general industrial use.

It seems well established that high exposure to solvent mixtures among pregnant women will increase the risk of spontaneous abortions. Among specific solvents, the best evidence is available for toluene. However, decreasing occupational exposures in recent decades have likely resulted in reduced risk for spontaneous abortions. A number of studies have suggested that maternal and paternal exposure to mixed solvents may increase the risk of congenital malformations. However, no specific type of defect or syndrome has repeatedly been associated with solvent exposure. The summary evidence on effects of organic solvent exposure on female and male fecundity is so far inconclusive. Thus, several studies have suggested

that occupational organic solvent exposure during pregnancy may damage the fetus. Current hygienic standards are usually not based on the possibilities of reproductive effects, and it seems warranted to keep solvent exposure of pregnant women far below these standards.

Specific agents

This section will mainly address specific effects of individual solvent compounds. Irritant effects and effects on the skin will not be discussed, although the agents listed certainly share such effects with other solvents. Similarly, the solvents listed may elicit the same central nervous symptoms as described in previous sections in this chapter.

n-Hexane and Methyl-n-butyl ketone

During the 1960s and early 1970s, several outbreaks of polyneuropathy were described among shoe and leather workers in countries that used glues containing n-hexane. The workers developed glove and stocking symmetric sensory dysfunction in the hands and feet, with the feet normally being affected first. In more severe cases, motor function was also affected, manifested by proximal muscular weakness. The air concentrations of n-hexane in these cases were high, with average exposures above 100 ppm. Occupational groups with lower exposure, 20 ppm and above, have shown indications of a subclinical polyneuropathy manifested as mean value decrements in neurophysiologic test results, including nerve conduction velocities. Symptoms of polyneuropathy have also been described among workers exposed to methyl-n-butyl ketone. The cases show sensory impairment with loss of superficial pain, sensitivity to temperature change and diminished light touch and vibration in the toes. Methyl ethyl ketone is not thought to be toxic to peripheral nerves by itself, but may potentiate the effect of n-hexane and methyl-n-butyl.

Animal experiments have shown that the peripheral neurotoxicity of n-hexane and methyl-n-butyl ketone is caused by a common metabolite, 2,5-hexanedione. In fact, it has been shown that other diketones with the same distance between the ketone groups share this ability to damage peripheral nerves. These metabolites appear to cause a disturbance in the axonal transport in large myelinated fibers. Nerve biopsy specimens show axonal swelling followed by myelin retraction at the nodes of Ranvier, and masses of neurofilaments in the axons. Axonal degeneration starts distally.

If signs of polyneuropathy are present, the most important treatment is removal from exposure. After discontinuation of exposure, recovery occurs slowly, reflecting the regeneration of peripheral nerve axons. Residual permanent impairment has been noted in severely injured individuals. It has been possible to find substitutes for methyl-n-butyl ketone in almost all applications, and the use of this solvent should be limited.

Benzene

Heavy benzene exposures are known to induce pancytopenia (see Chapter 21). The first account of this association

was published in 1897²² and described four female workers who died from aplastic anemia after a few months of benzene exposure. Since then, a vast number of case reports have been published. It is unclear if the granulocytes, erythrocytes, or platelets are differentially susceptible to benzene. Pancytopenia is typically dose dependent and is unlikely to appear until the time-weighted average exposure levels have reached at least one order of magnitude above the current hygienic standards in industrialized countries.

Benzene is an established human carcinogen. The first case reports on the association between benzene exposure and leukemia were published in 1928. During the 1960s and 1970s, large series of cases of leukemias among benzene-exposed workers were published, and these reports later were confirmed by convincing epidemiologic and experimental evidence.

It was previously believed that benzene induced acute myelogenous leukemia only, but more recent studies have strongly indicated that other forms of leukemia and lymphomas may be caused by benzene exposure. Exposure-response calculations in recent studies have suggested that benzene may pose a significant cancer risk at low exposure levels. Exposure to 1 ppm of benzene, 8 hours per day, 5 days per week during 40 years was in one study estimated to increase the risk of leukemia by about 70%.²³ The US EPA currently estimates the lifetime risk of cancer associated with exposure to 1 ppm of benzene to range from 7.1×10^{-3} to 2.5×10^{-2} .²⁴ The time from first exposure until the diagnosis of the tumor is shorter, 10 years on average, for benzene-induced leukemias than for most other occupational cancers.

There are no well-validated screening tests for early diagnosis of benzene-induced hematopoietic malignancies. To monitor exposed populations, cytogenetic methods may be used. Benzene induces chromosomal aberrations in peripheral blood lymphocytes. A recent study has shown that a time-weighted average exposure of 0.3 ppm may induce an increased number of micronuclei in peripheral blood B-lymphocytes.

Benzene-induced tumors are not known to have distinct features. They are diagnosed and treated in the same way as are the same tumors induced by other causes. Restriction from further benzene exposure is essential in diagnosed cases.

Toluene

Toluene is used as a sniffing agent, and several case series have been published of symptoms and signs among long-term sniffers. Tremor, ataxia, and memory impairment are the most commonly encountered findings, but heart dysrhythmias (including death), decreased sense of smell, optic atrophy, hearing impairment, and peripheral neuropathy may also occur. In workers with long-term occupational exposure, there is an increase in neuropsychiatric symptoms.²⁵

Styrene

Styrene may induce a mild neuropathy predominantly of a sensory type, as evidenced by sensory nerve conduction

velocities. The neuropathy may manifest itself as increased pain and tingling in the limbs, although the effects at time-weighted average air concentrations around 100 ppm and below are typically subclinical. The effects seem to be largely reversible over a period of 4 weeks. Styrene is suspected of being carcinogenic based on the fact that its metabolite, styrene oxide, is an established carcinogen. However, styrene oxide seems to be readily degraded in humans. Cytogenetic effects have been found in workers exposed to comparatively low levels of styrene, i.e., around 25 ppm. There are a few animal carcinogenicity studies with somewhat contradictory results. Epidemiologic studies carried out in the glass-reinforced plastics industry, in which styrene exposures are highest, have been inconclusive to date. The International Agency for Research on Cancer has concluded that styrene is possibly carcinogenic to humans (group 2B).²⁶

Methylene chloride

Methylene chloride is metabolized to carbon monoxide. The hygienic standard for carbon monoxide has been set to avoid carboxyhemoglobin (COHb) levels above 5%, because such levels have been reported to increase ischemic symptoms among patients with angina pectoris. Exposures to 100 ppm of methylene chloride may produce COHb levels just above 5%. However, the biotransformation to COHb becomes saturated if the exposure exceeds 250 ppm, and COHb levels above 10% among non-smokers are unlikely to be the result of methylene chloride exposure. The epidemiologic studies performed thus far have found an incidence of heart disease in methylene chloride exposed workers that is comparable to the incidence in the control populations. Methylene chloride causes several types of tumors in experimental animals, and the evidence for carcinogenicity was considered sufficient by the International Agency for Research on Cancer. However, the few epidemiologic studies carried out so far have shown inconclusive results for classification as a Group 2B agent (possibly carcinogenic to humans).²⁷

Carbon tetrachloride and chloroform

The use of carbon tetrachloride as a solvent has been accompanied by numerous case reports of hepatotoxicity, including hepatic and renal necrosis. Chloroform is also, hepatotoxic although at higher doses. It has been shown that the hepatotoxicity of these solvents is caused by the metabolic activation with formation of reactive metabolites that attack macromolecules in the hepatocytes, as well as lipid peroxidation.

These solvents interact with agents capable of inducing the microsomal enzyme system of the liver. Accordingly, barbiturates and alcohol may potentiate the hepatotoxicity. There is also a convincing report of an interaction between occupational exposure to isopropyl alcohol in conjunction with carbon tetrachloride. Usually, the hepatic effects resolve after discontinuation of exposure, depending on the degree of injury.

After heavy short-term exposures, carbon tetrachloride may induce renal failure in humans as a result of acute

tubular necrosis. Carbon tetrachloride causes hepatic cancer in animal experiments, and cases of hepatic cancer have also been described in exposed humans. It is possible that the carcinogenicity of carbon tetrachloride is associated with its potential to induce toxic hepatic damage. Chloroform causes hepatic and renal tumors in rodents. The acute solvent toxicity to these tissues might contribute to the carcinogenicity.

Trichloroethylene

In a classic study published in 1955, Grandjean and coworkers showed an increased prevalence of neuropsychiatric symptoms with increasing exposure among workers exposed to trichloroethylene in the mechanical engineering industry.²⁸ They also diagnosed a psychorganic syndrome characterized by intellectual impairment with memory deficiencies and affective changes. A strong exposure-response relationship was observed with the prevalence of this syndrome increasing at higher exposure levels. The authors concluded that the prevalence of neuropsychiatric symptoms and signs was definitely increased at exposure levels above 40 ppm.

Trichloroethylene exposure at high concentrations may induce trigeminal neuropathy with facial numbness and weakness of the masticatory muscles. In fact, this observation led to the unsuccessful use of trichloroethylene as a remedy for trigeminal neuralgia. However, trigeminal neuropathy does not seem to occur at the exposure levels currently prevalent in industrialized countries.

There are a few case reports of serious hepatic injury after occupational exposure to trichloroethylene and methyl chloroform. Trichloroethylene can interfere with alcohol metabolism in the liver. Flushing of the face and neck and severe nausea are induced if alcohol is ingested in conjunction with high exposure to these solvents. Accordingly, the clinical picture mimics the effects of the drug disulfiram (Antabuse).

There is significant evidence of the carcinogenicity of trichloroethylene in experimental animals. In humans three highly relevant cohort studies have demonstrated an excess incidence of liver and biliary tract cancers as well as non-Hodgkin lymphomas. The IARC has concluded that trichloroethylene is group 2A (probable human carcinogen).²⁹

Perchloroethylene

Women working in laundries and dry-cleaning jobs seem to have an increased risk of primary hepatic cancer. Exposure to chlorinated solvents, particularly perchloroethylene, is a likely cause. Several studies have also shown excesses of non-Hodgkin lymphomas, esophageal and cervical cancers among perchloroethylene-exposed workers. The IARC has classified perchloroethylene as probably carcinogenic to humans (group 2A) based on sufficient evidence in experimental animals and limited epidemiological evidence.²⁹

Methanol

Methanol may damage the retina and induce blindness after ingestion of sufficient amounts. Occupational exposure,

however, does not seem to induce ocular toxicity because the bioavailability by the inhalation route is not sufficient for this effect to occur.

Ethylene glycol

Ethylene glycol may induce acute tubular necrosis and renal failure in humans after ingestion. However, this effect has not been seen after occupational exposures because the low volatility of the compound precludes sufficiently high air exposures.

Carbon disulfide

Carbon disulfide has pronounced central nervous system effects. Psychoses are well-described among heavily exposed workers. Exposure to carbon disulfide may also contribute to the development of Parkinson's disease. Decreased libido and loss of potency have been repeatedly reported among exposed men.³⁰

Exposure to carbon disulfide has been shown to increase the incidence of myocardial infarction in several studies (see Chapter 24). Carbon disulfide alters fat metabolism and increases arteriosclerosis. A successful preventive program directed toward carbon disulfide-induced coronary disease was instituted in a Finnish viscose rayon plant.³¹ In the early 1970s, the carbon disulfide concentrations in the plant were lowered from 30 ppm and above to 10 ppm, and workers with coronary risk factors were removed from exposure. Because of these measures, the previously heavily elevated coronary mortality rate was reduced to levels in the general population by 1980, with an estimated 40 lives saved among a cohort of 343 men.

Dimethylformamide

There are several recent reports on the hepatotoxicity of dimethylformamide, which currently seems to be the most widely used of the hepatotoxic solvents. The hepatotoxicity of dimethylformamide depends on metabolic activation. This solvent is easily absorbed through the skin, which makes it particularly dangerous. Usually, the hepatic effects resolve after the discontinuation of exposure. Dimethylformamide may also interfere with alcohol metabolism in the liver. Severe nausea and flushing of the face and neck may occur if alcohol is ingested in conjunction with exposure to this solvent. Accordingly, the effect is similar to that of the drug disulfiram.

Tetrahydrofuran

Tetrahydrofuran is a common component of glues and may produce hepatic and renal damage at high concentrations.

Ethylene oxide

Ethylene oxide is a gas at room temperature and is a highly reactive agent. It irritates the respiratory tract and the skin, and may induce allergic contact dermatitis. High exposures greater than 500 ppm have induced peripheral neuropathy. Ethylene oxide is mutagenic in bacterial test systems and animal experiments. Cytogenetic studies in humans have shown dose-related chromosomal changes. Ethylene oxide is carcinogenic to experimental animals,

with leukemia and brain cancer being induced in a dose-related manner. In epidemiological studies, the most frequently reported association has been with lymphatic and hematopoietic cancer; stomach and breast cancer excesses have also been reported. The International Agency for Research on Cancer²⁶ considers ethylene oxide carcinogenic to humans, based on limited evidence in humans and sufficient evidence in experimental animals.

BIOLOGIC MONITORING

For some common solvents, the solvent itself or some metabolite may be measured in end-exhaled air, blood, or urine to monitor the amount of the solvent taken up by the body. Biologic monitoring has advantages compared with air-concentration measurements because it accounts not only for the respiratory uptake at rest, but also for the workload and uptake through the skin. Biologic monitoring may also be used to assess the function of personal protective equipment. However, the common use of biologic monitoring is still as an alternative to air-exposure measurements, and the following comments will mostly concern such practice.

Inhalation exposure and uptake may vary considerably from day to day as well as within shift, due to fluctuation of the solvent concentration in air. Concentrations in the biologic determinants (i.e., the solvent or its metabolite) change in a similar fashion. Therefore, determinants with short biologic half-life indicate current or very recent exposure, while determinants with long half-life indicate the integrated exposure over an extended time period. These conditions are important to remember when interpreting results of biologic monitoring.³²

Table 40.5 lists the solvents for which the ACGIH has proposed or is considering biologic exposure indices (BEI), i.e., a biologic standard intended to measure approximately the same exposure level as the threshold limit values proposed by the ACGIH. However, the BEIs themselves are not shown because proposed standards vary by country and tend to shift substantially over time. To obtain currently acceptable limits, the reader may refer to the standards published by the health and safety authorities in each country.

It seems that urinary metabolites of trichlorethylene and styrene provide the most commonly used biologic indicators of solvent exposure. Usually, the combined urinary excretion of mandelic acid and phenylglyoxylic acid gives a better estimate of the preceding styrene exposure than any of these styrene metabolites separately. However, mandelic acid is often used alone and is an acceptable indicator of styrene exposure at low exposure levels. Measurements of styrene in the blood or exhaled air show large interindividual differences and should not be used to quantify the exposure.

Trichloroethanol and trichloroacetic acid are excreted in the urine after trichloroethylene exposure. Trichloroacetic acid has a long half-life, around 3 days, and will integrate the exposure over several days. Trichloroethanol has a much shorter half-life and may give a reasonable estimate

Solvent	Indicator	Comments
n-Hexane	2,5-Hexanedione in urine	Exposure quantitation at low exposures
Benzene	S-Phenylmercapturic acid in urine	Background level
	Muconic acid in urine	Background level
Toluene	Hippuric acid in urine	Non-specific, insensitive. Toluene exposures around 100 ppm needed to mirror exposure
	Toluene in blood	
	O-cresol in urine	Background level
Xylene methyl	Hippuric acid in urine	Exposure quantitation at low exposure
Styrene	Mandelic acid	Non-specific
	Phenylglyoxylic acid in urine	Exposure quantitation at low doses
	Styrene in blood	Exposure quantitation at low doses
Trichloroethylene	Trichloroethanol and trichloroacetic acid in urine	Indicator of exposure
	Free trichloroethanol in blood	Non-specific, exposure quantitation at low doses
	Trichloroethylene in blood and end-exhaled air	Non-specific indicator of exposure
Methyl ethyl ketone	Methyl ethyl ketone in urine	
Carbon disulfide	2-Thiothiazolidine-4-carboxylic acid in urine	
Dimethylformamide	N-methylformamide in urine	
	N-Acetyl-S-(N-methylcarbamoyl) cysteine in urine	Indicator of exposure
Methyl chloroform	Methyl chloroform in end-exhaled air	Large interindividual variation
	Total trichloroethanol and trichloroacetic acid in urine	Large interindividual variation, non-specific indicator of exposure
		Non-specific
Perchloroethylene	Total trichloroethanol in blood	
	Perchloroethylene in end-exhaled air	
	Perchloroethylene in venous blood	
	Trichloroacetic acid in urine	Large interindividual variation. Non-specific indicator of exposure
Acetone	Acetone in urine	Non-specific
Chlorobenzene	Total 4-chlorocatechol and total p-chlorophenol in urine	Non-specific
	2-Ethoxyacetic acid in urine	
2-Ethoxyethanol and 2-ethoxyethyl acetate		
Ethyl benzene	Mandelic acid in urine	Non-specific
Methanol	Methanol in urine	Non-specific, background level
Methyl isobutyl ketone	Methyl isobutyl ketone in urine	

Table 40.5 Biologic monitoring of solvents

of the exposure during a particular shift. The combined excretion of the metabolites has also been suggested to estimate the exposure.³³

Hippuric acid is a toluene metabolite, but it is also a metabolite of benzoic acid. Thus, it is often present in the urine in significant amounts without any toluene exposure. Toluene exposures below 100 ppm could not be effectively quantified by hippuric acid excretion.³⁴ In the future, toluene in the venous blood may prove to be a successful method for biologic monitoring of toluene exposure.

Benzene exposure can be determined by analyzing phenylmercapturic acid in urine. The method is sensitive and can detect even low-level environmental exposures. Although exhaled air analysis, in general, is unreliable for exposure quantification, it seems that benzene levels in exhaled air currently are the best estimate of benzene exposure.

Methyl hippuric acids are specific metabolites of the corresponding xylene isomers. They give a reliable estimate of xylene exposure. However, because the xylenes are usually used in solvent mixtures, the practical use of this indicator has been limited.

MONITORING OF EXPOSED GROUPS

Most solvents share the ability to irritate mucous membranes and to affect the central nervous system and the skin. In general, the monitoring of exposed groups should focus on these effects. Skin problems are easily diagnosed, and the exposure conditions causing the damage are often apparent. However, subtle effects on the central nervous system are not easily diagnosed. These effects cause vague and non-specific symptoms that generally lack objective correlates. Thus, questionnaires have been developed to monitor the solvent effects on groups of exposed workers.

The Swedish Q16 questionnaire, reproduced in Figure 40.4, is a simple 'yes or no' instrument containing 16 questions. It was developed from clinical experience with long-term solvent-exposed workers. Understanding of the questions was checked between exposed workers, physicians, and psychologists. The questions were investigated for reliability through test-retest procedures and for validity by showing the anticipated dose-response relationships in exposed and non-exposed groups. The intercorrelations

Questionnaire 16 (Q16)	
Question	Yes No
1. Do you have a short memory?	10. Are you less interested in sex than what you think is normal?
2. Have your relatives told you that you have a short memory?	11. Do you have palpitations even when you don't exert yourself?
3. Do you often have to make notes about what you must remember?	12. Do you sometimes feel an oppression in your chest?
4. Do you often have to go back and check things you have done such as turned off the stove, locked the door, etc?	13. Do you perspire without any particular reason?
5. Do you generally find it hard to get the meaning from reading newspapers and books?	14. Do you have a headache at least once a week?
6. Do you have problems concentrating?	15. Do you often have a painful tingling in some part of your body?
7. Do you often feel irritated without any particular reason?	16. Do you have any problems with buttoning and unbuttoning?
8. Do you often feel depressed without any particular reason?	
9. Are you abnormally tired?	

Figure 40.4: The Swedish Q16 questionnaire, developed from clinical experience with long-term solvent-exposed workers.

between the replies to the different questions were also checked. The Q16 has been used in several languages but is validated only in the Swedish version. Recent reports have shown that the Q16 is efficient in encephalopathy.³⁵ A review of the experiences of the Q16 from its use in different countries is available.³⁶

At present, the Q16 seems to be the best instrument available to monitor the solvent effects in groups exposed particularly to solvent mixtures. If an individual gives six or more yes replies, this should be considered an indication for an interview with a physician to elucidate the character and origin of the symptoms. If the symptoms have occurred after a period of heavy solvent exposure and there is no other obvious explanation, it may be reasonable to refer the patient to a occupational health department for further examination, including psychometric testing.

Apart from the effects on the central nervous system, it might be necessary to investigate the specific effects of some compounds. For example, carbon tetrachloride, chloroform, and dimethylformamide cause hepatic effects that may be monitored with conventional liver tests. These solvents are also nephrotoxic, and their nephrotox-

icity could be monitored with tests assessing tubular and glomerular functions (see Chapter 25). A few hexacarbon solvents may damage peripheral nerves at high concentrations, and monitoring for this effect may be appropriate. In general, however, compliance with present hygienic standards in industrialized countries should protect the large majority of exposed workers from such specific effects.

Chapter 41

Chemicals in the Plastics, Synthetic Textiles, and Rubber Industries

Steven Markowitz

PLASTICS INDUSTRY

Plastic materials are one of the fastest growing parts of the chemical industry in the United States. The industry produced 86 billion pounds of plastics in 2000 and experienced a 34% increase in production from 1967 to 2000. This industry employs 2% of the workforce in the United States and is geographically spread throughout the country in many thousands of plants that manufacture and process plastic resins and compounds. The plastics industry represents a \$330 billion economic sector.

Much of this industry's growth has been facilitated by rapid changes in plastics technology, which in turn enable increasingly diverse uses of plastics materials. Although the bulk of plastics is used in packaging and consumer products, newer uses of plastics are being developed, especially in building and construction, in which more than 20% of all plastics is currently used. Plastic materials have significantly displaced glass and wood for many industrial and commercial purposes and are rapidly encroaching on the traditional domain of numerous metals.

The prominence of the plastics industry necessarily has important ramifications for occupational health, especially in terms of the size of the exposed population and the nature and range of potential exposures. In 2000, the plastics industry employed 2.4 million workers in approximately 21,000 establishments in the United States. The majority of these workplaces and their workers are involved in processing plastics and in the fabrication of products, with many fewer involved in transforming basic materials into plastic resins. This workforce is potentially exposed to thousands of chemical substances that are used in the production and modification of plastics. Like most chemical substances in the workplace, many of the chemicals used to make plastics have not been fully evaluated for toxicity. Hence, the clinician is faced with an increasingly daunting task of understanding the relationship between the health problems of workers and their complex and frequently unstudied occupational exposures.

It is necessary, therefore, to use a sound general approach in the evaluation of workers and others who may be exposed to chemical agents in the formation, processing, and combustion of plastics. Such an approach requires a basic understanding of the plastics industry, recognition of the opportunities for exposure to various toxins, knowledge of the well-documented serious hazards in the industry, and finally, an appreciation of the relative deficiency

in the current scientific database on the potential health effects of plastics materials.

The production of finished plastic pieces has three principal components: (1) the synthesis of plastic polymers, (2) the mixing and compounding of additives to the resin material, and (3) the conversion of the compounded polymer into useful products (Fig. 41.1). These components are achieved in different and distinct processes, use largely different sets of materials, and usually occur at different worksites. Hence, although there may be some overlap in hazards that are related to these components of the plastics industry, sufficient differences exist to warrant recognition of the specific hazards that accompany each.

The manufacture of the plastic polymer is achieved by converting basic raw materials (which are simple organic chemicals, usually derived from petroleum fractions) from the monomeric state to the relatively pure polymer, which is called a resin. A monomer is a low molecular weight molecule with the capacity to combine covalently with itself to form a repeating chain, termed a polymer. The resultant high molecular weight polymer consists of a backbone with attached side groups of radicals. Polymers vary in the chemical nature of their backbone and side groups and, thereby, have different properties. Other factors, such as the distribution of molecular weight, degree of crystallinity, and extent of cross linking between polymer chains, also determine the physical properties and, therefore, potential utility of plastic polymers. Two or more different monomers can be reacted in different combinations, usually in the presence of a catalyst, such as an organometal compound, to form a copolymer.

The first phase of production of plastics, polymerization, is usually achieved in large-scale operations performed in closed systems (Fig. 41.1). The exposure may be to the raw materials, the chemical intermediates, the catalysts, or the polymer products. Significant exposure to plastic monomers is, for the most part, restricted to this phase of plastics manufacturing. Workers employed in this phase of the industry experience a variable degree of exposure, depending on the age and capitalization of the plant and the type of job performed by the worker. The resins produced in this industry are usually formulated into pellets, granules, or powders for shipment to plants that compound and process the resin.

Plastic resins are usually mixed or compounded with additives to acquire added desired qualities in the second phase of plastics manufacture (Fig. 41.1). Although the

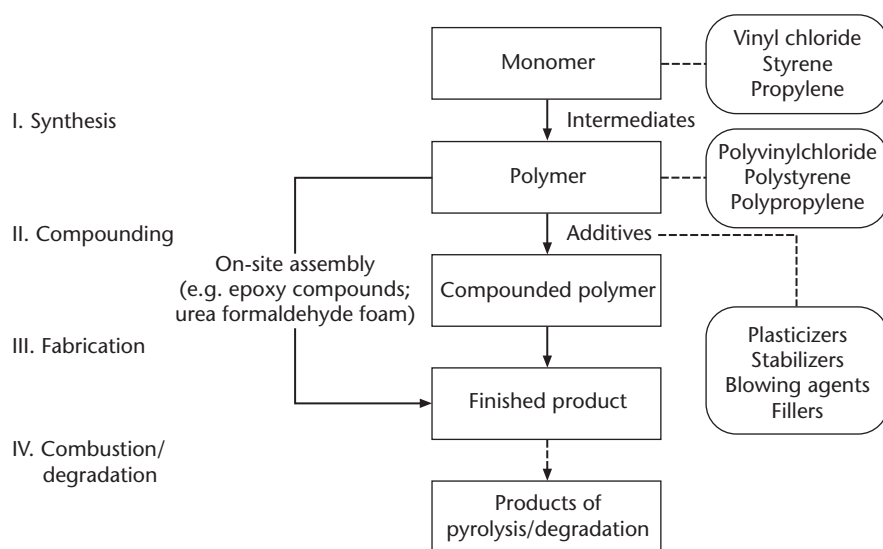

Figure 41.1: General paradigm for plastics production, fabrication into products, and degradation.

chief health concerns in this phase center on the potential hazards associated with the additives, exposure to the polymer and residual monomer leaching from the polymer should not be neglected. These additives include plasticizers to enhance flexibility, fillers to provide bulk, reinforcers to lend strength, blowing agents to act as a foaming mechanism, impact modifiers to improve strength and process ability, stabilizers to prevent thermal degradation and oxidation, antistatic agents to reduce friction and/or electrical charges, and others with self-explanatory functions, such as flame retardants, catalysts, lubricants, and colorants. By the tonnage used, the major additives are fillers, reinforcing fibers, and plasticizers, which account for more than 75% of the total volume of additives.

Additives are principally divided into two groups: (1) fillers and reinforced fibers, which are usually minerals and metals, and (2) chemical additives, which most often involve organic chemicals. The major fillers in order of the quantities used include calcium carbonates, kaolin and other silicates, carbon black, and wood flour. More than three-quarters of all fillers are used in polyvinyl chloride and unsaturated polyester products. Fiberglass is the chief reinforcement fiber used in plastics. Among the chemical additives, phthalates, including diethylhexyl phthalate and diisodecyl phthalate, represent the most important plasticizers used, with additional limited use of epoxy compounds and organic phosphates. The major colorant is titanium dioxide pigment, with a much lesser role played by cadmium, chromium, and iron oxide. Among the organic pigments, phthalocyanine blue and phthalocyanine green are the most important agents.

The major stabilizers include, in order of importance, barium-cadmium soaps, lead compounds, organotin, and calcium-zinc soaps. The additives significantly expand the range of potentially hazardous exposures of workers in the plastics industry.

In the third phase of plastics manufacture, the transformation of compounded resins into finished products requires the application of heat and/or pressure to the

formulated materials, and subsequent shaping by molding, blowing, and other processes. Even in this final phase, workers in the plastics processing industry may be exposed to unreacted monomers, intermediates, or additives retained in the formulated resin materials. Overheating of resins may lead to the formation of combustion products that have not been fully characterized, but may be toxic. Finally, finishing processes, such as cutting and grinding of materials, may create polymer dust exposure; although this step of the plastics production industry has been traditionally considered the least hazardous.

Selected important plastics systems do not follow these orderly phases. The various components of finished epoxy resins and polyurethane foams (see subsequent sections) are often assembled and reacted at the site of use of the finished products. The potentially hazardous exposures presented by the agents involved may therefore not be restricted to a relatively circumscribed group of workers at centralized sites where conditions may be carefully controlled. Rather, the field use of these plastics may lead to uncontrolled occupational and environmental exposures to relatively large numbers of users who are unfamiliar with the attendant hazards.

Workers other than those directly employed in the plastics industry may have important exposures to plastics and related materials. Combustion products of plastics represent a major concern to fire fighters because residences and offices are increasingly filled with these products. Users of plastics products, such as food wrappers, are exposed to combustion products, such as hydrogen chloride and phosgene, and have developed respiratory disease as a result. The hazards inherent in the use of plastics materials are clearly not confined to the plastics industry workforce.

Table 41.1 lists the most important plastic polymers and synthetic textiles in the order of the volume currently produced in the United States. Plastics are broadly categorized as thermoplastics, which can be reprocessed, and thermosets, which are chemically altered with application of heat and, therefore, cannot be reheated without losing

Polyethylene
 Polypropylene
 Vinyl chloride/polyvinyl chloride
 Fluoropolymers (Teflon)
 Epoxy resins
 Amino resins
 Acrylics (including acrylamide)
 Polyurethane
 Plastic additives
 Polyamides (nylon)
 Polyesters
 Rayon

Table 41.1 Major plastics and synthetic textiles

Organ/disease	Examples of agents
Skin	
Contact dermatitis (allergic and irritant)	Epichlorohydrin Formaldehyde
Vitiligo	Hydroquinone
Toxic epidermal necrolysis	Acrylonitrile
Scleroderma-like changes	Vinyl chloride
Lung	
Irritation	Ethyl acrylate Formaldehyde Epichlorohydrin
Asthma	Isocyanates Phthalic anhydride Isocyanates Trimellitic anhydride Epichlorohydrin
Hypersensitivity pneumonitis	Isocyanates Anhydrides (phthalic, trimellitic)
Pneumoconiosis	Phenolic resin dust
Polymer fume fever	Polyvinyl chloride Polytetrafluoroethylene
Bone	
Acro-osteolysis	Vinyl chloride
Liver	
Hepatitis	Vinyl chloride
Cirrhosis	Vinyl chloride
Nervous system	
Peripheral neuropathy	Methyl methacrylate Styrene Acrylamide
Encephalopathy	Vinyl chloride Styrene
Cancer	
Brain	Formaldehyde (suspected) Vinyl chloride (reported)
Leukemia	Formaldehyde (reported) Acrylonitrile (reported) Vinyl chloride (reported)
Lymphoma	Styrene (suspected)
Liver (hemangiosarcoma)	Vinyl chloride (known)

Table 41.2 Selected occupational diseases in the plastics and synthetic textiles industry

essential properties. Most of the polymers in Table 41.1 are thermoplastics, with the exception of the phenolics, polyurethanes, epoxies, urea, and melamine, which are thermosets.

Table 41.2 presents an overview of the spectrum of diseases that have been observed following exposure to one or more agents used in the plastics industry. Of principal concern have been the organs of direct contact, the skin and the respiratory system, including effects of irrita-

tion, allergy, and carcinogenicity. Additional details are presented by the specific agent in the following sections.

Polyethylene

Ethylene

Polyethylene is an important bulk plastic with high- and low-density forms. Low-density polyethylene is used principally in the manufacture of films, sheets, and layered packaging materials. High-density polyethylene is usually molded into containers, toys, and housewares.

In the polymerization phase, ethylene is the monomer used to produce polyethylene. Indeed, ethylene is the raw material used in the greatest volume in the plastics industry and ranks among the ten chemicals with the highest tonnage produced in United States. Ethylene is used in the formation of other monomers or intermediates, such as styrene, ethylene oxide, and vinyl chloride, which are used to make polystyrene, polyurethane, and polyvinyl chloride (PVC), respectively. Small amounts of ethylene are also used as a refrigerant and as a fruit-ripening agent. Ethylene is derived from the cracking of petroleum and, to a lesser extent, from the processing of natural gas. Ethylene production in the United States was 40 billion pounds in 1994.

Ethylene is highly combustible when exposed to heat or flame, and can react vigorously with oxidizing chemicals. It acts as a simple asphyxiant, posing a hazard by the displacement of oxygen from the breathing atmosphere. The anesthetic potential of ethylene has been exploited clinically; however, its tendency to produce hypoxia, its explosiveness, and its variable clinical utility have limited its use. The clinical experience with its use as an anesthetic agent has limited relevance to the occupational setting because the concentrations of ethylene used in anesthesia were much higher than those typically experienced in the workplace. A review by the International Agency for Research against Cancer (IARC) in 1987 identified no data on ethylene's carcinogenicity from human or animal studies.

The thermal degradation products of polyethylene include carbon monoxide, acrolein, and formaldehyde. Asthma has been reported among workers heating polyethylene film as part of food-wrapping activity; the film used reportedly contained no additives. However, this entity is much more often reported in food wrappers exposed to the pyrolytic products of PVC film.

Polypropylene

Propylene

Polypropylene is a bulk plastic characterized by relative strength, heat resistance, and durability. It is used principally in molded products and in fibrous form in carpeting and clothing. Polypropylene materials, such as pipes and moldings, are also increasingly welded in small workshops to produce custom items. Such use presents opportunities for exposure to polypropylene combustion products outside the more widely recognized exposures entailed in the manufacture of polypropylene.

The polymer is formed from propylene in the presence of a solvent (e.g., xylene or butyl alcohol) and an organometal catalyst (e.g., titanium trichloride). Propylene, like ethylene, is obtained through the cracking of petroleum hydrocarbons. Although it is mainly used as a monomer in the formation of polypropylene, it also serves as a fuel and as a raw material in the production of acrylonitrile, isopropyl alcohol, polyurethane, epoxy resins, and other plastics. It is second only to ethylene as a raw material in plastics manufacturing, with approximately 23 billion pounds produced and used in the United States in 1994, primarily to make 15.7 billion pounds of polypropylene. Like ethylene, propylene is highly flammable when mixed with air or oxygen. The liquid form of propylene can cause freezing burns of the skin or eyes. It is a simple asphyxiant, and it can produce progressive symptoms and signs of hypoxia with increased exposure.

While polypropylene manufacture has generally been regarded as a safe industrial process, epidemiologic studies have raised concern regarding an association with colorectal cancer. An epidemiologic study of workers in polypropylene manufacture demonstrated a 5.6-fold elevation in colorectal cancer incidence, occurring chiefly among workers less than 60 years of age and with a duration of employment of at least 20 years.¹ A subsequent company-sponsored colorectal polyp screening program found an increased prevalence of colorectal adenomatous polyps in the same workforce, especially among mechanical and process workers with a latency of at least 20 years.² A detailed case-control analysis indicated that the excess prevalence of polyps was limited to two processes within the plant, and was probably not due to confounding.³ In the only other relevant study, from a synthetic textile plant, workers employed for more than five years in the polypropylene and cellulose triacetate extrusion unit showed a 5.5-fold excess in colon cancer incidence and mortality.⁴

Vinyl chloride, polyvinyl chloride, and related chemicals

Vinyl chloride

Vinyl Chloride

Vinyl chloride ranks among the top 20 chemicals in terms of the volume produced in the United States, with 13.8 billion pounds manufactured in 1994. It is principally produced by the thermal cracking of ethylene dichloride. Almost the entire production of vinyl chloride in the United States is devoted to the manufacture of PVC, which is used to make pipes, wire and cable coating, packaging material, housewares, and automotive parts. Small amounts of vinyl chloride are used to make mixed polymers, such as vinyl chloride-vinyl acetate, vinyl chloride-acrylonitrile, and vinyl chloride-vinylidene chloride.

Nervous system effects Vinyl chloride is an anesthetic at high levels of air-borne exposure in the range of 3000–10,000 ppm. Symptoms of central nervous system toxicity, including headache, lightheadedness, and dizziness, were commonly reported by workers in PVC polymerization plants until the 1970s; even loss of consciousness was not uncommon. After the carcinogenic effect of vinyl chloride was reported in 1974, the air-borne levels of exposure to vinyl chloride decreased dramatically, leading to the disappearance of notable central nervous system symptoms. Of interest is a study reporting a mild distal axonal neuropathy in the majority of vinyl chloride workers at a PVC polymerization plant in Italy.⁵

Skeletal and vascular effects Vinyl chloride causes acroosteolysis, a unique syndrome consisting of resorption of bone from the terminal phalanges of the fingers and toes, Raynaud's syndrome, and scleroderma-like skin alterations. This syndrome was first reported in the late 1950s, and was documented in 3–6% of workers studied in the 1960s and the 1970s. Variable changes include cortical bone defects (termed transverse or half moon) in the distal phalanges of the fingers and toes, with subsequent complete resorption of bony tufts in severe cases. These bony abnormalities have a characteristic appearance on x-ray; the large bones are occasionally involved, with the appearance of cystic lesions and areas of increased radiolucency; there may also be alterations in the patella and sacroiliac joint. Bony lesions are usually painless.

Raynaud's syndrome in the hands and feet may be seen in a small percentage of exposed workers as part of the acroosteolysis syndrome. More commonly, symptoms of numbness, tingling, and sensitivity to cold are reported, without the dramatic vascular changes characterized by Raynaud's syndrome. Some workers also have thickened and tense skin that is suggestive of scleroderma. The pathogenesis of this disorder is not known but may involve a primary effect of vinyl chloride on the arteries and arterioles of the extremities. Alternatively, immunologic alterations may be important in the pathogenesis of this disease, as suggested by the fact that cryoglobulins have been reported in a large percentage of acro-osteolysis cases.

Historically, acro-osteolysis occurred among workers with high levels of exposure to vinyl chloride, most often among workers who clean PVC reactor vessels with exposure to vinyl chloride in the thousands of parts per million; fewer cases have occurred following drastic reductions in exposure.

An interesting case of Raynaud's phenomenon and severe polymyositis in association with anti-Jo1 antibody was recently reported in a man with long-term vinyl chloride exposure.⁶ Whether vinyl chloride initiates a myopathic process has not been otherwise investigated.

Hepatic effects Vinyl chloride causes non-malignant and malignant liver disease, including inflammation and a characteristic periportal fibrosis (see Chapter 26.1). The observed hepatotoxicity ranges from the asymptomatic presence of liver function abnormalities to hepatic fibrosis with accompanying portal hypertension, esophageal varices, and splenomegaly. Hepatic fibrosis may be present without abnormalities in liver function tests. The pathology of vinyl chloride-associated hepatotoxicity includes a characteristic pattern of hepatoportal sclerosis, capsular, and subcapsular fibrosis; and focal irregular dilatation of the sinusoids. Cross-sectional studies of workers in the mid-1970s found that 10–25% of vinyl chloride workers had liver function abnormalities, not all of which could be ascribed to the chemical. Excess hospitalization rates for liver cirrhosis were found among Taiwanese vinyl chloride workers.⁷ A marked increase in cirrhosis-related mortality was observed in the combined European vinyl chloride industry study.⁸

Cancer Vinyl chloride-induced cancer was first demonstrated in animals in 1971. Three years later, hemangiosarcoma of the liver was observed in three vinyl chloride workers. The association of this rare tumor with vinyl chloride was further confirmed by the reporting of a total of 27 cases among vinyl chloride workers in the United States and Europe by 1975. Like arsenic and thorotrast, vinyl chloride is one of the few agents known to cause hemangiosarcoma of the liver. Most afflicted workers have had long-term vinyl chloride exposure, and the disease has developed following a 10–15-year latency period. As of 1999, there were approximately 200 reported cases of vinyl chloride-associated angiosarcoma of the liver, mostly from the US and Europe.⁹

Vinyl chloride has been associated with other cancers, although none have demonstrated the strength and consistency of the relationship between vinyl chloride and hemangiosarcoma of the liver. The largest study to date, involving 3191 deaths among 10,109 workers at 37 plants in the United States, was undertaken by Mundt and others on behalf of the Chemical Manufacturers Association (CMA).¹⁰ Significant increases in cancer of the brain, connective tissue, and soft tissue were identified, especially among workers with 20 or more years of cumulative exposure to vinyl chloride. Smaller Swedish¹¹ and German studies have also found an increase in brain cancer risk among vinyl chloride workers, although a major British study¹² and the European cohort study as a whole⁸ did not observe the same magnitude of risk. Wong and associates, who investigated the US cohort prior to Mundt, found an increase in the risk of cancer of the biliary tract and of hepatic tumors other than hemangiosarcoma;¹³ this has recently been confirmed in a Taiwanese study.¹⁴ An excess lung

cancer risk has been reported in some smaller studies, but has not been corroborated in larger studies. Increased cancer risk among vinyl chloride workers has also been observed for malignant melanoma, thyroid cancer, and lymphopoietic cancers.

Respiratory effects Vinyl chloride and PVC are associated with a variety of non-malignant respiratory diseases. In a large cross-sectional study reported in 1976, Lilis and others found that approximately 20% of workers at two PVC polymerization facilities had linear-reticular and, less frequently, nodular opacities on chest x-ray studies.¹⁵ Subsequent cross-sectional studies of PVC manufacturing workers also showed small opacities on the chest radiographs, although at lesser rates.¹⁶ Both obstructive and restrictive dysfunction has been observed. Notably, the study with the highest rate of pneumoconiotic opacities also demonstrated the highest rate of pulmonary function abnormalities.¹⁷ The accumulated data suggest that there may be more than one disease process present in these studies, characterized by both pulmonary fibrosis and chronic obstructive pulmonary changes. Wong and coworkers found a significant excess in mortality from chronic obstructive pulmonary disease in vinyl chloride and PVC workers, providing further evidence that vinyl chloride and PVC, especially the latter, cause chronic airway obstruction of clinical significance.¹³

There have been additional case reports of granulomatous pulmonary reactions and desquamative interstitial pneumonitis in association with exposure to PVC dust. Of interest is a report of a PVC worker with dyspnea, irregular opacities on chest x-ray studies, and restrictive pulmonary dysfunction, who underwent a lung biopsy. The results showed pulmonary fibrosis and a granulomatous reaction. Similar pathologic findings have been produced in rats exposed to PVC dust.¹⁸ In another case report, a group of investigators have documented a case of interstitial pneumonitis verified by histopathologic studies in a worker cleaning PVC from a reaction vessel.

The pyrolytic products of PVC film and associated adhesive labels can cause respiratory irritation and asthma, commonly known as meat wrappers' asthma. This was first noted in case reports in the early 1970s, and has been corroborated by cross-sectional epidemiologic studies of meat wrappers. In this work setting, PVC plastic wrap is cut with a hot knife, causing PVC degradation and production of hydrogen chloride and di(2-ethylhexyl) adipate. Pyrolysis of an accompanying price label adhesive, when present, may produce other allergenic agents, such as phthalic anhydride and dicyclo-hexylphthalate, with independent bronchospastic responses.

Vinylidene chloride

Vinylidene Chloride

Vinylidene chloride is used primarily in the formation of copolymers with vinyl chloride or acrylonitrile. It is produced from ethylene dichloride and vinyl chloride through successive chlorination and dechlorination reactions. The combustion products include hydrogen chloride. Vinylidene chloride is an irritant to the eyes, mucous membranes, and lungs. Exposure to high concentrations in the air causes narcosis. Chronic exposure to vinylidene chloride has been shown to cause fetal, hepatic, and renal damage in animals.

Vinylidene chloride causes neoplasms in animals, including renal adenocarcinomas.¹⁹ It is mutagenic in short-term bacterial assays. The two epidemiologic studies completed to date showed no increase in cancer deaths among vinylidene chloride-exposed workers, but were limited by the occurrence of few deaths and a short latency.¹⁹

Ethylene dichloride

Ethylene dichloride, or 1,2-dichloroethane, is a chemical intermediate in the production of vinyl chloride. It is additionally used in the manufacture of acrylic adhesives, rubber cement, leather and metal cleaners, and rubber goods. Approximately 18 billion pounds of this agent were used in the United States in 1993. Ethylene dichloride has an odor that is generally considered pleasant and may not be detectable at levels that are hazardous. Important combustion products include phosgene, hydrogen chloride, acetylene, and vinyl chloride, presenting an irritant and carcinogenic hazard.

Early Eastern European reports of morbidity associated with occupational exposure to ethylene dichloride in a variety of industries indicate that irritation of the mucous membranes, liver function abnormalities, and central nervous system symptoms can result from chronic exposure to this chemical. Ethylene dichloride has also been found in the breast milk of women occupationally exposed to the agent, necessitating an avoidance of exposure in women during breast feeding.

In a recent review (1999), IARC concluded that there is sufficient evidence of the carcinogenicity of ethylene dichloride in animals, and therefore it is a potential human carcinogen.¹⁹ In general, epidemiologic studies suggest ethylene chloride may contribute to a significant elevation in mortality from lymphatic and hematopoietic cancer and, in one study, cancer of the stomach, although there were other coexisting exposures.¹⁹

The National Institute for Occupational Safety and Health (NIOSH) has recommended that workers exposed to ethylene dichloride receive an annual examination, including a medical and work history, assessing cardiovascular, pulmonary, neurologic, and liver function; the benefit of specific surveillance tests in this setting is unproven.

Fluoropolymers

Tetrafluoroethylene

Polytetrafluoroethylene (PTFE) is a polymer of tetrafluoroethylene with the commercial name Teflon. PTFE, when heated to 315–475 degrees C, produces polymer fume fever, an illness clinically similar to metal fume fever. First described 40 years ago, this syndrome is characterized by fever, chills, malaise, cough, and chest pain. Some individuals may also experience joint pains, nausea, and vomiting. Polymer fume fever is usually a self-limited illness that occurs within several hours following exposure to the pyrolytic products of PTFE, and resolves within a few days. Although most affected workers have only the described symptoms, there have been case reports of pulmonary edema occurring as part of the clinical picture of polymer fume fever. Complete resolution of the syndrome following an attack is typical, although long-term studies have not been performed. One case report found pathologic evidence of interstitial pulmonary fibrosis in a worker after repeated episodes of polymer fume fever.

Polymer fume fever has occurred in a variety of environments in which PTFE has been used, including generation of PTFE aerosol as a mold-release spray. PTFE-impregnated or contaminated material can also be a source of exposure.²⁰ The pyrolysis required for the syndrome to develop may occur as a result of the industrial process or as a result of the burning of contaminated cigarettes (e.g., smoking during work breaks). The exact pyrolytic products responsible for the syndrome have not been identified, but suspected agents include carbonyl fluoride, tetrafluoroethylene, hydrogen fluoride, and other fluorinated compounds.

Epoxy resins

Epoxide Ring

Epoxy resins are polymers containing an epoxide ring, which are formed through the reaction of uncured resin material with a curing agent. The uncured resin consists of epichlorohydrin, diluents, fillers, and pigments. The principal diluents are glycidyl ethers, especially the diglycidyl ether of bisphenol A, and various solvents. Important curing agents include acid anhydrides and aliphatic and aromatic amines. Epoxy resins differ from many other plastics in that they are cured at the site of use of the final product. Epoxy resins are used as adhesives, laminating materials, reinforcing agents, and surface coatings.

While most of the health effects of epoxy resins have now been associated with specific components of the resin, some health problems have been associated with epoxy resins per se. Lymphocytopenia was identified in a screening program of pattern and model makers, particularly automobile-manufacturing workers, who have myriad exposures. A history of epoxy resin and plastic dusts exposures provided the highest relative risks for low lymphocyte counts.²¹ Shipyard workers using epoxy resin-based paints showed higher rates of cough, dyspnea, and cross workshift declines in FEV₁ compared to unexposed shipyard painters.²²

Epichlorohydrin

Epichlorohydrin

Epichlorohydrin is widely used in the manufacture of epoxy resins, pharmaceuticals, plasticizers, adhesives, and various elastomers. The current Occupational Safety and Health Administration (OSHA) Permissible Exposure Limit is 2 ppm as an 8-hour time-weighted average, although NIOSH has recommended that the exposure be at the lowest level possible.

Epichlorohydrin is a strong irritant and allergen, and principally affects the skin, mucous membranes, and respiratory tract. There is limited evidence of hepatotoxicity in humans. Animal studies have demonstrated both liver and kidney injury following exposure to epichlorohydrin.

Epichlorohydrin is an animal carcinogen. Elevated rates of chromosomal aberrations and sister chromatid exchanges have been documented in workers exposed to epichlorohydrin.²³ Several cohort mortality studies have been completed, including investigations at two major United States epichlorohydrin-producing facilities. An earlier finding of excess leukemia in a cohort mortality study was not confirmed in a recent update of the same cohort.^{24,25} However, a nested case-control study of lung cancer in a different epichlorohydrin-exposed cohort demonstrated an excess risk of lung cancer associated with epichlorohydrin exposure.²⁶ A European study with a limited number of deaths, and low statistical power identified no increased risk of lung cancer. IARC classifies epichlorohydrin as a probable human carcinogen.¹⁹

Epichlorohydrin is a possible reproductive toxin. Oral administration of epichlorohydrin produces irreversible infertility in male rats, after a single high dose. In limited human studies to date, no alterations have been noted in sperm count and morphology or in the fertility status of workers exposed to epichlorohydrin.

Glycidyl ethers

Glycidyl ethers are principally used with epichlorohydrin to form epoxy resins. The diglycidyl ether of bisphenol A is the major agent used in this class; others include n-butyl

Glycidyl Ether

glycidyl ether and phenyl glycidyl ether. These agents are clearly responsible for some of the irritation and sensitization that have been observed among epoxy resin manufacturing workers; however, the relative disease-producing role of the glycidyl ethers as compared to epichlorohydrin and various amines may be difficult to determine. Newly introduced glycidyl ethers, such as ortho-cresyl glycidyl ether and diethylene glycol diglycidyl ether, also cause allergic contact dermatitis.²⁷

Animal studies show that some glycidyl ethers may cause testicular atrophy in rodents, as well as a range of hematopoietic abnormalities, including atrophy of lymphoid tissue and bone marrow toxicity. Studies of these effects in humans have not been completed, but the repeated demonstration of these effects in animals has raised substantial concerns.

Diglycidyl resorcinol ether is a confirmed animal carcinogen, and there is limited evidence that the diglycidyl ether of bisphenol A is an animal carcinogen. The potential carcinogenicity of the glycidyl ethers in humans has not been well investigated.

Acid anhydrides

Acid Anhydride

This family of chemicals includes well-known agents, such as phthalic anhydride, trimellitic anhydride, and maleic anhydride, and other lesser known agents, such as tetrachlorophthalic anhydride, hexahydrophthalic anhydride, and himic anhydride, all of which have been shown to cause human disease. Acid anhydrides have a variety of uses and are commonly employed agents in industry. As noted previously, acid anhydrides are used as curing or hardening agents for epoxy resins. They are also used in the production of plasticizers, polyester resins, and alkyd resins, the latter of which are important in the formulation of paints, varnishes, and reinforced plastics. Phthalic anhydride is the most commonly utilized agent, with a volume of nearly 1 billion pounds produced in the United States in 1994.

Clinical effects Acid anhydrides are severe direct irritants and have caused chemical burns of the skin, corneal ulceration, epistaxis, and hemoptysis. These severe irritant effects were more common in the 1940s and 1950s, when the exposure levels were considerably higher than they are at present.

Hypersensitivity to acid anhydrides may result in allergic rhinitis, conjunctivitis, urticaria, and asthma. Indeed, acid anhydrides are among the most well-documented agents capable of producing occupational asthma. Several dozen published reports have been cited as documenting acid anhydride-induced asthma, mostly caused by phthalic anhydride and, to a lesser extent, trimellitic and maleic anhydride.²⁸

Inhalation challenge tests have documented acid anhydride-induced asthma. Nearly all patients that have been tested to date show a dual response to bronchoprovocation, including an initial fall of the forced expiratory volume in 1 second (FEV₁) within the first hour, and a second decline in FEV₁ several hours after exposure. Very low exposures to acid anhydrides in the bronchoprovocation protocol are often sufficient to induce the asthmatic response in sensitized individuals.

Almost all workers with acid anhydride-induced asthma have immunoglobulin E (IgE) antibody that is specifically reactive to an acid anhydride-protein conjugate, as demonstrated by RAST testing. Such specific IgE antibody can also be found, although uncommonly, in workers without asthma who are merely exposed to acid anhydride. More recently, an IgG antibody specific for acid anhydride was identified in exposed patients with asthma, but may not represent a specific marker of clinical hypersensitivity.

Most documented cases of acid anhydride-related asthma occur within the first few years of exposure. As in other causes of occupational asthma, the symptoms may improve after leaving the work environment, but bronchospasm sufficient to require medication has been demonstrated to persist following cessation of exposure.

Another syndrome associated with exposure to acid anhydrides is a condition described as 'trimellitic flu' (also known as 'late respiratory distress syndrome'), which has been shown to occur following exposure to trimellitic or phthalic anhydride. This syndrome includes myalgias, malaise, fever, and respiratory symptoms, which occur following a workshift. The chest x-ray studies in affected workers are usually normal, but may document the presence of extrinsic allergic alveolitis. Except for the prominence of respiratory symptoms, this syndrome is similar to polymer or metal fume fever. An immunologic origin for this syndrome is likely; however, a direct toxicity of the relevant acid anhydride has not been excluded.

Besides direct irritation, asthma, rhinitis, and late respiratory distress syndrome, trimellitic anhydride has been shown to cause, albeit rarely, pulmonary hemorrhage, also called pulmonary disease-anemia syndrome.²⁹ This syndrome is characterized by hemoptysis, pulmonary infiltrates, and hemolytic anemia. Lung biopsy results show non-specific alterations of acute lung injury. This syndrome, which has usually followed high exposure to trimellitic anhydride, may be severe and requires emergency medical attention. Whether this response represents hypersensitivity or direct toxicity is unknown.

The mortality of workers exposed to acid anhydrides has not been well investigated. A case-control study of lung cancer in a factory in Italy, that produced and used,

phthalic anhydride reported a significant increase in lung cancer after controlling for cigarette smoking.³⁰ The extent to which phthalic anhydride may be responsible for the observed excess lung cancer risk is unclear. The limited animal studies performed to date have not confirmed that phthalic anhydride is a carcinogen.

Evaluation The clinical evaluation of symptomatic workers varies according to the clinical syndrome that is present. In cases of asthma, inhalation challenge testing is generally not necessary when the presence of asthma and the acid anhydride exposure are both documented. Measuring the level of acid anhydride-specific IgE antibody may be helpful. The diagnosis of the late respiratory distress syndrome may be delayed unless a high level of clinical suspicion is maintained. Any exposed worker with symptoms suggestive of a syndrome involving pulmonary hemorrhage requires immediate evaluation.

Biologic monitoring of a number of the phthalic anhydrides is possible, assessing metabolites in urine or serum.³¹ Protein adducts have also been measured and show excellent correlation with urinary metabolites; and these have the advantage of providing a measure of cumulative exposure of several months rather than current exposure.³²

Prevention Awareness by exposed workers and their physicians about the spectrum of health problems associated with the acid anhydrides is essential. Exposure should be restricted to as few workers as possible, and to the lowest achievable levels. There is some evidence that very low levels of phthalic anhydrides may not be associated with disease; a recent longitudinal study showed that a large number of workers exposed to a mean of < 2 micrograms/m³ did not develop any evidence of respiratory disease during a three-year period.³³ Nonetheless, minimizing exposure is essential. Proper engineering controls, supplemented by personal protective equipment, are the mainstays of prevention. In general, early identification of individuals who demonstrate clinical hypersensitivity to acid anhydrides is prudent to reduce or eliminate the exposure.

Amino resins

Amino resins are produced by the combination of formaldehyde and an amine, principally melamine or urea. The primary products include urea-formaldehyde foam, adhesives, laminates, and various textile finishing materials designed to reduce creases. In addition to possible occupational exposures, this class of materials has posed potential environmental concerns to consumers using formaldehyde-based products.

Formaldehyde

Formaldehyde is a widely used raw material in the manufacture of plastic resins and other commercially important products. It has found broad industrial application because of its high reactivity, low cost, and colorless nature. One half of all formaldehyde production in the United States is

Formaldehyde

used to make urea-formaldehyde and phenolic resins. The dominant uses of these formaldehyde-based resins are in the production of plywood, particle board, foam insulation, and a variety of molded plastic items. The remaining formaldehyde production is used to make melamine, pentaerythritol, hexamethylenetetramine, fertilizers, and other materials. Formaldehyde has an important use in the textile industry; it forms the basis of products that render textiles crease proof, flame resistant, and shrink proof. Formaldehyde has antiviral and antibacterial properties and has been used extensively in cosmetics, embalming fluids, and selected medicines. The United States produced approximately 7.6 billion pounds of aqueous formaldehyde in 1993.

Clinical effects Formaldehyde has a pungent odor and is highly irritating to the skin, eyes, and lungs. Sensitivity to formaldehyde varies, and some irritant effects can be experienced at or below the current legal standard of 0.1 ppm PEL, established by OSHA. Exposure to this chemical may result in tolerance, although 1–2 hours following cessation of exposure, the characteristic odor and effect of formaldehyde once again become apparent. The severe effects on the lungs after high exposure may include chemical pneumonitis or pulmonary edema.

Formaldehyde has been known to cause skin sensitization since the early 1900s. It has been linked to asthma, although not commonly. Such formaldehyde-induced asthma may be related to its irritant properties; there is also evidence of an immunologic mechanism. A six-year follow-up study of workers who produced urea-formaldehyde observed that exposed workers experienced similar respiratory symptoms as an unexposed group, but exposed non-smokers suffered a mean decline in FEV₁ that was 50% higher than unexposed non-smokers; no similar exposure-related effect was seen among smokers.³⁴

Formaldehyde causes dose-related, site-specific cancer in animals. Studies in the late 1970s and early 1980s demonstrated an unequivocal increase in squamous cell carcinoma in the nasal passages in rats; the evidence was sufficient for IARC to conclude that formaldehyde is an animal carcinogen. Formaldehyde is a potent mutagen and genotoxic agent, inducing mutations, elevated rates of lymphocyte sister chromatid exchanges, and chromosomal aberrations.

In 1995, IARC revised its designation of formaldehyde as a probable human carcinogen (group 2A).³⁵ Epidemiologic evidence favors a causal link between formaldehyde and nasopharyngeal and sinonasal cancer. Additional studies variably show excess rates of other types of cancer such as leukemia and cancer of the lung and brain; interpretation has been challenging, given confounding occupational exposures and heterogeneity of

findings according to type of workers (e.g., professionals versus industrial workers).^{36,37}

Evaluation and prevention The evaluation of suspected work-related health problems among formaldehyde-exposed workers should center on the known irritant and allergic effects of this chemical on the skin, mucous membranes, and respiratory tract. With respect to medical surveillance, formaldehyde is one of the few agents for which OSHA has specific provisions. These provisions include a medical questionnaire, physical examination, and spirometry, that apply to all workers who are exposed to formaldehyde at or above the action level (OSHA PEL 0.75 ppm time-weighted average) or at or above the short-term exposure level (2 ppm for 15 minutes). Physicians should be aware that OSHA requires the employer to provide the examining physician with a copy of its formaldehyde standard, a description of the worker's job duties, relevant exposure monitoring data, information concerning personal protective equipment, and the results from previous medical examinations.³⁸

Urea

Urea

Urea is used in combination with formaldehyde to produce resins and adhesives, and is also used in the production of melamine. Urea is among the top 20 most commonly produced agents in the United States, with most of its use devoted to the production of fertilizer and livestock feed. Urea has low toxicity in the occupational setting. Most of the human experience with urea exposure is related to the former medicinal use of urea as a diuretic agent.

Melamine

Melamine

Melamine is an important chemical substance, which is usually mixed with formaldehyde to make amino resins for use in laminates, molding compounds, surface coatings, paper coatings, textile printing, and adhesives. Melamine and urea production combined was 3.2 billion pounds in the United States and Canada in 2000. Melamine can be hazardous when burned because its pyrolytic products include hydrogen cyanide.

Melamine has produced urinary calculi with associated epithelial hyperplasia and transitional cell carcinoma of

the bladder in rats. The human toxicity of melamine is obscured by its usual mixture with formaldehyde and other agents with better documented toxicity. A review of animal studies by IARC in 1987 noted that there was insufficient evidence concerning the animal carcinogenicity of melamine.³⁹

Acrylics

Methyl Acrylate

The acrylics are a group of plastics having in common the formation of polymers of acrylate esters. The principal acrylic monomers include methyl methacrylate, methyl acrylate, ethyl acrylate, and butyl acrylate. These are high-volume monomers. There are a large number of acrylate-based compounds, which may be used in combinations, thereby complicating characterization of occupational health effects.

These polymerized esters are best known as substitutes for glass under the trade names of Lucite (methyl acrylate) and Plexiglas (ethyl acrylate). They can be easily molded and have been widely used in the production of dentures and surgical prostheses. They are also widely used as surface coatings; as coatings for textiles, paper, and leather; and as a component of adhesives.

The acrylic monomers are variably irritating to the mucous membranes, skin, and respiratory tract, with ethyl acrylate having the highest irritant potency. The odor threshold of ethyl acrylate is below 1 ppm and, therefore, should serve as a warning prior to the development of irritant effects. Methyl methacrylate is known to be irritating at less than twice the permissible level established by OSHA. These monomers are also known to produce dermal sensitization. Recent studies of acrylic-induced contact dermatitis include a broad range of acrylates, and suggest that some of the more recently introduced acrylates may be potent sensitizers.⁴⁰ Asthma has been associated with acrylates in case reports for at least 20 years, but a recent epidemiologic study implicates acrylate-based materials, especially rapidly drying glues, as having some of the highest relative risks among occupational exposures known to cause asthma.

Methyl methacrylate has limited nervous system toxicity. Dental technicians who molded methyl methacrylate by hand experienced finger paresthesias. Sensory nerve conduction velocities of the digits were significantly slowed, possibly representing direct local toxicity to the nerves. A single case of a dental technician with long-term exposure to methyl methacrylate and generalized peripheral neuropathy has been reported.⁴¹ Another cross-sectional study of workers exposed below the permissible exposure level set by OSHA reported a high prevalence of headaches, increased prevalence of pain in the extremities, loss of memory, fatigue, and sleep disturbances.

Ethyl acrylate is unique among the acrylic monomers as an established animal carcinogen. Epidemiologic studies of methyl methacrylate-exposed workers producing polymer in the United States and England have suggested an increased risk of colon cancer, but results are mixed and inconclusive.⁴²

Hydroquinone

Hydroquinone

Hydroquinone is an important polymerization inhibitor for acrylic monomers and vinyl acetate, and is a raw material in the production of rubber antioxidants. Hydroquinone is also important as a photographic developer and reducer.

Hydroquinone is irritating to the skin, mucous membranes, and respiratory tract. Exposure to air-borne hydroquinone has been known to produce corneal ulcers. This chemical has also rarely been associated with the development of vitiligo. Oral ingestion of hydroquinone produced gastrointestinal irritation, as evidenced by nausea, vomiting, abdominal cramps, and diarrhea, in several dozen American sailors who inadvertently drank hydroquinone-contaminated water when the ship's water system was connected to automatic photodeveloping machines on the ship.⁴³

In a French factory, workers chronically exposed to hydroquinone had reduced ventilatory capacity (FEV₁) and flow rates in comparison with the control group, suggesting that hydroquinone may produce airway obstruction. Elevated levels of IgG and IgE were also found in the hydroquinone-exposed group.⁴⁴

Hydroquinone is an animal carcinogen, producing renal adenomas in rats.⁴⁵ Epidemiologic studies are negative to date, but have involved few people, limiting statistical power.⁴⁶ Hydroquinone is a metabolite of benzene and may be responsible, at least in part, for the leukemogenesis caused by benzene.⁴⁷ IARC currently rates hydroquinone as not classifiable with respect to human carcinogenicity.

Acrylamide

Acrylamide

Polyacrylamide, the polymeric form of acrylamide, is not generally considered a plastic material but is relevant, because the industrial production process is similar to that of the plastics. Polyacrylamide is principally used to bind and remove suspended solids from waste water, to increase water viscosity in oil recovery processes, to strengthen and

retain fibers and pigments in paper making, and to coat surfaces. Minor uses include textile treatment, cosmetic preparations, gel chromatography, and electrophoresis.

The principal routes of exposure of acrylamide are through dermal contact and inhalation. Retention of the monomer in the polymer has been a concern, although improvements in the polymerization process have led to a decrease in monomer to less than 1% of the polymer resin.

Peripheral neuropathy is the dominant effect of acrylamide (see also Chapter 28.2). First described in 1953, the symptoms of the sensorimotor neuropathy include weakness, diminution of all sensory modalities, and evidence of sympathetic nervous system involvement, including excessive sweating and cold extremities. Distal changes in the nerves of the extremities precede proximal involvement. Limited central nervous system involvement may occur, as demonstrated by ataxia, vertigo, and alterations in mood, orientation, and memory. Desquamation of the skin of the palms and soles has accompanied the neurologic illness in exposed workers.

Acrylamide is a recognized animal carcinogen. In a mortality study of 8508 workers who manufactured acrylamide, an elevation in thyroid and lung cancer was found, though without apparent dose relation to acrylamide exposure.⁴⁸ A statistically significant excess of pancreatic cancer was also found among workers with higher acrylamide exposure, with some evidence of a dose-response relationship. Additional insight about the potential for acrylamide to cause human cancer awaits further follow-up of this cohort and additional studies. IARC considers acrylamide to be a probable human carcinogen.⁴⁹

Hemoglobin adducts of acrylamide have been used as a biomarker of internal dose and have demonstrated a dose-response relation with peripheral nervous system symptoms.⁵⁰

Polyurethane

The polyurethanes are mainly used to make rigid and flexible foams and surface coatings. They are formed through the reaction of isocyanates and di- or polyfunctional alcohols. Additional materials, such as amines and glycols, may be used in small amounts. Isocyanates are the most important occupational health hazard in polyurethane manufacture and application.

Isocyanates

Isocyanate

Isocyanates are an important family of low molecular weight chemicals; the most notable examples are toluene diisocyanate (TDI), methylenediphenyl diisocyanate (MDI), and hexamethylene diisocyanate (HDI). The industrial use of isocyanates exploits their high chemical reactivity, making them useful as cross-linking agents. The production of TDI alone was 875 million pounds in the United States in 1994.

Isocyanates are of particular interest in occupational medicine because of their capacity to cause respiratory disease at remarkably low levels of exposure. The current OSHA standard for exposure to TDI, for example, is 0.005 ppm (5 parts per billion), which is several orders of magnitude lower than the OSHA time-weighted averages for most industrial chemicals.

Diisocyanates, especially TDI and MDI, are principally used in the production of polyurethane foams, which may be rigid or flexible. MDI is more commonly used for rigid foam, whereas flexible foam is produced with TDI. Rigid foams are often generated at the site of use, principally as insulation material, and may present opportunities for uncontrolled exposures. Polyurethane foams are used in upholstery, insulation material, and packaging. Isocyanates are also used in the production of adhesives, rubbers, surface coatings, elastomers, and spray paints. Workers at risk for isocyanate-related disease include those who manufacture isocyanates, those who manufacture or apply polyurethane products (such as foam), and those who use polyurethane products (such as varnishes and spray paints).

Isocyanates vary in their capacity to produce disease. MDI has a vapor pressure several hundred times lower than that of TDI and HDI, and it is therefore much less volatile than the latter agents. If used under similar conditions, MDI produces lower ambient isocyanate levels than does TDI or HDI. Although HDI has the same vapor pressure as TDI, the former often exists as three molecules bound together, lowering its vapor pressure and decreasing its likelihood of significant air-borne isocyanate exposure to vapor. However, all isocyanate compounds present an exposure risk in aerosol form, during spraying or generation of mists.

Clinical effects Isocyanates cause significant respiratory disease in humans (Table 41.3). The respiratory toxicity of TDI was first documented in animal experiments in 1941, prior to the significant commercial use of isocyanates. Important commercial use of isocyanates occurred following the Second World War and did not begin in the United States until 1953. The first report of human respiratory toxicity of TDI was by French investigators in 1951. Many cases of isocyanate respiratory disease were reported soon thereafter, and by 1962 a review article of the published literature cited 222 cases of respiratory illness caused by TDI exposure.

Respiratory irritation results from isocyanate exposure, affecting both the upper and lower airways, with symptoms ranging from cough and mucus production to chemical pneumonitis and pulmonary edema, as occurred with methyl isocyanate exposure during the Bhopal incident in

Direct irritation of the respiratory tract
Asthma
Chronic obstructive pulmonary disease
Hypersensitivity pneumonitis
Pulmonary disease-anemia syndrome (hemorrhagic pneumonitis)

Table 41.3 Respiratory diseases associated with isocyanates

1984. Irritant symptoms resulting from isocyanate exposure occur in a dose-related fashion with many workers experiencing irritation of the nose and throat at or above 30–70 ppb of TDI, with significant lower respiratory tract irritation at higher levels of exposure. Notably, a ten-year follow-up of some of the victims of the Bhopal methyl isocyanate leak indicates a high prevalence of persistent respiratory symptoms and small airway dysfunction.⁵¹

In recent decades isocyanate-induced asthma has become the most common form of occupational asthma (see also Chapter 19.2).⁵² This is the most common and best studied respiratory effect of the isocyanate group of compounds. Isocyanate-induced asthma occurs with variable latency following the initial exposure, although characteristically the asthma develops within two years of exposure. The asthma develops at air-borne isocyanate levels that are well below those producing the irritant symptoms previously described. Exposures below the current time-weighted average standard of 5 ppb for TDI have been shown to cause sensitization and asthma; this may be the result of higher transient peak exposure levels. After a worker has become sensitized to isocyanates, respiratory symptoms may appear at levels far below permissible limits. Once sensitized, asthma often becomes persistent, with non-specific bronchial hyper-reactivity. Although antiasthmatic therapy may control or prevent symptoms in affected individuals, a lethal attack of asthma may unexpectedly occur. There are several reports in the literature of deaths among young TDI- or MDI-sensitized workers receiving antiasthmatic therapy, following continued exposure to isocyanates at work. In addition, therapy may not alter the natural history of asthma, and continued exposure to isocyanates may lead to more severe and sustained reactions that may generalize to agents other than isocyanates.

After complete cessation of exposure, respiratory symptoms and bronchial hyperactivity may continue for years. In a long-term follow-up of 245 cases of isocyanate-induced asthma, Finnish investigators found that over 80% still had asthmatic symptoms ten years following initial diagnosis.⁵³

Workers affected by isocyanate-induced asthma typically have bronchospastic symptoms several hours after the initial exposure, that is, at the end of the work day or a delayed response in the evening after work. On returning to work the following day, a similar temporal pattern recurs. Isocyanate inhalation challenge tests demonstrate a similar pattern of late physiologic response, as well as dual responses. Three important caveats exist about the use of the specific inhalation challenge tests. First, isocyanate inhalation challenge tests may be positive in affected workers, despite normal methacholine challenge tests. Second, the isocyanate inhalation challenge test may yield a false-negative result if testing is performed after a significant amount of time elapses since the last exposure to the offending agent. Third, availability of such testing is limited, and can only be performed at specialized medical centers with experience in specific inhalation challenge testing.

Population-based studies of TDI-exposed workers show that 5–20% of workers exposed to TDI may become sensitized to the chemical. There seems to be no relationship between a history of allergy or atopy and the development of isocyanate-induced asthma. The pathogenesis of isocyanate asthma has yet to be fully elucidated. Isocyanate-specific IgE antibodies have been demonstrated in some isocyanate-sensitive individuals by radioallergen sorbent testing, but exposure to isocyanates in the absence of respiratory symptoms has also been associated with the development of such antibodies in workers. It appears that only a small proportion of isocyanate-sensitive individuals, i.e., approximately 20%, have these IgE antibodies. IgE antibodies are, thus, highly specific but not very sensitive indicators of isocyanate-induced asthma. Alternative, though not mutually exclusive, mechanisms for bronchospasm include pharmacologic effects on adrenergic receptors and direct inflammatory effects; the epidemiologic and clinical data strongly suggest an immunologic basis. The role of a cell-mediated response to isocyanates is currently under active investigation.

Longitudinal observation of occupational groups exposed to TDI has demonstrated that chronic airflow limitation may develop in individuals who are not specifically sensitized to it. An investigation of polyurethane foam manufacturing plant workers showed an excessive decline in FEV₁ during a two-year follow-up at exposure levels less than 1–9 ppb.⁵⁴ A prospective study of workers at a new TDI manufacturing factory showed an excessive decline in lung function only in non-smokers with the highest cumulative TDI exposure. Most TDI exposures in this study were below 5 ppb.⁵⁵ In an earlier British study of workers exposed to levels of TDI of 20–50 ppb or higher, no differences in respiratory symptoms or pulmonary function were observed between the study group and a control group of unexposed workers. Different study methods and settings may in part explain the variable findings in these studies.

Both TDI and MDI have been shown to cause hypersensitivity pneumonitis.⁵⁶ Although much less common than asthma, extrinsic allergic alveolitis may occur in at least 1% of isocyanate workers with symptoms. IgG antibodies against the offending isocyanates are usually found in the serum and bronchoalveolar lavage fluid. Isocyanates have also recently been reported to cause hemorrhagic pneumonitis.⁵⁷ A recent case report described dyspnea, hemoptysis, patchy pulmonary infiltrates, and high serum levels of isocyanate-specific IgE and IgG antibodies in a spray painter with exposure to multiple isocyanates. This may be the same syndrome as the pulmonary disease–anemia syndrome that has been reported among workers exposed to phthalic anhydride.

There has been recent interest in the risk of cancer associated with isocyanates. According to an IARC evaluation in 2000, animal experiments demonstrate sufficient evidence of carcinogenicity to designate TDI an animal carcinogen; there is limited evidence of carcinogenicity for MDI.⁵⁸ Epidemiologic studies are limited but show possible excess in non-Hodgkin's lymphoma, rectal cancer, and pancreatic cancer.⁵⁹

Evaluation and prevention The diagnosis of isocyanate-induced asthma is based on a history of exposure to isocyanates and the presence of the characteristic temporal bronchospastic response. Inhalation challenge testing with isocyanate test material may be useful in confirming the causal relationship, particularly when methacholine challenge testing is negative or, in questionable cases, where it is necessary to demonstrate the specificity of bronchospasm to isocyanate exposure. After isocyanate-related asthma develops in a worker, it is essential that he or she be removed from any further isocyanate exposure.

Workers who are routinely exposed to isocyanates should be educated about the respiratory effects of such exposure and should undergo a biannual respiratory symptom review and spirometry. There is currently no rational basis for excluding atopic individuals from jobs involving potential exposure to isocyanates.

Plastics additives

Azodicarbonamide

Azodicarbonamide is a blowing agent for a variety of plastic and rubber polymers, including PVC, polyurethane, polyethylene, acrylonitrile-butadiene-styrene resins, and elastomers. It is widely used as an additive in the plastics industry, although not in a high volume relative to the polymers with which it is compounded. When heated, azodicarbonamide releases a large amount of gas, which produces the desired blowing effect.

This chemical has been known for the past 20 years to produce asthma. The asthma usually develops within the first year after onset of exposure. There is a characteristic late bronchospastic response, i.e., at the end of a work-shift or during the evening following exposure. Because there may be other allergenic agents in the work environment where this chemical is used, the diagnosis of azodicarbonamide-induced asthma is dependent on a clear temporal relationship between the exposure and related symptoms, as well as demonstration of bronchial hyper-reactivity on specific inhalation challenge test.⁶⁰ Cross-sectional studies of workers exposed to this chemical in both a manufacturing facility and plastic injection molding facility observed that as many as 20% of workers may have bronchospastic symptoms in association with azodicarbonamide exposure.⁶¹ Allergic contact dermatitis has also been reported in a few exposed individuals.

Hexamethylenetetramine and other amines

Hexamethylenetetramine (hexamine) is an important amine used predominantly as a curing agent for urea-formaldehyde and phenolic resins. Hexamine is also used in the rubber industry to prevent vulcanized rubber from 'blocking', as well as an accelerator. Approximately 80 million pounds of this agent were produced in the United States in 1994. Hexamine hydrolyzes to ammonia and formaldehyde in an aqueous environment and has thus been used as a oral antibacterial agent (e.g., mandelamine).

Its pyrolytic products include nitrogen oxides, carbon monoxide, carbon dioxide, and formaldehyde.

It has been known for decades that hexamine is a skin and respiratory irritant. A recent cross-sectional study of workers at a hexamine production plant observed no relation between respiratory symptoms and pulmonary function abnormalities, though workers were well aware of irritant dermatitis caused by hexamine.⁶² Oral hexamine use in clinical settings been noted to cause gastrointestinal distress, bladder irritation, dermatitis, and urticaria.

A variety of other amines have been associated with the development of asthma, including dimethylethanolamine, ethylenediamine, piperazine, and dimethylaminopropylamine. Because numerous amines are used in curing plastic resins, including phenolic, epoxy, and polyurethane resins, it is reasonable to expect that these agents may contribute to the occupational asthma that occurs in resin production. The role of amines may be obscured by the presence of other allergenic agents, such as isocyanates and anhydrides. In a recent Swedish study, Belin and coworkers documented airway obstruction in workers in a polyurethane foam-producing plant in which the air-borne concentration of isocyanates was extremely low and the air-borne concentration of a catalytic amine, N-methylmorpholine, was 10,000 times higher than that of the isocyanates.⁶³ Even when the role of isocyanates and other well-recognized allergens cannot be excluded, it is worth considering the potential role of amines when respiratory symptoms are present in workers with these multiple exposures.

Diethylhexyl phthalate (DEHP)

DEHP and other phthalates are the major agents used as plasticizers, which impart flexibility to plastic compounds. These additives may represent a substantial amount, as much as 20–40% by weight, of plastics such as PVC. Other polymers in which these plasticizers are used include synthetic rubber and polystyrene. DEHP, also known as dioctyl phthalate, is an irritant of the skin and respiratory tract. Animal studies have shown evidence of testicular, renal, developmental, and pulmonary toxicity associated with DEHP exposure; similar toxicity in humans has not been well described.⁶⁴

Of considerable interest is whether DEHP represents a human carcinogen. A review by IARC in 2000 concluded that DEHP was not classifiable as to carcinogenicity in humans.⁵⁷ There is sufficient evidence that DEHP causes cancer in animals, particularly liver tumors in mice and rats. Adequate human epidemiologic data are not available for the assessment of possible carcinogenic effects in humans. However, the carcinogenicity of DEHP in animals has generated concern, not only because of the potential occupational exposure to DEHP, but also as a result of the potential exposure to the general public through leaching of DEHP from plastic bags used to store blood and intravenous solutions. Biologic monitoring of DEHP metabolites in urine has been demonstrated to be a useful means of quantifying exposure.⁶⁵

SYNTHETIC TEXTILES

Synthetic textiles are fibrous forms of plastics. The overall production process described in Figure 41.1 also applies to this subgroup of plastics. Indeed, many of the materials used in plastics production are also used in the manufacture of synthetic textiles. Examples include styrene and the anhydrides. Surprisingly few data are available specifically on the occupational health aspects of finished synthetic fibers.

Nylon

Nylon

Nylon is formed through one of two means: (1) by the condensation of an acid, such as adipic acid, and an amine, such as hexamethylenediamine, or (2) by the polymerization of a lactam, such as caprolactam. Adipic acid is the major organic acid used as a raw material in the production of nylon. A small amount of adipic acid is additionally used in the production of polyurethane resins, plasticizers, and synthetic lubricants. Caprolactam is almost exclusively used in the manufacture of nylon, i.e., polycaprolactam. Nylon fibers are used in textiles, tire cords, and related fabrics; nylon plastics are molded to form various consumer products, including housewares and appliances.

Adipic acid and caprolactam are irritating to the eyes, skin, and throat. There is additionally a convincing case report of a worker with moderately severe asthma after repeated exposure to adipic acid. The worker had an immediate bronchospastic reaction following inhalation of a low dose of adipic acid; the reaction was prevented by a prior administration of cromolyn sodium.

In a mortality study of nylon manufacturing workers, there was a statistically significant excess in mortality from bladder cancer, which occurred largely in workers after 20 years from first employment. Another type of nylon (nylon 11) using a different monomer, 11-aminoundecanoic acid, caused transitional cell carcinomas of the urinary tract in rats. No human data relating to exposure to nylon 11 or its monomer are yet available.

Polyester

Polyester

Polyesters are produced by the condensation of an acid anhydride, such as phthalic anhydride, and an alcohol, such as ethylene glycol. The polyester polymer can be subsequently mixed with other materials, such as styrene and hydroquinone. The hazards associated with these raw materials are described in other sections.

Polyester polymer has demonstrated mucous membrane and respiratory toxicity. Workers grinding buttons made of polyester resin commonly report irritation of the throat and eyes during exposure to polyester dust. These symptoms were corroborated by mild but statistically significant decrements in mid-expiratory flow rates during 8-hour work shifts. A later report by the same investigators observed reduced preshift mid-expiratory flow rates and an excess in cough, phlegm, and dyspnea in exposed workers compared with a control group.

A mortality study of workers manufacturing polyester resin reported an increased rate of lung cancer among production workers, although this elevation was not statistically significant. A significant excess was observed in maintenance workers; cigarette smoking did not appear to be the cause of the observed excess in lung cancer.⁶⁶

Rayon

Carbon Disulfide

Viscose rayon, also known as artificial silk, is one of the earliest synthetic fibers, with production beginning in the early 1900s. Rayon is formed through the treatment of alkali cellulose with carbon disulfide. Carbon disulfide, a highly volatile solvent, causes most of the toxicity experienced by rayon manufacturing workers. The toxicity of carbon disulfide has been known for 150 years and has been the subject of many reports in the first half of the 20th century. Carbon disulfide causes prominent central nervous system effects, ranging from headaches, dizziness, and irritability in mild cases, to mania, hallucinations, delirium, suicidal ideations, and coma (carbon disulfide psychosis) in severe cases. The solvent also causes a sensorimotor peripheral neuropathy.⁶⁷ Carbon disulfide has been associated with an increased risk of coronary artery disease. Exposure to carbon disulfide has been more effectively controlled in recent years, preventing more severe neurologic illness so well documented in the first half of the 20th century (see also Chapter 28, neurology).

SYNTHETIC RUBBER INDUSTRY

The use of synthetic rubber far outweighs that of natural rubber, accounting for approximately 70% of all rubber production. Although the number of applications of synthetic rubbers has increased in recent years, overall growth has been modest, with a 30% increase in production during

the two decades from 1967 to 1988. Of the rubber polymers, styrene-butadiene polymer is the most important, representing nearly 40% of the entire production of elastomers. Other rubber polymers in decreasing order of volume produced include polybutadiene, ethylenepropylene, butadiene-acrylonitrile (nitrile), and polychloroprene (neoprene).

Like the plastics industry, the synthetic rubber industry has distinguishing characteristics that are essential to the recognition of the occupational hazards of the industry. The synthetic rubber industry shares the basic paradigm of production common to the plastics industry, i.e., the production of a polymer, also known as an elastomer, which is further processed into a finished product. The processing of rubber polymers represents the major sector of the synthetic rubber industry, including tire manufacture, and is highly complex compared with most plastics-processing operations. The synthetic rubber industry uses hundreds, if not thousands, of chemical agents, many of them additives. Furthermore, the profile of agents used in the industry has changed significantly over time, necessitating caution in applying the results of studies of health effects in prior decades, especially those evaluating carcinogenic risks of the industry, for currently exposed workers.

Given the large number of agents used, formation of complex and sometimes uncharacterized chemical mixtures, and relative complexity of the manufacturing process in the rubber industry, many epidemiologic studies of the rubber industry characterize exposures by the department or step in the manufacturing process, rather than by the specific exposures of individual workers. When possible, the role of individual agents, such as styrene, benzene, and β -naphthylamine in producing disease has been identified. More commonly, diseases have been associated with working in a department, such as mixing or curing, or another step in the production process.

The production of finished rubber materials requires two separate manufacturing processes, namely: (1) the formation of raw polymer, and (2) the conversion of the polymer to the finished rubber product. The first step is similar to that of plastic polymer production, with large-scale operations using bulk materials in enclosed systems. Because the number of important monomers and their polymeric forms are relatively few, the scope of the occupational health problems intrinsic to polymer production is more limited, though not fully characterized. The transformation of the raw polymer to finished rubber goods may be simple, similar to the comparable processes in plastics production, or it may be highly complex, such as in the 40-step process required to make tires. Major steps in the complex production of tires and selected other rubber goods are shown in Table 41.4.

Each step may involve characteristic and identifiable exposure or exposures to unknown chemical intermediates or byproducts of chemical reactions occurring throughout the production process.

Production step	Potential exposures
1. Mixing or compounding: combining the raw polymer with additives	Elastomers Reinforcers (carbon black) Fillers (amorphous silica, clays) Vulcanizers (sulfur, selenium) Accelerators (thiurams, thiocarbamates) Retarders (salicylic acids) Activators (zinc oxide, stearic acid) Plasticizers (phthalates) Antioxidants (phenylenediamines) Extenders (mineral oils) Pigments (titanium, cadmium, organic dyes) Solvents Processing aids (aromatic mineral oils)
2. Milling: thorough blending and heating of assembled ingredients	Fumes of elastomers and/or additives Antitacking agents (kaolin, soaps)
3. Extrusion and calendaring: shaping and cutting of rubber compound and application of rubber onto textile fabrics or steel cords	Solvents (naphtha, hexane, toluene) Adhesives Formaldehyde
4. Assembly: fabricating the desired piece	Solvents (haptene, methanol, naphtha) Mold-release agents (silicones, soaps) Tacking agents (phenolic resins)
5. Curing or vulcanization: applying heat and pressure to the piece in a mold, press, or autoclave to effect cross-linking reactions	Mold-release agents Lubricants (solvent based) Curing fumes (complex mixtures)
6. Finishing: trimming, grinding, cleaning, and painting to produce the final product	Solvents Rubber dust Inks and paints

Table 41.4 Steps in synthetic rubber production

Styrene

Styrene

Styrene is an essential monomer in several of the most important rubber polymers, and it is additionally used in plastics production. The production of styrene in the United States in 2000 was 10.8 billion pounds and is increasing steadily. More than one-half of all styrene production is used to make polystyrene, the third leading plastic polymer after PVC and polyethylene. Most of the remainder is co-polymerized with acrylonitrile and/or butadiene to form elastomers. A small but important use of styrene is as a cross-linking agent and diluent in unsaturated polyester resin application, particularly in the boat-building industry, where excessive styrene exposure has been well documented.

Styrene is an irritant to the mucous membranes and respiratory tract at air-borne levels of 100 mid-expiratory 200 ppm, two to four times OSHA's current permissible exposure level of 50 ppm. Acute exposures to 50 ppm styrene in experimental settings are documented to cause irritation.

The impact of styrene exposure on the lungs is not well understood. Several cross-sectional studies of exposed workers demonstrate elevated rates of respiratory symptoms including chest tightness and wheezing. These symptoms have not been accompanied by well-characterized changes in pulmonary function. This important topic deserves further study.

Styrene has demonstrated hepatotoxicity in animals and in humans.⁶⁸ In a large cross-sectional study of polystyrene workers, the elevated γ -glutamyl transpeptidase activity was associated with high styrene exposure. No other liver function tests showed a relationship to styrene exposure. A recent study of two groups of workers exposed to styrene below 50 ppm were found to have mild subclinical hepatic injury as evidence by increased levels of bilirubin, alkaline phosphatase, and hepatic transaminases in exposed workers compared with controls (see also Chapter 26.1).⁶⁹

Styrene is toxic to the central and peripheral nervous systems.⁷⁰⁻⁷² Exposure to high levels of styrene causes light-headedness, headache, and altered balance (as evidenced by an abnormal Romberg's test). A high prevalence of abnormal electroencephalograms has been found among styrene-exposed workers in a number of studies. Studies of subclinical toxicity using neurobehavioral tests demonstrate abnormalities in psychomotor performance, visual memory, and vigilance. There is also limited evidence that styrene can affect verbal learning and logical memory, at or below 50 ppm. Neurologic symptoms and selected neurobehavioral deficits (visuomotor performance and perceptual speed) may persist for several years following cessation of exposure.⁷³ In the few neurophysiologic studies evaluating the effects of styrene on the peripheral nervous system, sensory nerve conduction deficits have been consistently found, including workers with styrene exposure below 50 ppm.

Exposure to styrene has been weakly associated with an increase in a variety of lymphatic and hematopoietic malignancies, including leukemia, lymphoma, and multiple myeloma, in numerous epidemiologic studies. Other studies have not confirmed these associations. Study groups have had varying degrees of exposure to potentially confounding carcinogens, such as benzene, acrylonitrile, and butadiene, obscuring the relationship between styrene exposure and cancer. There is only limited evidence that styrene is an animal carcinogen. However, styrene-7,8-oxide, a metabolite of styrene in humans, is a confirmed animal carcinogen. IARC has rated styrene as a possible carcinogen (Group 2B) since 1994, based on limited evidence in experimental animals and inadequate evidence in humans. IARC designates styrene-7,8-oxide as a probable human carcinogen (Group 2A).⁴⁹

Acrylonitrile

Acrylonitrile

Acrylonitrile is used principally in the manufacture of rubber copolymers and acrylic fibers. Acrylonitrile is among the top 50 chemicals produced in the United States, with 2.5 billion pounds produced domestically in 1993. Acrylonitrile production has grown rapidly. Approximately one-quarter of the acrylonitrile is copolymerized with butadiene and/or styrene to form acrylonitrile-butadiene-styrene, styrene-acrylonitrile, and butadiene-acrylonitrile (nitrile) resins. These elastomers are three of the major synthetic rubbers currently manufactured.

Clinical effects

Acrylonitrile is a well-known irritant to the mucous membranes and skin. Toxic epidermal necrosis had been reported among patients who were exposed to a fumigant containing carbon tetrachloride and acrylonitrile. Acrylonitrile may be hepatotoxic, but the nature and extent of the toxicity are not clear.

Systemic acrylonitrile poisoning can cause headaches, fatigue, nausea, and light-headedness initially, but may cause severe asphyxia and death in some cases. Much of the acute toxicity of acrylonitrile likely results from the metabolism of acrylonitrile to form cyanide, which is further metabolized to thiocyanate. Treatment of acute acrylonitrile toxicity is similar to that of cyanide poisoning, i.e., with amyl nitrate and sodium thiosulfate, although therapeutic efficacy may be limited by the formation of cyano metabolites other than cyanide that are not amenable to these antidotes. The role of hydroxycobalamin to bind cyanide and its metabolites is being explored.

Acrylonitrile is a well-documented animal carcinogen. Numerous epidemiologic studies have been completed in the US and in Europe and do not show consistent elevations in cancer risk. The largest US study demonstrated an elevation in risk of lung cancer among acrylonitrile workers in the highest quintile of cumulative exposure.⁷⁴ IARC considers acrylonitrile to be a probable human carcinogen (Group 2A).¹⁹

Evaluation and prevention

Clinical evaluation of acrylonitrile-exposed workers should center on the dermatologic, respiratory, and central nervous system effects of the agent. Biologic monitoring may be conducted through measurement of urine acrylonitrile or thiocyanate levels. Facilities using acrylonitrile should have an easily accessible cyanide poisoning antidote kit. Proper training in the use of the kit should be conducted.

OSHA-mandated annual medical surveillance provisions include a complete work and medical history, physical examination, chest x-ray studies, and screening for occult stool blood. Liver function tests are also advisable.

1,3-Butadiene

1,3-Butadiene

1,3-Butadiene is used principally as a comonomer in the manufacture of polymers with acrylonitrile and styrene or as a monomer in the formation of polybutadiene. Less important uses are as an intermediate in the production of adiponitrile, polychloroprene, and captan. The US production of 1,3-butadiene was 3.1 billion pounds in 1993.

At high levels of exposure, 1,3-butadiene is an irritant and can produce central nervous system depression. Despite the volume of 1,3-butadiene produced in the United States, few cases of toxicity have been reported. Initial symptoms of acute toxicity include blurred vision, drowsiness, fatigue, headache, and nausea.

In 1996, OSHA lowered the permissible exposure level for 1,3-butadiene to 1 ppm as an 8-hour time-weighted average with a short-term limit of 5 ppm. In recognition of its carcinogenicity, NIOSH recommends that occupational exposure to 1,3-butadiene be at the lowest feasible concentration. The principal health concern about 1,3-butadiene is its carcinogenicity. In 1998, IARC reviewed available studies on 1,3-butadiene and designated it as a Group 2A carcinogen, with sufficient evidence in animals and limited human evidence of carcinogenicity. In animal assays, 1,3-butadiene causes tumors at multiple sites in multiple species, including lymphomas in mice. Epidemiologic studies link exposure to 1,3-butadiene to leukemia and lymphomas.⁷⁵

Biomonitoring for 1,3-butadiene exposure can be achieved in research settings through the measurements of urinary metabolites [1,2-dihydroxy-4-(N-acetylcysteinyl)-butane and 1-hydroxy-2-(N-acetylcysteinyl)-butene] and hemoglobin adducts, the latter being most highly associated with measures of 1,3-butadiene exposure.⁷⁶

HEALTH HAZARDS

As noted previously, exposures in rubber manufacturing are numerous, complex, and often not fully characterized. Hence, the occupational health problems associated with the manufacture of rubber goods, especially tire production, have been described and are best reviewed by the specific activity within the industry or by the whole industry rather than by exposure to individual agents.

Skin disease

Rubber additives are the principal agents responsible for the dermatitis observed among rubber workers and consumers who wear rubber articles. Allergic skin reactions have been associated most frequently with mercaptoben-zothiazole, phenylenediamine derivatives, and thiuram

accelerators. Irritant dermatitis has also been caused by a number of different agents.

Respiratory disease

Rubber manufacturing causes chronic lung disease. Increased rates of cough, phlegm production, dyspnea, and wheezing have been reported in the mixing, milling, and curing departments of tire factories. Pulmonary function testing of exposed groups has shown predominantly obstructive changes [reduction in FEV₁, and/or FVC₁ (forced vital capacity ratio)] measured prior to work shifts. Cross-shift declines in FEV₁ have also been documented for rubber workers exposed to adhesives containing hexamethylenetetramine and resorcinol.

Talc, which was commonly used as an antitacking agent, has caused frank talcosis in rubber workers, and has been associated with respiratory morbidity and airway obstruction, even in the absence of chest radiographic abnormalities. When crystalline silica with a high content of the crystalline moiety was used as a substitute for talc, silicosis resulted. Carbon black exposure may also produce a pneumoconiosis.

Cancer

The cancer experience of rubber manufacturing workers has been the subject of intense epidemiologic research during the last four decades. Although the complexity of the industry has led to considerable variability in the carcinogenic risks measured, certain conclusions are warranted. An excess risk of death from bladder cancer (standardized mortality ratios ranging from 200 to 500) was observed in earlier studies and is believed to be the result of antioxidants containing β-naphthylamine. More recent cohort and case control studies show lower levels of risk, i.e., less than twofold, or, frequently, no increase in risk. Interestingly, a sixfold increase in risk has recently been observed among workers using the aromatic amines, toluidine and aniline, to produce a rubber accelerator.⁷⁷

Excesses of leukemia and, to a lesser extent, lymphoma are observed among rubber workers.⁷⁸ Workers in a variety of parts of the industry, especially calendering, curing, and tire building, experienced a two- to fourfold increase in leukemia compared with reference populations. Benzene may be an important etiologic agent given the widespread use of this solvent in the industry in past decades.

Other cancer sites reported to show increased risk among rubber workers are the lung and stomach (standardized mortality ratios ranging from 100 to 250). In addition, the rates of cancer of the prostate and colon have been elevated in several studies; the evidence in favor of an occupational etiology for these cancer sites is considered to be limited by IARC. Finally, one or more studies have noted increases in the rates of cancer of the brain, thyroid, and pancreas. A review of the studies pertaining to the relationship between employment in the rubber industry and cancer can be found in the IARC monograph on the rubber industry.⁷⁹

Chapter 42

Organic Nitrogen Compounds

Joel D Kaufman, Chris Carlsten

Organic nitrogen compounds, such as amines, amides, nitrates and nitrochemicals, encompass a wide range of specific agents, with industrial applications usually related to their highly reactive chemical nature. This chemical reactivity also frequently affects biologic systems, and makes nitrogen compounds important hazards in the work environment. Some of these chemicals have figured prominently in the history of occupational health and, as a result, occupational exposures have been markedly reduced or eliminated. In many other cases, however, when an agent is not considered replaceable, or when the health effects are not sufficiently well recognized to force substitution of a less toxic chemical, exposure remains an important concern.

EXPOSURE SETTINGS

Forty years ago, the recognized occupational health effects of organic nitrogen compounds primarily concerned exposure to the benzidine dyes in the dye-making and textile industries, and to the nitrates in the manufacture of explosives. Although concern about these agents remains, the largest group of agents in this class today are chemical reagents used in a variety of advanced technologic applications, including resin systems and advanced composite materials. In addition, the health effects of some nitrogen-containing agents have been exploited for medicinal purposes, and many of these agents are encountered in the pharmaceutical industry. Other agents are created as intermediates in chemical manufacturing processes or are used routinely as laboratory reagents. The biotechnology industry and research community use many organic nitrogen compounds; achieving exposure controls in the laboratory represents a continuing challenge. Still other agents are primarily encountered as drugs of abuse (e.g., amyl nitrate) and will not be addressed here. A summary of organic nitrogen compounds, including applications and health effects, is provided in Table 42.1.

ENVIRONMENTAL MANAGEMENT

No guidelines apply to managing all of the wide-ranging hazards presented by this group of chemical agents. One general problem with these chemicals is that the skin represents a major route of exposure, often accounting for a large fraction of the systemic bioavailable dose. Occupational and environmental management strategies, therefore, cannot rely only on reducing the air-borne

concentration of the contaminant, but must also provide barriers to skin exposure. The choice of gloves and other skin protection strategies must be tailored to the particular agent; glove materials that are impermeable to some agents may not provide an effective barrier to other organic nitrogen compounds.

CLINICAL EFFECTS

Organic nitrogen compounds vary tremendously in their toxic effects, but some general patterns exist and can be used to understand the nature of the occupational and environmental hazards. Major categories of effects appear repeatedly throughout this group, and a discussion of each of these follows. Table 42.1 indicates which of the common effects can be seen with individual agents and lists other important toxic effects.

Methemoglobinemia and hemolytic anemia

A variety of nitrogen-containing substances, including certain nitrates, nitrites, and aromatic amines, have the capacity to oxidize the heme moiety in the hemoglobin of erythrocytes, resulting in methemoglobin (MetHb), which is darkly pigmented and a poor carrier of oxygen. The agents that produce this effect are classified methemoglobin-formers. Methemoglobinemia can result in tissue hypoxia, with cyanosis and the potential for ischemic complications.

Occupational or environmental contact with MetHb-formers is common, but the agents differ in their ability to oxidize hemoglobin. In addition, the physiologic response to these agents is variable, although some of the differences are predictable. Individuals who are heterozygous for the traits that cause congenital methemoglobinemia (hemoglobin M disease or MetHb reductase deficiency) are at increased risk for complications with exposure, and those with glucose-6-phosphate dehydrogenase (G-6-PD) deficiency are much more likely to experience hemolytic anemia when exposed to these oxidizing agents.

Methemoglobinemia may develop following exposure to chemical agents (e.g., sodium nitrite in food processing or a variety of amine dyes), pharmaceutical agents (e.g., nitroglycerin [NTG], topical anesthetics, or dapsone), explosive materials (e.g., di- or trinitrotoluene, or nitrite-contaminated well water). A selected list of organic nitrogen MetHb-formers, primarily from occupational exposures, is included in Table 42.1.

Agent	Use	MethHb	Vas	Car *	Irr	Sens ♦	Hep	Comments/Notes
Aliphatic Amines <i>Alkyl monoamines</i> methylaniline	intermediate for dyes, pesticides	—	—	—	M/R/D	—	—	as with allylamine, may increase atherosclerosis in susceptible individuals (i.e. diabetics)

Agent	Use	MethHb	Vas	Car *	Irr	Sens ♦	Hep	Comments/Notes
chloroaniline	curing agent for polyurethane; intermed. in manufacture of dyes, solvents, pesticides	+	-	?	-	-	+	mutagen; renal toxin in rats
chlorodinitrobenzene	lab reagent, explosives, dyes	+	-	?	D	D	-	retrobulbar neuritis, peripheral neuropathy dermatitis: vesiculopapular or exfoliative hemolytic anemia
diaminodiphenyl sulfone (DDS or dapsone)	pharmaceutical (antibiotic); curing agent for composite and epoxy resin systems	+	-	-	-	-	+	
dichlorobenzidine	dyestuffs, curing agent in plastics, rubbers	-	-	*	D	-	-	
diethylaniline	herbicide manufacture	+	-	?	-	-	-	
dimethoxybenzidine	dyestuff (blue)	-	-	?	-	-	-	animal carcinogen
dimethylaminoazobenzene	dyestuffs, fat indicator (Sudan stain), analytic reagent	-	-	†	D	D	-	
dimethylaniline	chem. intermed. for dyes, vanillin, lab reagent, catalyst in resin systems	+	-	?	-	-	-	CNS depression
dinitrobenzene	chem. intermediate for man-made fibers, dyes, explosives; lab reagent	+	-	-	R	-	?	hemolytic anemia; ocular toxicity
dinitrophenol	wood preservative, pesticide, lab reagent, chem. intermed. in dyes, photo developers	-	-	-	M/D	+	+	uncouples oxidative phosphorylation with resulting chemical asphyxia, hepatic/renal failure
dinitrotoluene	explosives, dyes, chem. intermed. in isocyanate production	+	+	†	-	-	+	2,6 but not 2,4-isomer is animal carcinogen (see text) hemolytic anemia animal carcinogen
3,3'-dichlorobenzidine	dye-making, curing agent in plastics, rubber, urethane	-	-	†	D/R	-	-	
methylene dianiline	chemical mfg, curing agent for resins, urethanes and epoxies	-	-	†	M/D	D	+	cholestatic hepatitis, skin staining
4,4'-diaminodiphenylmethane methylene bis-2-chloroaniline (MOCA or M-BOCA)	corrosion inhibitor, dyemaking curing agent for urethane, epoxy, and other resin systems	+	-	†	-	-	-	hematuria as acute effect
naphthylamine	chem. intermed. for dyes, rubber, pesticides	+	-	†	-	-	-	hemorrhagic cystitis as acute effect, 2-naphthylamine is human carcinogen while evidence for 1-naphthylamine not strong hemolytic anemia
nitroaniline	red/yellow, orange dyes; corrosion inhibitor, chem. intermed.	+	-	-	-	-	+	hemolytic anemia; animal carcinogen
nitrobenzene	chem. intermed. for pharmaceut. dyes, pesticides, isocyanate, preservative/constituent of paints, polishes, scents, dyes, explosives	+	-	?	M/D	-	+	
4-nitrophenol	leather treatment; lab reagent, fungicide, biocide	+	-	-	M	-	-	possible renal toxin
nitrotoluene	dyestuffs, explosives, detergents	+	-	-	-	-	-	potent sensitizer with usual exposure; rhodomyolysis/acute tubular necrosis, hemolytic anemia in poisoning
phenylenediamine	cosmetics, dyestuffs, photog. chemicals, metal cutting oils, chem. agent in polymers, fibers	-	-	-	D/M	D	+	acute renal failure; skin staining; poisoning may be similar to dinitrophenol
picric acid	explosive, fuel additive	-	-	-	D/M	-	-	
trinitrotoluene	explosive	+	-	-	M/D	-	+	skin staining; aplastic anemia; cataracts
toluidine	dyestuffs, exchange resins, rubber processing	+	-	†	M	-	-	hemorrhagic cystitis, ortho isomer is probably human carcinogen
2,4-toluenediamine	photographic developer, dyestuffs, intermed. for TDI	+	-	?	M/D	D	?	see text; skin staining; gastritis; animal carcinogen

Table 42.1 (Cont'd) Toxicity of organic nitrogen compounds

Agent	Use	MethHb	Vas	Car *	Irr	Sens ♦	Hep	Comments/Notes
Aliphatic Nitro Chemicals								
nitromethane	chemical coatings, fuels, explosives, solvent	–	–	–	M/D/R	–	–	CNS effects – narcosis
nitroethane	solvent, propellant, chem. intermed.	–	–	–	R/M/D	–	–	fulminant hepatic failure, CNS effects – intoxication, headache
2-nitropropane	coatings, propellant, fuel additive, chem. intermed.	+	–	†	M	–	+	very potent respiratory irritant, mild methemoglobinemia
tetranitromethane	fuel additive, lab reagent, explosive	+	–	?	M/R/D	–	+	severe gastroenteritis if ingested, severe pneumonitis if inhaled, reports of cardiac necrosis
chloropicrin (trichloronitromethane)	pesticide, rodenticide, soil fumigant	–	–	–	R/M/D	–	–	epileptiform seizures w/o sequelae
Aliphatic Nitrates								
cyclonite or RDX (trimethylene trinitramine)	explosive	–	–	–	–	–	–	skin staining
ethylene glycol dinitrate	explosive, fuel	+	+	–	–	–	–	CNS effects – headache, chronic metabolite (propylene glycol) is possible renal toxin
nitroglycerin	pharmaceuticals, explosives	+	+	–	–	D	–	see text for discussion of cancer risk
propylene glycol dinitrate	explosive, fuel	+	+	–	R	–	–	animal carcinogen
pentaerythritol tetranitrate (Penitrate)	pharmaceuticals, explosives	+	+	–	–	–	–	metabolized to cyanide and formic acid, management should be as for cyanide
Nitrites								
methyl nitrite, ethyl nitrite, butyl nitrite, amyl nitrite	pharmaceuticals, deodorants, fuel additives, chem. intermed.	+	+	?	–	–	–	neurotoxin – see text; alopecia areata headache, nausea CNS effects, partially metabolized to release cyanide
Miscellaneous								
acetamides	solvent, plasticizer, stabilizer	–	–	?	mild M	–	–	CNS effects, animal carcinogen
acetonitrile	solvent in hydrocarbon extractions, nail removers, high pressure liquid chromatography (HPLC) reagent	–	–	–	–	–	–	limited information on general toxicity
acrylamide	see text	–	–	†	D	D	–	GI irritation; possible kidney toxicity
acrylonitrile	comonomer, used in rubber, plastics, coatings, adhesives, acrylic fiber, chem. intermediate, pesticides	–	–	†	R	D	+	central, peripheral neurotoxin; liver toxin
benzotriazole	anticorrosive chem. intermediate, lab reagent, plastics stabilizer	–	–	–	R/?	D	–	CNS effects; bladder cancer in rats secondary to melamine-induced stones corneal edema, ulceration
1,1-dimethylhydrazine (UDMH)	rocket fuel, organic chemicals, chemical intermediate	–	–	?	M/R/D	–	+	
1,2-diphenylhydrazine	anti-sludging agent, chemical intermediate, reagent flame retardant	–	–	†	–	–	–	
hexamethylene tetramine (HMT or methenamine)	pharmaceuticals; curing agent for resins used in plastics and explosive manufacture	–	–	–	–	–	–	
hydrazine (sulphate)	pharmaceuticals, organic chemicals, rocket fuel, lab reagent, soldering flux	–	–	–	R	D/R	–	
melamine	laminated resins (frequent comonomer with formaldehyde)	–	–	see note	–	–	–	
morpholine	solvent for resins; defoaming agent, emulsifier, corrosion inhibitor,	–	–	–	D/R/M	–	–	

Table 42.1 (Cont'd) Toxicity of organic nitrogen compounds

Agent	Use	Methb	Vas	Car *	Irr	Sens ♦	Hep	Comments/Notes
piperazine symptoms piperidine	chemical intermediate pharmaceuticals, insecticides, plastics	–	–	–	–	D/R	–	urticaria; anticholinergic and extrapyramidal
	pharmaceuticals, dyes, explosives, solvents, lab reagent, fuel additive, curing agent for resins	–	–	–	D/M/R	–	?	Possible CNS depression
pyridine pyrrolidine	pharmaceuticals chem. intermed.: pharmaceuticals, pesticides, rubber curing agent for epoxies	–	–	–	R/D/M M/R	–	+	renal toxic, CNS depression
quinoline	pharmaceuticals, paints, dyestuffs, lab reagent, corrosion inhibitor, fungistat	–	–	?	R/M	–	–	CNS depression

Methb: Methemoglobinemia; Vas: Vasoactive; Car: Carcinogenicity; Irr: Irritant; Sens: Sensitization; Hep: Hepatotoxicity.
 + indicates a preponderance of evidence in support of the effect; – indicates a preponderance of evidence unresponsive of the effect; and ? indicates equivocal evidence
 † For cancer, indicates this agent should be considered a probable or certain human carcinogen; ? this agent is an animal carcinogen or potent genotoxic agent, although sufficient human evidence is lacking. It
 should be considered a possible human carcinogen; – based on available information, carcinogenic activity is not suspected.
 M, this agent is a mucous membrane (eye, nose, throat) irritant; R, this agent is a lower respiratory tract irritant associated with acute effects and the potential for delayed pulmonary edema; D, this agent is a skin
 irritant.
 ♦ R, this agent has been noted to sensitize the respiratory system and is associated with asthma; D, this agent has been noted to sensitize the skin and is associated with allergic contact dermatitis.

Table 42.1 (Cont'd) Toxicity of organic nitrogen compounds

Although many nitrogen-containing compounds cause methemoglobinemia in animal studies, the effect is not clinically significant in all cases. For some chemicals, such as nitromethane, the agent's heme-oxidizing potency is too weak to cause toxicity in most occupational or environmental settings. For other agents, such as propylene glycol dinitrate, other toxic effects (vasoactive effects, in this case) are present and require attention at lower exposure levels than MetHb formation.

MetHb levels have been proposed for biologic monitoring of exposure to nitrate chemicals. Currently, dose–effect relationships for this response are not sufficiently predictable to use these levels for ongoing monitoring, although there is great potential for development of methods for biologic monitoring in the future. In instances when a recent high level of exposure to a potent MetHb-former (such as aniline) is suspected, however, MetHb concentration can provide a useful confirmation.

Acute and chronic effects

Significant methemoglobinemia has effects typical of other causes of tissue hypoxia. The severity of clinical effects, which can range from no symptoms to coma, depends on the degree of poisoning, presence of concomitant anemia, hypoxemia (from lung or heart disease), or ischemic vascular disease. Typical early complaints include headache and fatigue. Findings of acrocyanosis, with bluish discoloration of the fingertips, toes, ears, and lips, often precede any symptoms. Methemoglobinemia has no specific chronic effects, aside from those associated with hypoxic injury.

Clinical evaluation

Cyanosis unresponsive to oxygen administration and 'chocolate brown' blood (when dried on filter paper) strongly suggest the diagnosis of methemoglobinemia; laboratory evidence of normal oxygen saturation and elevated MetHb concentration provides confirmation. The initial evaluation should identify a history of relevant exposure, as well as family or personal history of anemia or hemoglobinopathy. Laboratory studies should include hemoglobin determination, oxygen saturation level, and spectrophotometric measurement of MetHb. Recently, several commercial oximeters, including a bedside device, have been shown to be better than conventional photometric analysis in terms of reproducibility and accuracy of methemoglobin concentration measurements.¹ Further studies are necessary to determine whether the instruments perform equally well under diverse clinical circumstances; importantly, methylene blue administration will interfere with these measurements. The presence of Heinz bodies and evidence of hemolytic anemia on a peripheral blood smear indicate a more severe oxidant stress on red blood cells and raise the suspicion of an underlying G-6-PD deficiency.

Management

Unless symptomatic, methemoglobinemia should be treated simply by removing the offending exposure. When

treatment is needed, methylene blue (MB) is administered intravenously (1 mg/kg). Recently, high-dose riboflavin has been shown *in vitro* to be effective in reducing nitric oxide-induced MetHb,² but it is not yet clear whether this is safe or effective in clinical practice. N-acetylcysteine, while reducing MetHb *in vitro*, failed to do so in a randomized, controlled trial of human volunteers.³ In severe cases unresponsive to MB, if significant hemolysis is present, or if the patient has known G-6-PD deficiency (so that methylene blue is contraindicated because of its additional oxidant activity), exchange transfusion should be provided as initial therapy. In such cases automated red blood cell exchange may be superior to conventional exchange.⁴

Prevention

Reducing potential exposure to MetHb-formers is the cornerstone of prevention. Attention must be paid to inhalational, dermal, and oral routes of exposure. At present, the use of MetHb in biologic monitoring, while specific, may be inaccurate in assessing the potential exposure hazards. In environments in which exposure is suspected, the presence of elevated MetHb levels should trigger engineering modifications; however, normal spot MetHb levels are insufficient to determine that exposure levels are safe.

There is no question that certain individuals (e.g., those with G-6-PD or MetHb reductase deficiency and those with hemoglobin M disease) are at increased risk from the health effects of exposure to nitrogen compounds that oxidize heme. Current environmental control techniques can achieve exposure levels that protect even these sensitive workers. If such workers are identified in a worksite with potential MetHb-former exposure, they should be screened periodically with complete blood counts, MetHb level and peripheral blood smears to be certain that adverse effects are not occurring. Blood work every 6 weeks for the first 3 months, followed by blood work every 6 months, is an appropriate schedule for most sensitive individuals. The finding of significant methemoglobinemia or hemolysis, even if asymptomatic, warrants medical removal while the offending exposure is reduced.

Vasoactive effects and coronary artery disease

The activity of nitrate esters on the vascular system was first exploited when NTG was employed to reduce blood pressure in 1847. The related occupational hazard was first noted shortly after Nobel incorporated NTG into dynamite in the late 19th century; untoward vasodilatory effects were described in dynamite workers and their families. Since that time, the effects of NTG have been extensively used for pharmacologic purposes; NTG and other nitrates are major medications in treatment regimens for coronary artery disease. The potential for vasoactive nitrates to cause occupational hazards persists during the use and production of associated pharmacologic agents, explosives, related propellants, and chemical products.

Two clinical vascular syndromes of occupational nitrate toxicity are clearly described, characterized by acute vasodi-

lation and withdrawal vasospasm. Some evidence also exists for a third syndrome, in which chronic occupational exposure to certain nitrates may increase the risk of atherosclerotic coronary artery disease. The vasoactive agents typically implicated are NTG, ethylene glycol dinitrate (nitroglycol or EGDN), and propylene glycol dinitrate (or Otto Fuel II torpedo propellant).

Acute effects

With acute exposure to nitrate vasoactive compounds, general vasodilation occurs. Symptoms include a severe and usually throbbing headache, flushing, palpitations, light-headedness, nausea, vomiting, and occasionally alcohol intolerance. Physical examination may demonstrate hypotension, tachycardia, and evidence of vasodilation. In heavily exposed individuals with pre-existing coronary artery disease, the generalized vasodilation combined with reflex tachycardia may reduce coronary artery perfusion pressure and precipitate angina.

Habituation occurs if exposure to the vasodilating nitrates continues over several days, and the exposed individual may no longer notice the acute effects. With continued exposure, the vascular system develops a dependence on nitrates. As a result, withdrawal from exposure can be accompanied by vasoconstriction, with resulting headache, angina, myocardial infarction, or in extreme cases sudden cardiac death. Worldwide, dozens of cases of sudden death, typically occurring on a Monday morning (after a weekend away from exposure), were reported among explosives workers in the 1950s. Angina and sudden Monday death were described in individuals in whom coronary artery disease could not be demonstrated either by arteriography or autopsy. Sporadic cases continue to occur.⁵ The typical toxicokinetics of nitrates, with withdrawal effects occurring shortly after exposure ends, do not explain the timing of the angina and sudden death that occurs days after removal from exposure, and prior to re-exposure, in occupationally habituated individuals.

Chronic effects

Whether or not any of the above effects lead to significantly increased long-term cardiovascular risk in current or former workers is unclear. Earlier studies by Hogstedt and colleagues did not show such an association.⁶ Two cohorts of Swedish dynamite workers (EGDN and NTG exposed) demonstrated an excess of chronic heart and cerebrovascular disease, most notably among those with greater than 1 year of exposure and 20 years of latency since their first exposure. Deaths occurred long after exposure ended. A subsequent study with larger populations did not detect an increase in long-term mortality, though it did find higher risk of acute mortality in those less than 45 years old.⁷ In a recent small case-control study,⁸ occupational history of exposure to dynamite was not significantly associated with greater risk of myocardial infarction (including events distant in time from original exposure). At this time it is prudent to consider chronic nitrate exposure a potential but unconfirmed risk factor for atherosclerotic cardiovascular disease.

Clinical evaluation

The approach to the individual with vasoactive nitrate exposure is guided by the clinical presentation. All possible information on the type and duration of likely exposure, and the timing of last contact, should be obtained. In the setting of acute exposure or withdrawal vasoconstriction, a history of vasodilatory symptoms and headache or angina should be elicited. Physical examination, including orthostatic blood pressure measurement, supplemented by 12-lead electrocardiography, will guide the management. With several of these agents (e.g., Otto Fuel II), yellow skin staining can confirm both the presence and at least one route of exposure. Because these agents also oxidize hemoglobin, the MetHb level should be measured.

Management

The treatment is directed by the clinical presentation. Removal from exposure is the first step, and if dermal exposure is suspected, the exposed skin should be carefully washed. If marked postural blood pressure changes are found, fluid resuscitation with intravenous normal saline is indicated. In the appropriate exposure withdrawal setting (8–72 hours since the last exposure), evidence of ischemia by history or electrocardiographic studies indicates vasoconstriction, which should be managed conventionally. Dermal, sublingual, or intravenous NTG should be considered acutely to treat the severe withdrawal symptoms of the nitrate-habituated worker; subsequent withdrawal can then be managed in a supervised medical setting. The management of the chronic vascular effects is no different from that related to any other cause.

Prevention

Before exposure levels were controlled, nitrate-habituated explosives workers recognized the symptoms of withdrawal and prevented them by inserting NTG into their hat bands to maintain vasodilation through the weekend. Concern surrounding nitrate-withdrawal deaths led to precautions that reduced exposure to nitrates in munitions production. Continued vigilance is required to keep exposures low as new agents and processes are introduced.

For many vasoactive organic nitrogen compounds, including EGDN, dermal exposure can be the major source of systemic absorption and bioavailability; therefore, isolated control of air concentrations is inadequate to control exposure. Given the capability of engineering controls, inhalation and dermal exposures should be kept at a level below the threshold of the vasoactive effect, which varies for each agent. If this goal is met, it should never be necessary for workers to use nitrates or other vasodilators to prevent withdrawal symptoms.

In developed countries, it has been customary to screen potential nitrate-exposed workers with some combination of physical examination and resting and exercise electrocardiographic studies, and to exclude individuals with abnormal results for workplace exposures. Although these tests may seem prudent, there is no good evidence that this type of screening is effective in reducing morbidity or mortality, and the false-positive rate for such tests is likely

Figure 42.1: Aromatic amines in wide use, currently or in the past.

to be unacceptable in a working population. In addition, cases of sudden death have occurred in young, previously healthy individuals who have 'passed' these screening tests, indicating that the screening tests cannot effectively predict susceptible individuals. It is likely that the level of exposure, and not merely susceptibility, is most important in determining adverse effects. It remains judicious to limit occupational exposure to vasoactive organic nitrogen agents for individuals with a clinical history of coronary artery disease, cardiomyopathy, or life-threatening arrhythmias. In addition, exposed workers should be well informed about the toxicity of these agents, and regularly asked about the presence of headache, light-headedness, or other evidence of exposure; if symptoms are found, action should be taken to identify and reduce the exposure.

Biologic monitoring may have a role in the management of exposure to vasoactive organic nitrogen agents. Such methods are particularly attractive because of significant dermal absorption, that can be quantitated by determining the internal dose. Unfortunately, measuring the urine and serum levels of nitrates and their associated metabolites has not yet proven valid or practical for measurement of biologic exposure. For example, measurement of serum EGDN from the arm vein may represent the local concentration resulting from skin absorption and, hence, may overestimate systemic levels. Several new techniques, including gas chromatography-mass spectrometry and high-performance liquid chromatography, have been advanced to rival the traditional batch Griess assay for quantitative nitrate measurements. At this point, methodologic issues limit using these assays for routine monitoring. Methemoglobin levels, as noted above, remain non-specific and indicative only of gross exposure rather than a specific dose-effect relationship.

CARCINOGENESIS

Concern over the carcinogenicity of organic nitrogen agents stems from two lines of research regarding various chemical classes as follows: (1) several aromatic amines are demonstrated carcinogens by human epidemiologic and animal investigations, and (2) certain N-nitrosamines, which are potent animal carcinogens, may be encountered

directly or as a metabolite of an occupational or environmental exposure.

Aromatic amines

The structure for aromatic amines in wide use is shown in Figure 42.1. Benzidine and related aromatic amines (e.g., beta-naphthylamine, 4-aminobiphenyl, and related compounds listed in Table 42.1) were found in early epidemiologic studies to be the cause of excess bladder cancers in occupational cohorts. The relative risk of bladder cancer ranged from 8 to 87 among dyestuff, research, and rubber workers with significant exposures. These agents have subsequently been demonstrated to be potent animal carcinogens. Transitional cell cancer of the urinary bladder, renal pelvis, or ureter are the typical tumors seen in humans, primarily because of the urinary concentration of these genotoxic agents and their metabolites. Animal studies have also shown other bladder, liver, breast, and lung tumors related to carcinogenic aromatic amine exposure.

Although the use of these chemicals as dyestuffs has been curtailed, related chemicals that are probable human carcinogens are still used extensively in many industries. For example, agents such as methylene dianiline (MDA) and methylene bis-2-chloroaniline (M-BOCA) are curing agents in some contemporary resin systems. It can be expected that other carcinogenic aromatic amines, although less well studied, will find their way into advanced technologic processes. To illustrate, MDA and M-BOCA have been replaced in some applications by diethylene toluene diamine, an aromatic amine agent about which little toxicologic information is available.

N-Nitroso compounds and nitrate exposure

The general structure of nitroso chemicals and some examples are shown in Figure 42.2. Virtually all nitroso compounds have been found to be potent animal carcinogens, with malignant tumors occurring in many organs (respiratory tract, gastrointestinal tract, liver, kidney, bladder, and brain), relatively independent of the route of

Figure 42.2: Structure of generic and representative nitrosamines.

Figure 42.3: Generic nitrate structure and common nitro compounds.

administration. In rodent studies, symmetric dialkyl nitrosamines (where the two R groups are the same, such as N -nitrosodimethylamine) tend to produce tumors in the liver, lung, kidney, or bladder; the esophagus is a more frequent target organ for tumors caused by asymmetric nitrosamines.

In occupational settings, exposure is primarily encountered in the form of a chemical reagent, reaction intermediate, or contaminant. Exposed groups have included rocket fuel production workers, pesticide formulators, rubber workers, tannery workers, and laboratory workers. The use of sodium nitrate as a corrosion inhibitor in lubrication systems can lead to the formation of N -nitroso compounds and volatile exposure. Contamination of ground-water sources can lead to environmental exposure by ingestion route.

Public health concern has arisen over the potential for *in vivo* nitrosamine formation as a result of exposure to ingested amines, nitrates, and nitrites. Exogenous nitrate (Fig. 42.3) can be reduced to nitrite by colonizing bacteria, and nitrite leads to the development of N -nitroso compounds in the digestive tract. This pathway has resulted in carcinogenesis in laboratory animals. In addition, there is evidence to support the notion that dietary nitrite and nitrate intake may explain some of the large geographic differences in gastric, esophageal, nasopharyngeal, and colorectal cancer rates. The nitrate concentrations of cured and smoked meats are among the highest found in foods. However, the relationship between gastric cancer and occupational, environmental, or dietary nitrate exposure remains unclear. Recent epidemiologic studies have not consistently supported a strong relationship between dietary nitrate intake and cancer.⁹ However, as studies have focused on individual nitroso compounds and more specific dietary histories, this relationship may become better understood. One large recent study found that N -nitrodimethylamine specifically was associated

with colorectal but not other cancers.¹⁰ Another showed an association between nitrites/nitrosamines and nasopharyngeal cancer predominantly when the intake was high in early childhood.¹¹ It remains prudent to keep dietary nitrite exposure to a minimum.

Contamination of drinking water by nitrates is an issue of concern. The main source of nitrate is typically from fertilizer leaching into ground water,¹² though unusual sources, such as contamination from boiler fluid additives,¹³ also occur. Since these situations can result in chronic exposure situations, often high enough to result in methemoglobinemia and possibly spontaneous abortions,¹⁴ concern over chronic health effects is reasonable.

Prevention and management

Exposure to carcinogens must be prevented, and regulations generally are designed to eliminate or keep such exposures to a minimum. Rapid monitoring is not yet practical, although several new biochemical techniques designed for measuring nitric oxide radicals may be helpful in the future. Cancers related to organic nitrogen compounds are managed according to standard oncologic practice. If a cohort of workers is identified as being at elevated risk for a certain type of occupational cancer (such as workers exposed to a bladder carcinogenic aromatic amine), it is appropriate to implement a medical surveillance program.

HEPATOTOXICITY

Given the chemical reactivity of organic nitrogen compounds, it is not surprising that several agents in this group are potent hepatotoxins. A few of these chemicals will be discussed briefly here. Further details on the clinical presentation, evaluation, management, and prevention of hepatotoxicity are found in Chapter 26.1.

Trinitrotoluene

The structure of common nitro compounds such as trinitrotoluene is provided in Figure 42.3. An estimated 500 workers who were exposed to the explosive trinitrotoluene (TNT) in Great Britain during World War I developed severe clinical hepatitis manifested by jaundice and a mortality rate of 25%. The incidence of hepatic effects was estimated to be approximately 5% of exposed individuals. The usual pattern of hepatotoxicity was characterized by subacute or acute hepatic necrosis. The onset of clinically apparent disease may be delayed for up to 4 months following initial exposure, although biochemical markers, such as elevated aspartate aminotransferase, alanine aminotransferase, and bilirubin levels, and histologic abnormalities are typically present earlier. This chemical is reported to cause measurable methemoglobinemia without overt cyanosis at exposure levels lower than those associated with hepatitis. If hepatic necrosis occurs, it can persist for months following removal from exposure. If exposure ends prior to extensive liver damage, the prognosis for recovery is good. Aplastic anemia has also been reported with TNT exposure. Trinitrotoluene-exposed individuals should be monitored

with liver function studies, methemoglobin levels, hematocrit, and white blood cell count.

2-Nitropropane

The animal hepatocarcinogen 2-nitropropane (2-NP) (Fig. 42.3), widely used as a solvent in spray coatings and epoxy resin systems, can cause fulminant hepatitis following brief, high-level exposure.¹⁵ The pathophysiology likely involves free radical formation and rapid hepatocyte necrosis. After a single overexposure episode, there can be a deceptive period without overt clinical illness, followed by progressive hepatic failure over the course of days to weeks. The National Occupational Exposure Survey estimated that 185,000 American workers were exposed to 2-NP in 1980. Inadequate epidemiologic and laboratory knowledge exists regarding the toxicologic and pharmacokinetic properties of this chemical to determine a specific dose–effect relationship. As a result, although hepatotoxic effects are usually noted at exposure levels greater than 25 ppm, no safe level of exposure has been established. When substitution of this ingredient is not possible, exposed workers should be educated regarding its toxicity and provided with proper protection from inhalational and dermal exposure. Agents containing significant concentrations of 2-NP should not be used in confined space without well-engineered ventilation or supplied air respiratory protection. Neither biologic monitoring nor medical surveillance guidelines are currently available.

Methylene dianiline (MDA)

MDA (4, 4'-diaminodiphenylmethane) is used in the production of methylenediphenyl diisocyanate (MDI) and commonly encountered as a curing agent in reinforced plastics or 'advanced composites'. It is a hepatotoxin and a probable human bladder carcinogen. The hepatotoxic effects can be variable, but one clear pattern is cholestatic jaundice from bile duct injury,¹⁶ which is otherwise unusual among occupational hepatotoxins. In many cases, pruritus is the dominant initial symptom, and the most prominent laboratory abnormalities may be elevations of the alkaline phosphatase and bilirubin levels, rather than the transaminase levels. Portal inflammation and bile stasis, without extensive parenchymal injury, characterize the histologic picture of the acute cholestatic injury. If exposure ends before fibrosis occurs, the prognosis for full recovery is thought to be good.

MDA is absorbed through the skin, with prominent dermal route of exposure; biologic monitoring should ideally supplement other exposure indices. Dermal pads or glove testing have not yet been standardized, and still do not quantify actual in-vivo exposure. Urine concentration can theoretically be used to more practically integrate recent dermal exposure. However, while development of a 'dermal occupational exposure limit' via urinary MDA excretion remains promising,^{17,18} practical workplace applications have yet to be established. Excretion rates peak at 6–11 hours following dermal exposure (slower than

for inhalational exposure), so urine monitoring should ideally be conducted several hours after exposures. In practice, post-shift monitoring has been common. While some had previously recommended 70 µg MDA per gram of creatinine as a urinary action level to reduce exposure to MDA, this is likely not low enough to ensure compliance with the current (1992) Occupational Safety and Health Administration (OSHA) MDA standard. Under this standard, which recognizes the potential carcinogenicity of MDA, the air-borne permissible exposure limit is 10 parts per billion as a time-weighted average, and MDA biomonitoring is not required.

SENSITIZATION AND IRRITATION

Organic nitrogen compounds, especially amino compounds such as the polyamines, have the capacity to act as antigens or haptens, with resulting potent sensitizing properties. The syndromes of allergic contact dermatitis, allergic rhinitis or sinusitis, and asthma typically require removal from exposure. A history of atopy does not accurately predict who will be affected by these exposures. These compounds, which are frequently encountered as curing agents in epoxy resin or urethane foam systems, can also be potent skin and mucosal irritants, which makes diagnosis and management more challenging.

The primary toxic effect of many organic nitrogen compounds is irritation of the skin, mucous membranes, or respiratory tract. As a general rule, any of the agents that cause respiratory irritation can, at high exposure levels, also precipitate lower respiratory injury with toxic pneumonitis or pulmonary edema.

DERMATOLOGIC EFFECTS

The most common skin manifestations of the agents in this group are allergic and irritant contact dermatitis. However, skin staining is also caused by many nitrosylated compounds and is important not only as a dermatologic cosmetic problem, but also to verify dermal (and probably systemic) exposure to a potentially toxic agent. The skin staining can be yellow to orange, or occasionally black and tattoo-like. Agents that commonly stain the skin include nitric acid, trinitrotoluene, EGDN, MDA, and dinitrophenol. Skin staining sometimes appears only hours to days after the exposure, when the chemical is oxidized on the skin, or when the chemical is incorporated into the skin's protein.

NEUROLOGIC EFFECTS

Although neurotoxic properties are not prominent among the organic nitrogen compounds, two agents, acrylamide and dimethylaminopropionitrile (DMAPN), are important exceptions. They cause characteristic toxic peripheral neuropathies. In addition, retinotoxic effects of several aromatic amines have been described. 1,4-bis(4-aminophenoxy)-2-phenylbenzene (a component of some advanced composite materials) damaged photoreceptors in rats.¹⁹

Although the rat retina may regain partial function with time, and ocular damage from occupational exposure has not been clearly demonstrated in humans,²⁰ the retinotoxicity of this compound raises concern about related aromatic diamines. Methylene dianiline has been reported to have similar retinotoxicity in guinea pigs and in one documented human exposure.²¹

Acrylamide

Reactive acrylamide monomer is encountered as an intermediate in the manufacture of polyacrylamides, which are widely used in laboratory electrophoretic gels and other synthetic products. It is used in dam foundations and tunnels and as a flocculation agent to separate solids from aqueous solutions, which is useful in mining operations, in the disposal of industrial waste, and in the purification of water supplies, among other applications as a polymer in industry. Acrylamide causes a fairly typical toxic distal neuropathy, with mixed sensory and motor findings. Early findings can include numbness, paresthesias, or hyperesthesias of the lower legs or feet, as well as complaints of coldness or muscle weakness. Only the reactive monomer is toxic; polyacrylamides are regarded as non-toxic. Acrylamide is well absorbed by the dermal route.

In certain applications, N-methylolacrylamide – which is likely a less potent neurotoxin – has become a substitute for acrylamide. Isocyanate-containing resins have been proposed as substitutes as well, but this substitution cannot be justified on a health basis due to the respiratory hazard created.

An epidemiologic investigation in a polymerization factory found a dose-response relationship between the air-borne acrylamide concentration and symptoms of peripheral neuropathy, with effects seen at exposure levels near the current OSHA exposure limit of 0.3 mg/m³. A lower level of 0.03 mg/m³ was subsequently adopted but later rolled back under court order in 1992 as part of the PEL revisions. NIOSH and ACGIH continue to recommend 0.03 as a time-weighted average, and several states also enforce this level.

In subacute or chronic intoxication, central nervous system signs, such as ataxia, can occur; encephalopathy has been noticed in significant acute poisoning. The neurologic effects²² frequently improve with removal from exposure. A syndrome with desquamation and sweating of the hands has been observed to accompany the peripheral neuropathy of acrylamide toxicity. In addition, fingertip dermatitis occurs following dermal exposure to acrylamide, and the presence of this finding indicates a level of exposure that is associated with neurotoxicity.

Hemoglobin adducts have been proposed as a proxy for exposure to acrylamide.²³ Hb adducts have been demonstrated to be present in acrylamide-exposed populations in which neurotoxic effects were documented.²⁴ While the presence of adducts is associated with exposure in epidemiologic studies, the usefulness in evaluating individual workers remains uncertain, and concern remains regarding confounding effects with concurrent smoking. Given

Figure 42.4: Nitriles. All contain the CN moiety, which may be released in vivo as cyanide ion.

acrylamide's status as a suspected carcinogen, exposures should be kept well below the levels associated with either dermatitis or neurotoxicity.

Dimethylaminopropionitrile (DMAPN)

Two clusters of neurogenic bladder dysfunction associated with DMAPN were reported in 1980,²⁵ with use of this agent as a catalyst in the manufacture of polyurethane foam. The pattern of neuropathy was unusual, in that it produced urinary symptoms, such as retention and hesitancy, more prominently than limb symptoms. The clinical syndrome also included sexual dysfunction, insomnia, and some muscle weakness and paresthesias. For unknown reasons, DMAPN appears to affect the sensory fibers of the sacral region selectively. Although the toxicologic mechanism for the neurotoxicity remains obscure, evidence exists that DMAPN exposure may result in in-vivo release of cyanide (as can all nitriles, see Fig. 42.4), and that it may inhibit certain glycolytic enzymes.²⁶ This agent has largely been eliminated from the workplace, although certain other aliphatic aminonitriles are suspected of sharing its neurotoxic risk.

Chapter 43

Metal Working Fluids

Peter S Thorne, Nancy L Sprince

INTRODUCTION

Metal working fluids (MWF) are materials used in transforming cast metal forms into finished metal products or components with precise dimensions. The scores of parts in automotive engines and transmissions are familiar examples. Machining processes include cutting, boring, hobbing, tapping, grinding, lapping, and honing. Each process requires the use of MWF tailored to the specific properties of the metals. The MWF serve three primary functions: removal of heat from the machine tool and the product, lubrication at the contact point between the product and the tool or abrasive, and removal of swarf. Swarf is the debris generated from the metal and the abrasive in the cutting or grinding process. In addition, MWF are formulated to inhibit corrosion during and after machining of the products, and to extend the life of cutting, boring, or grinding tools.

Three classes of MWF are in widespread use. First are the straight oils that are solvent-refined petroleum oils or high oleic agricultural-based lubricants without added water. Soluble oil MWF and semi-synthetic MWF represent the second class and are water-based emulsions that typically contain 3–15% oils when in use. The third class is the synthetic MWF that have no added oil and are used where high lubricity is not needed. The soluble oil and synthetic MWF have been used extensively in the past two decades. The chemical and microbiologic characteristics of these classes of MWF are described below in greater detail.

Occupational exposure to MWF is widespread and common for workers engaged in the manufacture of automobiles and trucks, farm equipment, aircraft, heavy machinery, and military hardware. Estimates of the number of US workers exposed to MWF vary. In their most recent National Occupational Exposure Survey, the National Institute for Occupational Safety and Health (NIOSH)¹ estimated that a total of 400,000 workers were exposed full time to MWF and 830,000 were exposed part time.² The United Automobile, Aerospace and Agricultural Implement Workers Union (UAW) has estimated that one-third of their one million members are exposed to MWF. The nature of the exposures and the resulting health effects depend on the types of MWF in use, the metals being machined, the operations performed, ventilation systems employed, and the degree of exposure. Early health concerns, reflecting the widespread use of straight oils, included lipoid pneumonia, oil acne and folliculitis, and skin cancer attributable to polycyclic aromatic hydrocarbons in poorly refined straight oils. The introduction

and widespread use of the water-based MWF have shifted concerns to contact dermatitis, respiratory effects, and the potential carcinogenicity of these MWF, which contain a number of chemicals and contaminants including chemical irritants, biocides, and micro-organisms, discussed further below.

CHARACTERISTICS OF METAL WORKING FLUIDS

The properties of the multitudes of commercially available MWF are quite variable and are proprietary. MWF are generally supplied by vendor companies that are separate from the manufacturer that uses the fluids. The MWF market is highly competitive and detailed product specifications are closely guarded secrets. The emulsion and synthetic MWF are supplied by the vendors as 'neat' concentrates that are diluted about 20-fold with water prior to use. Once in use, further additions are made including biocides and fungicides, anti-foaming agents, emulsifiers, corrosion inhibitors, potassium hydroxide, and additional MWF concentrate. Thus MWF used ('in-use' MWF) may contain a number of contaminants and substances not present in the concentrated 'neat' MWF supplied by the vendor.

Straight oils contain no water and are composed of paraffinic and naphthenic mineral oils or bio-based oils. These oils may be made from highly refined base oils or mildly treated, minimally refined oils. Some products also contain animal or vegetable oils. Additives such as sulfurized active fats, non-active fats and base oils, sulfurized-phosphorized hydrocarbons, polychlorinated paraffins, fatty esters, and antirust agents are common. Due to their higher cost, waste disposal problems, and inferior heat removing properties, use of straight oils has decreased somewhat in favor of synthetic MWF and emulsions. However, they continue to be essential for fine polishing operations such as honing. Recent advances in plant genetics have contributed to the advancement of bio-based lubricants. Oxidative stability, or the tendency to polymerize at high temperature, has been a problem with vegetable oils. However, soybeans have now been genetically engineered to produce a highly stable oil that is 84% oleic acid. Bio-based MWF formulated with high oleic soybean oils perform as well as petroleum-based fluids for some applications and present fewer disposal problems, including disposal costs, which can be substantial.

Emulsions (soluble oils and semi-synthetic fluids) are frequently made from higher viscosity base stocks rather

than straight cutting oils. Prior to use, these oils and special additives are diluted with water to provide an emulsified fluid with the cooling properties of water and the lubricating properties of oils. Surface-active emulsifying agents are added to facilitate the miscibility of the oil and the water phases. The emulsifying agents generally consist of sodium and amine soaps, such as sodium naphthenates, rosinsates and sulfonates. Other additives include coupling agents such as alcohols, glycols, and glycol ethers, and corrosion inhibitors, amines, fatty oils and sulfurized fatty oils. In addition, biocides for control of micro-organisms and compounds that increase lubricity are added. The terms soluble and semi-synthetic oil are used interchangeably by some, while others distinguish them by the degree of emulsification of the oils they contain. Typical components of neat soluble oil MWF are water (20–60%), light and heavy hydro-treated naphthenic petroleum distillates (20–40%), soluble petroleum sulfonic acids (5–20%), tall oil fatty acids (1–10%), plus diethanolamines, chloroalkanes, iminoethanols, oxazolidines, diaminoalkanes, and a variety of biocides. The pH of these emulsions is normally maintained above 8.5.

Synthetic MWF are water-based alkaline solutions containing ethanolamines and acid salts along with borates or phosphates added as corrosion inhibitors. Surfactants and silicones are added to provide detergent and lubricating properties to the blend. The operating pH of these fluids is usually about 9.0. Biocides of a variety of types are usually added by the user to control microbial growth since these synthetic fluids provide a medium suitable to support bacteria, yeasts, and molds. Synthetic cutting fluids are preferred in high-speed production machining operations because of their superior heat removal and stability characteristics.

A number of constituents may be contained within in-use fluids that were not associated with the neat MWF. After some period of use any of the MWF can reach 0.5–5% contamination with tramp oil (hydraulic fluid or oil that leaks past the seals of machining tools). In plants with large machining operations the MWF are present in as much as 5 million liter quantities and travel from the point of use to large sumps (20,000–400,000 liters) via flumes located beneath the floor. Thus, anything spilled onto the floor may pass into the MWF. Since the coolants are rarely discarded these foreign materials can accumulate. In addition, microbial degradation and thermal cracking of the MWF constituents lead to the formation of new and complex chemicals not in the original formulation.

MWF exposures are regulated under the OSHA permissible exposure limit (PEL) for oil mist that applies to 'heavy mineral oil mist, paraffin oil mist, white mineral oil mist'. The current OSHA time-weighted average (TWA) PEL is 5 mg/m³. PELs have been promulgated for relatively few of the other components found in MWF. In 1998, NIOSH published its Criteria for a Recommended Standard: Occupational Exposure to Metalworking Fluids.³ In so doing it recommended that metal working fluid aerosol exposures be limited to 0.4 mg/m³ (thoracic mass fraction)

based on a 10 hour per day, 40 hour per week TWA. Table 43.1 is a listing of many of the OSHA PELs, NIOSH recommended exposure limits (RELs), and ACGIH threshold limit values (TLVs) that pertain to environments where MWF are used. The ACGIH lists a TLV for 'oil mist, mineral' of 5 mg/m³ for the TWA when sampling only the aerosol fraction and has issued a 2002 notice of intended change to 0.2 mg/m³ TWA for the inhalable mass fraction (Table 43.1).

Exposure limits for other compounds potentially found in the machining environment are also provided in Table 43.1. Ammonia, sulfur dioxide, and hydrogen sulfide are vapors that may be present from microbial action on fluids. Ethanolamines, formaldehyde, glutaraldehyde, and chlorine may be in the formulation to inhibit microbial growth or may be released from biocides. Metals such as cadmium, chromium, and nickel may exist as suspended dust or as compounds in various oxidation states. Exposure limits for aluminum, iron, and zinc dust (not listed) are all above the 5 mg/m³ limit for oil mist.

All classes of MWF can support the growth of micro-organisms, but those containing water (soluble oil, semi-synthetic, and synthetic MWF) are especially prone to gross contamination with aerobic bacteria, yeast, and molds. Control of microbial growth is achieved principally by maintaining pH above 8.8, large scale filtration of the in-use MWF, continuous circulation of the fluids through sumps and flumes, and the addition of biocides directly or as a component of the MWF concentrate. The most commonly used biocides include isothiazolones, formaldehyde-yielding biocides such as triazines, and phenolic biocides such as O-phenyl phenol. With these control measures, viable microbial concentrations in the bulk MWF up to 10⁵/ml for bacteria and 10³/ml for fungi are generally regarded as acceptable so long as the organisms present are not pathogens or allergens. Excursions to 10⁶–10⁷/ml should prompt actions such as large scale centrifugation and reprocessing of the fluid, and addition of more MWF concentrate or biocide. When viable microbial concentrations reach 10⁸–10⁹/ml the system is usually considered unrecoverable without major reprocessing, biocide addition, and addition of neat MWF, and often would be discarded.

There have been several studies in which investigators have identified the culturable organisms contained within freshly sampled, water-based MWF, summarized in Table 43.2. In general, the most commonly found genera of mesophilic bacteria are *Pseudomonas* and *Acinetobacter*. However, in certain systems the spectrum of biocide sensitivity may dictate which organisms predominate. We have sampled several large systems that contain triazine biocides in which the predominant mesophilic bacteria were *Micrococcus luteus*. With a different biocide, perhaps some other genus could compete more effectively. Repeated system treatments with isothiazolone biocides can select for more resistant organisms such as mycobacteria. These organisms may also be more likely to induce pulmonary diseases, most notably hypersensitivity pneumonitis (HP). Sometimes fungi can be the primary

EXPOSURE ASSESSMENTS

In the course of large machining operations MWF are sprayed onto the area where the tool contacts the product at flow rates in the range of 5–50 l/min. The tools, and in some cases the products, are spinning at high speeds as well as moving laterally. Thus, coarse droplets and fine

aerosols may be dispersed widely. These aerosols are available for inhalation as well as dermal deposition. Geometric mean (GM) air-borne particulate concentrations of 0.16–1.24 mg/m³ have been reported in published studies over the past 10 years (Table 43.3). NIOSH has reported a steady decrease in aerosol concentrations over the past three decades.³

In facilities where large volumes of MWF are used, much of the aerosol is respirable. Chan et al⁴ studied the size characteristics of MWF aerosols in a transmission plant and found the gravimetric respirable aerosol fraction to range from 19% to 55%. Concentrations generally fluctuated between 0.5 and 2 mg/m³ with both larger sizes (2–20 µm) and smaller sizes (0.1–1 µm) of aerosols. Thorne et al studied size distributions of MWF aerosols in a large engine plant using eight-stage cascade impactors positioned where machinists stood.⁵ The calculated mean of the aerodynamic mass median diameters was 3.1 µm and the mean of the geometric standard deviations (GSD) was 3.0 µm. Woskie and coworkers reported similar, respirable MWF aerosols in a large machining facility with small single machine sumps,⁶ a mean aerodynamic mass median diameter of 3.4 µm and a GSD of 3.0 µm.

Bioaerosol exposures have been assessed carefully in several studies (Table 43.3). While the most important source is generally the MWF themselves, other sources of bioaerosols coexist in these environments and are often overlooked. Biofilms may develop on machinery or in air handling systems and these may contribute to the bioaerosol load. Biofilms in ventilation systems, many of which recirculate air after coarse filtration, may act as an amplification site for the organisms arising from the MWF. During some periods of the year, bioaerosols (especially fungi) may be carried in significant concentrations in the make-up air from outside. The concentrations of air-borne culturable micro-organisms in machining facilities typically fall in the range of 10²–10³ CFU/m³ (colony forming units/m³) with levels from 10⁴–10⁶ CFU/m³ viewed as excessive. It may happen that the levels of viable organisms are in the normal range but if one measures the total organisms (culturable and non-culturable) the values are one to three orders of magnitude higher. This may be the case if culture-based sampling methods are not selected properly to support the growth of the predominant organisms. It may also be the case after major biocide additions to a system that resulted in the sloughing of biofilms or the loss of viability of microbes in the MWF. There are no promulgated standards or recommended exposure limits for bioaerosols in the machining environment. Available methodology for bioaerosol sampling has been recently reviewed.⁷

Several studies have evaluated the role of air-borne endotoxins as a causative agent for acute respiratory health effects from MWF. Endotoxins arise from the cell wall of gram-negative bacteria and have been shown to induce cross-shift pulmonary function changes in occupationally exposed cotton workers, grain handlers, swine farmers, and potato processors.⁸ Several studies in the metal working environment have assessed exposures to endotoxin (Table 43.3). Geometric mean values were generally below

Table 43.3 Concentrations of airborne particulates measured in the machining environment

the 50 EU/m³ no-effect threshold suggested by the Dutch Expert Committee on Occupational Safety.⁹ Our recent studies of bulk MWF have found endotoxin concentrations ranging from 160 to 20,000 EU/ml. If soluble oil MWF containing 90% water and endotoxin at 20,000 EU/ml is aerosolized to a water-free particulate mass concentration of 1 mg/m³, the air-borne endotoxin level would be about 200 EU/m³.

Endotoxin is an important causal agent of pulmonary inflammation in a host of occupational settings.⁸ Because of the recognized presence of endotoxin at elevated concentrations in some machining environments, several studies have systematically evaluated endotoxin sampling methods. While a European occupational exposure guideline for endotoxin of 200 EU/m³ has been adopted,¹⁰ no permissible exposure limits or recommended exposure limits have emerged in the United States. This may be due, in part, to a lack of rigorously harmonized sampling and analysis methods. In 1994, Thorne et al published methods for endotoxin assay in bulk metalworking fluids and in air samples.⁵ Methods for assay of endotoxin in bulk MWF were evaluated by Brown et al¹¹ who found improved recovery of endotoxin from synthetic and semi-synthetic MWF using pyrogen-free

water with added Tween 20.¹¹ Without systematic evaluation, the American Society for Testing and Materials (ASTM) established a standard for estimation of air-borne endotoxin in machining environments. Subsequent systematic comparison by Thorne and coworkers¹³ of this method with four alternatives demonstrated poorer performance of the ASTM method than the alternatives.

Exposure assessment of many other contaminants of the machining environment is well established. These include vapors such as formaldehyde and hydrogen sulfide as well as metals such as cadmium or chromium. Methods of air sampling for the toxicants listed in Table 43.1 are available from the NIOSH Manual of Analytical Methods.

HEALTH EFFECTS

Health effects associated with exposure to MWF are listed in Table 43.4 and discussed below.

Skin

Because many jobs in metal working require manual operations, the workers' hands and forearms receive direct

Skin

Oil folliculitis/oil acne
 Oil keratoses
 Pigment abnormalities
 Irritant and allergic contact dermatitis
 Skin cancer (including scrotal)

Respiratory tract

Occupational asthma
 Hypersensitivity pneumonitis
 Cross-shift reductions in FEV₁ (variable results among the studies)
 Increased non-specific bronchial reactivity
 Increased respiratory symptoms compared with unexposed

Cancer (substantial evidence)

Larynx
 Bladder
 Skin (scrotum)
 Pancreas
 Rectum

Table 43.4 Health effects associated with exposure to metalworking fluids

exposure to the MWF. In addition, aerosol deposition, splashing, wet clothing, and transfer from hands allow MWF to contact skin in other parts of the body. Skin trauma from small metal fragments increases the potential for percutaneous absorption of MWF constituents. Straight oils have been associated with oil folliculitis/oil acne, oil keratoses, pigment abnormalities, skin cancer, and some cases of contact dermatitis, while water-based fluids more often cause irritant and allergic contact dermatitis.

Oil folliculitis (oil acne) (see also Chapter 44), resulting from chemical irritation and plugging of the follicular opening, has been reported in workers exposed to straight oils. The lesions include perifollicular papules, pustules, and comedones. The areas affected initially are the backs of the hands, fingers, and forearms. The thighs and abdomen may also be affected because of contact with oily clothing. The folliculitis, which is seen shortly after initial exposure to straight oils, may last for months. Keratolytic agents, antibiotics and isotretinoin have been used for treatment. Prevention of recurrences depends on decreased exposure to oils, appropriate hand washing, and protective clothing. One study showed decreases in the prevalence of oil acne over time associated with: (1) changes in the tool-setting operation, (2) a change from acid-refined to solvent-refined oils, and (3) provision of free work clothes.¹

The most common skin disease in workers exposed to water-based MWF is contact dermatitis (see also Chapter 29.1). In a study of newly hired machinists exposed to neat mineral oil MWF, the prevalence of contact dermatitis increased rapidly in the first three weeks of exposure and then remained constant at about 50%.¹⁴ Several studies have shown that time spent in contact with wet fluids is a risk factor for contact dermatitis from MWF. Other risk factors noted in epidemiologic studies are cigarette smoking, semi-synthetic MWF exposure compared with soluble MWF exposure,¹⁵ and increasing age.¹⁶ Conflicting results have been published concerning atopy as a risk factor.^{15,16} Prevalences vary widely among studies (6–67%), in part because of differences in the diagnostic criteria and variability in types and extent of exposure. The

rate of dermatitis is about two- to fourfold higher among workers exposed to MWF in studies comparing them with unexposed workers.³ Among groups of exposed workers, a pattern of intermittent outbreaks of dermatitis superimposed on a background of endemic contact dermatitis has been described.

The combination of irritant and allergic dermatitis is frequent. Some studies have reported an allergic component in close to one-half of exposed workers with contact dermatitis. Alkalinity, irritating emulsifiers, and micro-trauma from metal shavings are cited as the chief contributing factors for irritant contact dermatitis resulting from water-based MWF. Biocides in high concentrations, solvents used for degreasing, and strong detergents used for hand washing may contribute to skin irritation in those working with MWF.

Allergic contact dermatitis has been attributed to many components and additives of water-based MWF acting as sensitizers, including biocides, emulsifiers, corrosion inhibitors, pressure stabilizers, preservatives, antioxidants, and fragrances. Biocides have been cited as the most frequent causes, particularly among those who add the concentrated biocide solution to the in-use MWF. Common types of biocide associated with dermatitis include formaldehyde releasers and isothiazolinones. Sensitization to metals including chromium, nickel, and cobalt has been reported in metal workers with dermatitis. It is not clear whether the cause was dissolved metals in the cutting fluids or direct contact with the metals in current or past employment.

Contact dermatitis resulting from water-based MWF can present early on as a fine follicular eczema, followed later by a patchy, papular eczema on the backs of the hands and forearms. Although the clinical course is variable, many cases become chronic. One study of machine operators with soluble oil dermatitis reported high prevalence rates of chronic, non-healing dermatitis two years after the diagnosis, in those with and without ongoing MWF exposure. The prevalence rates of chronic, non-healing dermatitis were 78% and 70%, respectively.¹⁷ There may be a better prognosis for a subgroup of exposed workers with contact dermatitis from MWF if they are removed from exposure before the dermatitis has lasted longer than three months.¹⁸ Another study of machine operators examined at a dermatology clinic reported persistent dermatitis in 82% 1–5 years after evaluation. Discontinuing exposure did not improve the prognosis.¹⁹

Diagnosis

In general, the clinical pattern of oil folliculitis caused by straight oils is readily distinguished from the eczematous dermatitis resulting from water-based MWF. However, both irritant and allergic contact dermatitis may occur from exposure to some straight oils and their additives. Patch testing (see Chapter 29.1) may be useful in some cases, but is limited by both false-positive and false-negative results, as well as problems with clinical correlation due to the multifactorial etiology of contact dermatitis in workers exposed to MWF.

Treatment

Clinical treatment of individual workers with contact dermatitis from MWF does not differ from the general management of occupational contact dermatitis (see Chapter 29.1). Limiting or eliminating contact with MWF, use of non-irritating cleansers, application of emollient creams, and topical steroids are frequent recommendations.

Prevention

Measures for preventing occupational dermatitis caused by MWF are similar to those used to prevent other occupational dermatoses and include limiting exposure, protective gloves and clothing, worker education, and identification and removal of allergens. No studies have addressed the efficacy of plant-wide surveillance programs for the early detection of contact dermatitis. Nonetheless, surveillance coupled with strategies for decreasing or eliminating exposures in those affected may be useful in light of the high prevalence of contact dermatitis and the chronic nature of the dermatitis in many cases.

The prevention of oil folliculitis appears to be less of a problem than that for contact dermatitis. The prevalence is decreasing because of the increased use of water-based fluids, and the literature suggests easier treatment and prevention by routine measures of personal hygiene and protective clothing, including protective gloves, aprons, and footwear.

Respiratory tract

The reported respiratory effects of MWF in exposed workers include occupational asthma, hypersensitivity pneumonitis, cross-shift declines in FEV₁, and increases in non-specific bronchial reactivity. Respiratory symptoms, including cough and phlegm, have been reported in some studies without associated functional change. Lipid (lipoid) pneumonia has been reported historically in some workers exposed to MWF, but there is a paucity of recent reports. Legionnaire's disease due to contaminated MWF in an automotive plant has been reported.²⁰

Hypersensitivity pneumonitis (see also Chapter 19.6)

Reports of clusters of cases of respiratory disease consistent with hypersensitivity pneumonitis (HP) occurring at several automotive industry plants began appearing in the mid-1990s²¹ and were discussed at a 1996 NIOSH conference.²² Several additional clusters of HP have more recently been reported in groups of workers exposed to MWF.^{23–25} Most cases occurred at plants in which MWF aerosol exposures were maintained below 0.5 mg/m³.

Although the cause or causes of these clusters have not been definitely identified, aerosolized microbial contaminants from water-based MWF (including soluble, synthetic, and semi-synthetic MWF) are thought to be the most likely source. Recent attention has focused on unusual organisms found in water-based MWF, including fungi, gram-positive bacteria, and *Mycobacterium immunogenum*, a newly proposed non-tuberculous species closely

related to *M. chelonae*. It has been suggested that use of biocides to control the more common gram-negative bacteria in MWF may lead to the emergence of unusual organisms responsible for HP. Although case definition varied across the studies, at least 44 biopsy-confirmed cases of HP have been reported from ten plants. Biopsies showed granulomatous inflammation consistent with HP. In several cases, clinical improvements or resolution have been reported after removal from exposure to MWF. Some studies have emphasized a close association between HP and asthma in workers exposed to MWF, the likelihood that some cases may be missed due to the non-specific presentation and the unfamiliarity of healthcare providers in recognizing and diagnosing HP (see Chapter 19.6).

Recommendations for medical surveillance and monitoring of workers exposed to MWF from the OSHA Scientific Advisory Committee on MWF²⁶ have emphasized that a single physician-diagnosed case of HP should be viewed as a sentinel event triggering active surveillance of exposed workers, in addition to review of MWF fluid management records and environmental assessment of microbial species in MWF present at the onset of disease. Recommended medical monitoring tools include baseline and periodic questionnaires addressing respiratory and systemic symptoms and pulmonary function testing. Further clinical evaluation would be indicated for workers with persistent respiratory or non-specific symptoms and/or abnormalities on baseline or periodic tests (discussed in Chapter 19.6). Routine use of chest radiographs and serologic tests for antibodies was not recommended for surveillance purposes.

Asthma (see also Chapter 19.2)

Data concerning the relationship between exposure to MWF and asthma come from several sources, including case reports of asthma reproduced by specific challenge testing and sentinel event surveillance data. In addition, cross-sectional studies have compared questionnaire-derived prevalences of asthma in exposed workers with unexposed controls. Taken together, the evidence is convincing for an association between MWF exposure and occupational asthma.

Case reports^{27–29} have focused on individual workers who have been evaluated clinically after they presented with possible occupational asthma. In the largest case series,²⁸ 25 patients referred to an occupational respiratory clinic for possible occupational asthma were classified with definite or equivocal occupational asthma based on results of serial peak flow measurements. Of the 13 with definite occupational asthma, latency period ranged from immediate to 41 years. Nine had a history of workplace exposure only to soluble MWF, while one had only straight oil exposure and two had both soluble and straight MWF exposure. Six of the 13 underwent specific inhalation challenge testing with various MWF and constituents. Three of the six had positive challenge tests to unused soluble MWF, one reacted only to used soluble MWF, and two had inconclusive results. Another report²⁷ described two machinists with occupational asthma who had positive specific inhalation challenge responses to a component of used MWF,

triethanolamine, with latencies of over ten years and eight years respectively. Specific inhalation challenge tests were positive to heated MWF containing triethanolamine but not triethanolamine-free MWF in one case and to cold pure triethanolamine in the other. Both patients had persistent asthma symptoms requiring medication six months after stopping workplace exposure.

Results from the Sentinel Event Notification System for Occupational Risk assessing work-related asthma in Michigan from 1988 to 1994 showed that MWF was the second leading cause of work-related asthma.³⁰ They reported 86 cases (identified from physicians, hospitals, and worker compensation claims) from 45 plants, 22 of which had air sampling for MWF. Exposure at only one plant exceeded the OSHA TWA of 5 mg/m³ for oil mist. About 20% of 755 fellow workers of the sentinel cases reported work-related asthma symptoms. The results also suggested that workers exposed to soluble, semi-synthetic, and synthetic MWF were more likely to report respiratory symptoms, including work-related asthma, than workers exposed to mineral oils alone.

Because of transfer of workers affected by asthma to new work environments, it is difficult to assess exposure-response relationships and relative risk for asthma among currently exposed workers. Several recent studies suggest that workers exposed to MWF have a 2–3-fold increased risk for asthma symptoms.³ Increases in non-specific bronchial hyper-responsiveness have been reported in workers exposed to MWF in several studies, with positive associations between bronchial responsiveness and cumulative exposure to both soluble oil and synthetic MWF.^{31,32}

Respiratory symptoms

A number of cross-sectional respiratory morbidity studies have compared respiratory symptoms between workers exposed to MWF and unexposed controls, recently reviewed by NIOSH.³ All studies showed an increase in at least one respiratory symptom among the exposed. Symptoms with significantly elevated odds ratio in at least one study included cough, phlegm, chronic bronchitis, wheeze on most days, chest tightness, dyspnea, and acute eye, nose and throat irritation, with about a 2–7-fold increase in respiratory symptoms among the exposed. Two of these studies^{33,34} reported exposure-response relationships between aerosol exposure and respiratory symptoms. One study reported a specific exposure-response relationship between respiratory symptoms and air-borne levels of culturable fungi and bacteria.³³ All types of MWF were associated with increases in respiratory symptoms, although two studies^{33,34} suggested that synthetic or semi-synthetic MWF were associated with higher odds ratios than soluble MWF. Several studies reported cross-shift worsening of respiratory symptoms^{30,33,35,36} and improvements off work.³⁴ Air-borne aerosol concentrations varied among the studies, although mean concentrations were all less than 3 mg/m³.

Chronic lung function effects

Several cross-sectional studies^{32,33,35,37} have examined baseline FEV₁ and FVC in workers exposed to MWF compared

with unexposed controls (see also Chapter 19.4.) They have found either no difference^{32,33,37} or a slightly lower baseline FEV₁ and/or FVC among exposed workers.^{35,38} Associations between current total culturable bacteria and baseline FEV₁,³³ current exposure to soluble oil MWF and baseline FEV₁,³⁵ and lifetime exposure to straight oils and baseline FVC³⁸ have been reported. Due to the healthy worker effect, such studies, as well as studies of acute effects (see below), may underestimate the respiratory effects of MWF exposure.

Acute lung function effects

Results of studies assessing acute cross-shift reductions in FEV₁ among workers exposed to MWF compared with unexposed workers have produced variable results. Two studies reported a higher prevalence of cross-shift FEV₁ decrement in exposed workers.^{36,39} In one the highest risk was for those exposed to synthetic fluids and effects were observed at aerosol levels as low as 0.2 mg/m³. The other study³⁶ found, among exposed workers with lower baseline lung function, exposure-response relationships with thoracic particulate and viable plus non-viable bacteria. Two other studies reported no significant difference between exposed and unexposed workers.^{33,35} One of these latter studies,³⁵ however, showed that higher exposures to MWF (above 0.15 mg/m³ in their study) were associated with more frequent declines in cross-shift FEV₁ when both exposed and control workers were combined.

Lipid (lipoid) pneumonia

Although reported historically, there have been few recent reports of lipid pneumonia in MWF-exposed workers. Histopathologically confirmed lipid pneumonia was reported in a subject exposed to a water-based coolant, a straight oil lubricant, and kerosene in a steel rolling tandem mill.⁴⁰ His chest radiograph was reportedly normal, and restriction was found on pulmonary function tests. Other case studies have reported interstitial changes in exposed workers.^{41–43} However, no increase in respiratory morbidity was observed in two occupationally exposed groups.^{44,45} However, no chest radiographs were performed in either study. The one major respiratory morbidity study that included both chest radiographic and pulmonary function evaluation in exposed workers compared with office workers showed no evidence of parenchymal abnormalities attributable to exposure.⁴⁶ The frequency, risk factors, and course of lipid (lipoid) pneumonia caused by MWF exposure are not well defined at this time.

Cancer

The presence of carcinogens in MWF has prompted numerous investigations of cancer in exposed workers.^{13,47–58} Difficulties in evaluating these studies include variability in exposures and their classification, lack of exposure data in many, small numbers in some, and lack of information about confounding variables, such as cigarette smoking. NIOSH reviews of cancer mortality studies^{3,60} have found substantial evidence for associations between MWF and

cancers of the larynx, rectum, pancreas, skin/scrotum, and bladder, and more limited evidence for associations with stomach, lung, esophagus, prostate, colon, brain, and hematopoietic cancers.

With regard to the cancer sites linked with MWF by substantial evidence, the magnitude of risk, expressed as rate ratios, varied among the cancer sites. For laryngeal cancer, the rate ratios above 1.0 ranged from 1.05 to 2.5; for cancer of the rectum, 1.09 to 3.07; for cancer of the pancreas, 1.03 to 3.7; for skin/scrotal cancer, 1.06 to 10.5; for bladder cancer, 1.04 to 2.99.

For cancers of the skin/scrotum, larynx, and rectum, there is evidence to suggest a specific association with straight MWF exposure. For cancer of the pancreas, the evidence points to associations with synthetic fluids used for grinding and with straight MWF used for machining.

Metal working fluid exposures in these cancer mortality studies occurred prior to the mid-1970s. Because many changes have occurred in MWF since that time, it is not possible to extrapolate cancer risks from exposure after the mid-1970s from these earlier data. Temporal changes in carcinogenicity over time are likely, given the changes that have occurred in MWF over the last several decades. It has been suggested that changes in composition, reductions in polycyclic aromatic hydrocarbons and nitrosamine levels, and generally lower MWF exposure levels may reduce the carcinogenicity of MWF observed in future studies.

Medical surveillance and monitoring of exposed workers

NIOSH and the OSHA Metalworking Fluid Scientific Advisory Committee (SAC) have made recommendations for medical monitoring of workers exposed to MWF to enable early detection of respiratory and skin disorders caused by MWF. Both included recommendations for baseline and periodic examinations including standardized questionnaire (addressing symptoms and medical history), skin examination, and baseline spirometry. Both emphasized the need for monitoring workers in areas with known increased exposure to MWF and areas where sentinel cases of asthma, HP, or dermatitis have occurred. The OSHA SAC also made recommendations about medical removal, return to work, and medical removal protection of earnings, employment rights, and benefits. Medical surveillance in relation to cancer prevention among workers exposed to MWF has not been addressed.

Toxicology studies

Relatively few animal toxicology studies have been done to assess the acute and chronic effects of water-based MWF. Prior to 1990, several investigators studied oil mist inhalation representing automobile lubricating oil, cable oils, military foggers, food oils, and mineral oil.^{61–66} Few histopathologic changes or alterations in pulmonary function were observed below 100 mg/m³, and in several studies exposures exceeding 1000 mg/m³ did not yield significant differences from control animals.

More recently, toxicology studies have investigated the health effects of water-based MWF in irritation, inflammation, mucous cell hyperplasia, and HP models in mice, rats, and guinea pigs. Such studies have confirmed that MWF exposure at levels comparable to those present in today's workplaces can cause lung inflammation, airway hyper-responsiveness and HP, and have begun to identify the most likely etiologic agents in MWF. One study⁶⁷ used a mouse pulmonary irritation model to study the responses arising from acute exposures to aerosolized metal working fluids. The straight oil they tested was less irritating, both as neat and in-use MWF, than the synthetic fluid or the oil emulsions. Pulmonary irritation was minimal for MWF at gravimetric concentrations less than about 50 mg/m³. Three-hour exposures produced histopathologic changes (mild to moderate interstitial pneumonitis and broncho-pneumonia) at the 24-hour time point in some mice, with little difference between new and in-use fluids.

Gordon⁶⁸ conducted inhalation studies in guinea pigs to assess the acute respiratory effects as indicated by measurement of specific airway conductance (sGaw). Aerosolized in-use soluble oil MWF samples yielded 3000 EU/m³ endotoxin at 1 mg/m³ aerosol concentration and 19,000 EU/m³ endotoxin at 10 mg/m³. The sGaw decreased 0%, 7%, and 40% upon exposure to 1, 10, and 100 mg/m³, respectively, with greater responses upon inhalation of in-use MWF than unused MWF diluted similarly in terms of decrease in sGaw and several bronchoalveolar lavage assays. Gordon and Harkema⁶⁹ exposed rats to aerosols of used and unused MWF at 1 or 10 mg/m³, 3 hr/day for three days and investigated production of mucosal substances in airway cells. Exposure to used MWF at 10 mg/m³ (containing 8000 EU/m³ endotoxin) produced mucous cell metaplasia in the nasal septum and mid-level airways. Metaplasia was also observed with unused MWF at this exposure level.

Thorne and coworkers have conducted studies of the pulmonary effects of inhaled MWF and their associated endotoxin and bioaerosols in animal models of acute lung inflammation and in subchronic models of HP. One such study⁷⁰ demonstrated that in-use soluble oil MWF contaminated with endotoxin and gram-negative bacteria (*Pseudomonas aeruginosa*) induced lung inflammation in a dose-dependent manner from 100 to 50,000 EU/m³ of endotoxin activity, including marked neutrophilia and elevated pro-inflammatory cytokines, such as TNF- α and IL-6. The corresponding unused fluid produced responses no different from sham-exposed mice. Filter sterilization of the in-use fluid did not diminish the inflammatory potency of the MWF. Further studies in guinea pigs⁵ demonstrated acute pulmonary function changes with exposures as low as 3 mg/m³ for in-use MWF and 30 mg/m³ for neat fluids. Experiments in which the appropriately diluted neat MWF was spiked with endotoxin supported the hypothesis that endotoxin may be the most important agent for pulmonary inflammatory responses to MWF.

HP represents a cell-mediated immunologic pulmonary disease displaying a Th₁ phenotype, associated with cytokines interferon- γ (IFN- γ), IL-2, and IL-12. Lung responses to in-use MWF samples have recently been

evaluated using a murine model for HP.⁷¹ These studies investigated the potential for MWF contaminated with *Mycobacterium* species to induce HP and characterized the physiologic and immunologic responses to these MWF exposures. Mice were exposed by nasal aspiration to live *Mycobacterium chelonae* bacteria (isolated from an in-use MWF sample), live *Saccharopolyspora rectivirgula* bacteria (positive control), saline (negative control), or endotoxin (inflammation control). Mice were exposed for three weeks, followed four days later by acute challenge with the MWF. The positive control agent for HP, *S. rectivirgula*, induced significantly more total cells, lymphocytes and monocytes in lung lavage; an increased CD4+/CD8+ ratio; elevated IL-12 levels; and marked pulmonary lymphocytosis on histologic exam when compared to saline-treated controls. Mice treated with mycobacteria alone or MWF containing this organism had significantly elevated lung weights, total lavage cells, neutrophils, and increased CD4+/CD8+ ratio as compared to saline controls. However, when *M. chelonae* was administered at twice the dose of *S. rectivirgula*, cellular and cytokine responses were still lower than those observed in the *S. rectivirgula*-treated mice. These data suggest that mycobacteria-contaminated MWF produce HP-like changes in the mouse but with lower potency, a distinct response profile and a more focal pathology than induced by *S. rectivirgula*.

SUMMARY

A substantial number of workers are exposed to MWF in a wide range of industries. Although the health effects associated with MWF exposures have been studied for some time, developing a clear understanding has been complicated by the fact that the fluids contain multiple and variable substances and contaminants, and have changed considerably in their formulation. Importantly, even MWF with a consistent neat formulation differ markedly over time and between systems when in use, both chemically and microbiologically. This has made difficult the process of identifying causative agents for suspected adverse health effects. In the past two decades there has been a transition from oil-based to water-based MWF. Coincident with this has been a shift in the major health concerns. Whereas previously oil folliculitis and skin cancer were the major dermatologic concerns, now irritant and allergic contact dermatitis are potential important problems. Earlier concerns about respiratory disease focused on lipid (lipoid) pneumonia and the possibility of lung cancer. Now there is concern for asthma, bronchitis and HP. Epidemiologic studies have identified varying results with regards to MWF exposures and cross-shift pulmonary function changes.

Animal toxicology studies have identified mechanisms of MWF-induced inflammation and HP. Adoption of appropriate medical monitoring and surveillance programs is an important consideration for workers exposed to MWF. Attempts to identify causative agents in MWF include these toxicology studies and exposure monitoring for chemical irritants, biocides, micro-organisms, microbial toxins, and

studies of the influence of changes in formulation on airborne levels. Improved design of new machining equipment with enhanced containment and local exhaust to reduce aerosol distribution, carefully directed nozzles, and elimination of high pressure air jets for fluid removal have served to reduce exposures in new or retooled production lines. An important policy area is setting exposure limits to prevent effects that have been observed among workers exposed below current standards. The research and control efforts mentioned above should help to reduce exposures and the health risks associated with MWF.

Chapter 44

Oils and Petroleum Derivatives

Oyebode A Taiwo, Ben Hur P Mobo Jr

Petroleum refining has evolved continuously in response to changing consumer demand for better and different products. Present-day refineries produce a variety of products that can be classified broadly as fuels, petrochemical feed stocks, solvents, process oils, and lubricants. Physically similar materials may also be derived from other organic minerals, such as coal, woods, and other vegetable matter. Because of their physical and chemical properties, these simple derivatives of naturally occurring substances have found an enormous number of uses in energy, construction, and primary metal manufacturing industries such as steel and aluminum.

This chapter provides an overview of information useful in the recognition and prevention of health effects related to exposures to petroleum-derived fuels and their combustion products, as well as petroleum derivatives such as semi-solid tars, pitch, coke, and asphalt.

PETROLEUM-DERIVED FUELS AND COMBUSTION PRODUCTS

Petroleum or crude oil is a naturally occurring liquid mixture containing thousands of different hydrocarbon molecules as well as sulfur, oxygen, nitrogen, and trace metals such as vanadium, iron, arsenic, and nickel. Petroleum, which literally means 'rock oil', is formed by the decay of organic matter such as marine organisms and vegetation. While the chemical and physical properties of crude oil vary widely from source to source, the petroleum-derived products are primarily influenced by the refining processes. The refining operation typically commences with desalting, a process that removes inorganic salts, water, and water-soluble compounds. Crude oils are then sent for distillation, which physically separates the oil into fractions based on range of boiling points. The resultant fractions undergo further processing depending on product specifications and economic factors. Some of the common petroleum-derived products are listed in Table 44.1.

Exposure setting

Given the ubiquity of petroleum production and use, as well as the complexity of refining processes, the potential for occupational exposure to physical and chemical agents in a petroleum operation is significant. In addition, environmental exposure may ensue following industrial spills, home accidents, and refueling procedures. Some of the chemicals present in refining operations are listed in Table 44.2. Their

potential health effects are discussed in other chapters. The most important petroleum-derived products, gasoline and its constituents, and diesel and kerosene fuels, are discussed in this section.

Gasoline and gasoline constituents

Gasoline or petrol is a complex liquid mixture of saturated and unsaturated hydrocarbons used for internal engine combustion. It typically contains 62% paraffins (or alkanes), 7% olefins (or alkenes), 31% aromatics, and small amounts of alcohols, ethers, and additives.¹ In the past, additives included organolead compounds, which were phased out in the 1970s due to their adverse health effects. The health effects of these compounds are discussed in Chapters 39.7 and 40, respectively. These components were replaced with methyl tertiary butyl ether (MTBE), fuel ethanol, ethyl tertiary butyl ether, and tertiary amyl ether. Of these, the most prevalent additive is MBTE, which is present in 15% of today's gasoline formulations.

Human health effects of gasoline and its constituents

The main route of exposure to gasoline is inhalation of vapors. Symptoms of acute exposure include mucosal membrane irritation and central neurologic effects (headache, nausea, dizziness, blurred vision, and mental confusion).² Coma and death may ensue within minutes following a high-level exposure, with no evidence of respiratory distress.^{3,4} Long-term effects of occupational exposure to gasoline include chronic headache, fatigue, memory loss, and psychomotor and visuomotor dysfunction. Chronic gasoline abuse through sniffing can also cause ataxia, tremors, and encephalopathic changes.⁵

A limited number of animal studies have shown a relationship between exposure to gasoline vapor and the development of cancer.⁶⁻⁹ Human epidemiologic studies on lung cancer, kidney cancer, leukemia, and multiple myeloma have not shown statistically significant increases following chronic gasoline vapor exposure.^{10,11} However, recent studies have reported a 3.5-fold increased risk of nasal cancer in service station workers¹² and an increased risk of male breast cancer among workers in trades with exposure to gasoline and combustion products.¹³

Fuel oils

Kerosene and diesel oil are among the most common petroleum-derived products, and are generally classified as

Products	Common uses	Number of carbon atoms	Boiling point range (°C)
Natural gas	Fuel, chemical	1–2	–164 to –88
Liquified gas	Fuel gas	3–4	–44 to +1
Petroleum ether	Solvents	4–5	20 to 60
Gasoline	Motor gasoline	5–10	32 to 210
Naphtha	Cleaning fluids	5–10	65 to 204
Fuel oil	Kerosene, aviation fuel	5–16	40 to 300
Gas oil	Diesel fuel, heating	9–16	204 to 371
Waxes	Sealant	≥20	204 to 400
Bottoms	Asphalts	≥20	≥499

fuel oils. Kerosene, or fuel oil number 1, is heavier than gasoline and lighter than lubricant oils, and is commonly used as a heating fuel, cooking fuel, degreasing agent, and a solvent for asphalt coating. Diesel oil, or fuel oil number 2, is principally a blend of petroleum-derived compounds. Its grade varies with the alkane, alkene, cyclic alkane, and aromatic composition. Generally, kerosene and diesel oil have similar toxicologic profiles.

Human health effects of fuel oils

Fuel oils are less volatile than gasoline; therefore, dermal contact and ingestion are important routes of exposure. Inadvertent or intentional ingestion of fuel oils can lead to aspiration and may result in lipoid pneumonia, which is discussed later in this chapter.

Several skin conditions have been reported with exposure to diesel and kerosene, in both acute and chronic settings. These include irritant contact dermatitis due to the defatting effects of skin contact with fuel oil; allergic contact dermatitis, attributed to isothiazolines in diesel oil; and acne/folliculitis due to plugged skin follicles.^{14–17} Dermal contact with fuel oil has also been associated with increased incidence of skin cancer in animal studies, though this is not established in human studies. The mech-

anism of action is presumably related to the effects of polycyclic aromatic hydrocarbons (PAHs) contained in fuel oil.

Health effects of fuel oils have been reviewed by the Agency for Toxic Substances and Disease Registry (ATSDR), and include respiratory, gastrointestinal, renal, hepatic, cardiovascular, and hematological effects.¹⁸

VEGETABLE OILS

Oils derived from vegetable materials are primarily used as food products and, to a lesser extent, as lubricants and dispersants. Vegetable oils are highly biodegradable, and generally free of toxicity. The main work-related health effects are due to dermal exposure leading to irritant and allergic dermatitis.^{19–21} Two health effects are toxic oil syndrome (TOS), due to ingestion of contaminated vegetable oil, and lipoid pneumonia, caused by inhalation of oil mists (from vegetable, mineral, and fuel oils).

Toxic oil syndrome

TOS was first described in an epidemic that appeared in Spain in 1981. Nearly 20,000 people were affected and 457 died from this condition. TOS is attributed to the ingestion of rapeseed cooking oil adulterated with an aniline derivative,²² although the syndrome has never been reproduced in animal studies. Withdrawal of the rapeseed oil from the market resulted in marked decline of new cases.

The clinical course of TOS is variable. During the first 2 months of disease, the presentation variably includes fever, cough, rash, dyspnea, myalgia, pulmonary edema, and eosinophilia. Few patients have complete remission after the acute phase. Over the subsequent months, most patients develop skin tenderness, severe myalgia, subcutaneous edema, abnormal liver function tests, and pulmonary hypertension. During the early chronic phase, from 4 to 24 months, disease manifestations include weight loss, joint contracture, polyneuropathy, scleroderma, and sicca syndrome. In the late chronic phase, the disease is characterized by muscle cramps, chronic musculoskeletal pain, Raynaud's phenomenon, and carpal tunnel syndrome.²³

TOS has also been associated with other autoimmune diseases, particularly the eosinophilia–myalgia syndrome (EMS), due to ingestion of contaminated L-tryptophan products. An aniline derivative has been identified as a potential common contaminant in both syndromes.²⁴

Lipoid pneumonia

Lipoid pneumonia is a lung disease characterized by alveolar lipid accumulation from either endogenous or exogenous sources. Endogenous lipid pneumonia, also referred to as 'cholesterol' or 'golden' pneumonia, has been described in the setting of bronchiolitis obliterans, Wegener's granulomatosis, bronchial obstruction from tumor, tissue necrosis following radiotherapy and chemotherapy, fat emboli, pulmonary alveolar proteinosis, and lipid storage disease.²⁵

In contrast, exogenous lipid pneumonia is caused by aspiration or inhalation of fatty materials, including animal fats, mineral oil, vegetable oil, and fuels. It was first described in 1925 by Laughlen during autopsy of patients who had received mineral oil nose drops or oral laxatives. Exogenous lipid pneumonia has since been reported in various occupational and non-occupational settings. Some of these cases are listed in Table 44.3. The most frequent occupational exposure has occurred in the setting of oil mist or spray inhalation by metal workers.²⁶

Inhaled or aspirated mineral oils can enter the tracheo-bronchial tract without eliciting a cough reflex. Once deposited, they impair the mucociliary transport system. Lipids are rapidly taken up by alveolar macrophages, and the lipid-macrophage complex induces the release of inflammatory and fibrogenic mediators, which lead initially to inflammatory consolidation and later to fibrosis.

Risk factors associated with development of lipid pneumonia include extremes of age, impaired swallowing and cough reflexes, mental status change, history of gastroesophageal reflux, neurologic or psychiatric illness, and prolonged recumbent position.^{27,28}

The clinical manifestations of lipid pneumonia vary. Many patients are asymptomatic while others present with non-specific symptoms like cough, dyspnea, chest pain, hemoptysis, fever, fatigue, and weight loss.²⁷ More than half of patients have normal physical findings. Others may have dullness to percussion, crackles, wheezing, and finger clubbing.²⁹

Offending substance	Exposure setting	Route of exposure
Oil mists	Machine shops	Inhalation
Vegetable and animal oil	Fire extinguisher tester	Inhalation
Kerosene	Fire eater	Inhalation
Petroleum-coated tobacco	Tobacco smoke	Inhalation
Hair spray	Hairspray use	Inhalation
Shellac	Spray	Inhalation
Mineral oil sprays	Metal turner, cashier, insect extermination	Inhalation
Petroleum jelly	High-altitude pilot	Aspiration
Diesel-contaminated water	Survivors of torpedoed ships during WW1 and WW2	Aspiration
Olive oil	Mouthwash use	Aspiration
Lip balm	Excessive use	Aspiration

Table 44.3 Exogenous lipid pneumonia

Laboratory examinations may be normal, but elevated erythrocyte sedimentation rate and leukocytosis with neutrophilic predominance may occur. Pulmonary function tests may show a restrictive pattern; however, normal, mixed, and pure obstructive patterns have also been reported in a few cases.²⁷ Decreased diffusing capacity and exercise-induced hypoxemia have also been reported.²⁵

The radiographic pattern of lipid pneumonia is variable. Unilateral and bilateral ground glass opacities, as well as normal radiographic patterns, have been reported. Right and left lung fields are almost equally involved. Most cases involve multiple lobes, with some preponderance in the posterior and lower zones.²⁷ Alveolar consolidations, alveolar nodules, atelectasis, cavitary lesions, and small pleural effusion have also been reported (Fig. 44.1). Computed tomographic scan and magnetic resonance imaging may demonstrate presence of fat within the lung tissue (Fig. 44.2).

Bronchoalveolar lavage may show visible, if not stainable, oil droplets. Cytologic examination may demonstrate positive intracytoplasmic lipid staining of alveolar macrophages, which is fairly specific for lipid pneumonia (Fig. 44.3). However, the test sensitivity has been variable, in part due to technique difficulty.

In summary, because of the non-specific clinical presentation of lipid pneumonia, a thorough exposure history is

Figure 44.1: Exogenous lipid pneumonia. The chest roentgenogram shows a dense consolidation in the left lung field with diffuse increased opacification in the remaining left lung. The right lung is inflated, but otherwise normal. (Reproduced with permission from Spickard and Hirschmann.²⁹)

Figure 44.2: Exogenous lipid pneumonia. High-resolution computed tomographic scan of the thorax demonstrates extensive airspace filled with fat in the left lung, with mild involvement of the right lung. Bronchiectasis is present in the left, and emphysema in the right lung. (Reproduced with permission from Spickard and Hirschmann.²⁹)

Figure 44.3: Exogenous lipid pneumonia. The open lung biopsy specimen reveals numerous lipid-laden macrophages with prominent small vacuoles. In the center, intra-alveolar organization and fibrosis are present, the large vacant spaces representing accumulations of mineral oil (hematoxylin–eosin stain, $\times 80$). (Reproduced with permission from Spickard and Hirschmann.²⁹)

essential. A high index of suspicion is warranted due to the fairly low sensitivity and specificity of available diagnostic studies. The cornerstone in the management of lipid pneumonia is cessation of exposure, treatment of underlying infection, and provision of supportive care. Oral corticosteroids have been used with variable results. Prevention of exposure to aerosolized oil can be achieved through

enclosure or automation of the process, and local exhaust ventilation.

PITCH, ASPHALT, COKE, TAR, AND RELATED MINERAL DERIVATIVES

Exposure settings

Pitch, asphalt, coke, and tars are chemically related dense semi-solid carbonaceous materials that are used widely in construction and in the production of metals such as steel and aluminum. These materials are derived from petroleum (pitch), coal (coke and tars), wood (tars), or naturally occurring asphalt.

Crude coal tar is a byproduct from the formation of coke from coal. The coal tar is then distilled to yield a number of chemical oils, coal tar pitch, and creosote. Coal tar pitch is primarily used as a binder for electrodes in the aluminum reduction process and as the adhesive in membrane roofs. Creosote is a wood preservative used in railroad ties, marine pilings, and telephone poles.

Asphalt, also known as bitumen outside North America, is the residue from the fractional distillation of crude petroleum. It also occurs as a natural deposit residue from the evaporation and oxidation of liquid petroleum. Asphalt is primarily used for paving roads, waterproofing and roofing, electrical insulation, sound insulation, and pipe coating.

All of these materials are composed of high molecular weight, aliphatic and aromatic hydrocarbons with trace amounts of sulfur or metals. Although physically similar, these materials are chemically diverse. The health effects are largely related to the content of PAHs.

PAHs are a group of chemicals formed during incomplete combustion of almost any fuel. They occur in association with domestic heating, vehicle exhaust, waste incinerators, certain industrial activities, as well as cigarette smoking. They are transported through the atmosphere in the vapor phase and absorbed on particulate matter. PAHs are distributed widely in the human environment at low concentrations. With higher levels in many industrial environments, significant exposure occurs in workplaces such as gas works and coke, aluminum, iron, and steel plants, where these materials are handled.

Exposure in workers is primarily by dermal or inhalation routes. At low temperature, these materials are minimally volatile; their physical characteristics make it difficult to generate respirable dusts, therefore the major exposure route is dermal. Skin absorption of PAHs contributes significantly to total body burden and can account for over 50% of total uptake.^{30–33} Application of these agents is often performed at high temperature, especially in processes such as primary metal manufacture, like aluminum reduction, steel coking, or in coal gasification. Roofers, road workers, and manufacturers of construction materials also heat them as part of their regular work. This results in the generation of both vapors and fume volatiles

(e.g., coal tar volatiles). These volatiles may contain high concentrations of respirable PAHs.

Human health effects

PAHs are carcinogens with both primary DNA-binding and cancer-promoting properties in various experimental models. The carcinogenic potential of individual chemicals varies by many orders of magnitude.^{34,35} PAHs almost always occur in mixtures; therefore the carcinogenicity to humans cannot be linked to individual chemicals. Furthermore, because the proportions of specific PAHs are entirely different in each material, the overall carcinogenic potential of a given material cannot be inferred by measuring one or two other marker compounds, such as benzo[a]pyrene, as is often assumed.³⁶

A strong association between chronic PAH exposure and lung cancer in coke and gas manufacturers^{37,38} and lung and bladder cancer among workers in aluminum smelters³⁹⁻⁴¹ has been demonstrated in epidemiologic studies. Epidemiologic studies have also observed increased risk for laryngeal, renal cell, colorectal, and pancreatic cancers.⁴²⁻⁴⁴

Workers exposed to tars and related compounds are also at increased risk for skin cancers, primarily of the squamous type (see Chapter 30.10). Because construction workers may also have a high potential for exposure to ultraviolet light, synergistic effects may be important.^{42,45} Heating of tars and related compounds also creates the potential for serious burns, because the hot materials will adhere to the skin and continue to transfer heat until cooled or removed surgically.

The evidence for human carcinogenicity of creosote and asphalt remains limited, owing to relatively few studies published to date, and to methodological limitations, such as insufficient sample size and latency effects. Asphalt fumes contain primarily long-chain hydrocarbons and a lower PAH concentration compared to coal tar fumes. While epidemiologic studies on the carcinogenicity of asphalt have raised concerns, further characterization of risk is required to allow definitive conclusions.⁴⁶⁻⁴⁸

Prevention

Primary measures to prevent inhalation and dermal contact by coal tar pitch volatiles and similar agents are essential, especially when they are heated. Monitoring for benzene-soluble material (BSM) that includes all the particulate coal tar pitch volatiles is recommended. Several studies on PAHs in ambient air have demonstrated that benzo[a]pyrene is found consistently in different mixtures and correlates well with total exposure; therefore it is also used as an indicator compound for the presence of PAHs in the workplace. However, it should not be assumed that PAH control has been achieved based on the air levels of benzo[a]pyrene or other easily measured marker compounds; rather, the total levels of particulate should be kept to the absolute minimum.

As an adjunct for prevention, urinary 1-hydroxypyrene (1-OHP) is a useful biologic marker for occupational expo-

sure to PAHs in several work environments. This biomarker serves as an efficient complement to air-borne sampling, because of the significant dermal absorption of these compounds.⁴⁹ However, no direct relationship has been established between 1-OHP and cancer risk, therefore it is not a useful tool for quantitative risk assessment.^{50,51} Other metabolites, such as thioethers, or more mechanistically important compounds, such as PAH-DNA adducts, have not proved to be easily measurable or amenable to quantifying exposures of interest.^{52,53}

Chapter 45

Persistent Organic Pollutants

Jeffrey Derr, Peter Orris

'Persistent organic pollutants' (POPs), 'persistent toxic substances' (International Joint Commission), and 'persistent, bioaccumulative, and toxic pollutants' (US Environmental Protection Agency) are terms used to describe a group of organic carbon-based chemical compounds that possess a number of characteristics that distinguish them from most environmental pollutants. POPs are compounds that bioaccumulate, biomagnify, persist in the environment, and demonstrate a capacity for long-range geographic transport. While dominated by organochlorine compounds, POPs include a variety of chemical classes with the common property of biopersistence.

BIOACCUMULATION, BIOMAGNIFICATION, AND ENVIRONMENTAL PERSISTENCE

POPs have a prolonged half-life in the human body, and are extraordinarily slow to be metabolized and excreted. Due to their lipophilic properties, they tend to accumulate and concentrate in fatty compartments, including breast milk. The end result is that the concentration of the pollutant in the organism becomes far greater than in the surrounding environment, a process termed bioaccumulation.

Because organisms tend to accumulate concentrations of POPs in their tissues that are greater than the concentrations found in the food that they consume, tissue concentrations tend to be higher in organisms that are higher in the food chain. Through this process of biomagnification, large mammals, including humans, are often at the apex of these food chains and accumulate some of the highest levels of POPs in their fatty tissues. POPs enter the food chain through air-to-plant-to-animal and water/sediment-to-fish pathways. Most, though not all, human exposure to POPs occurs through food consumption. The usual processes that lead to environmental breakdown of pollutants include hydrolysis (breakdown by water), photodegradation (breakdown by light), and biodegradation (breakdown by micro-organisms). POPs are relatively resistant to most of these processes. For most POPs, hydrolysis does not play a major role. In general, photodegradation of POPs via photochemically generated free radicals is a more important mechanism than direct photolysis (direct breakdown by ultraviolet light). Photodegradation of POPs in water takes place at a rate approximately one-tenth that of air and is of minimal importance in the dark sediments of the lakes and oceans. Therefore, half-lives of POPs in aquatic sediments are prolonged, and POPs

bioaccumulate in organisms that feed in and around these sediments. Photodegradation in soil is limited to the top 1 mm of soil. Anaerobic biodegradation of POPs takes place in soil and aquatic environments, and its rate is dependent on a variety of factors, particularly temperature. For instance, the Baltic Sea half-life of dioxin, a classic POP, is 8 days in air, 167 days in water, and 37,500 days in soil and sediment.¹ These times are longer than would be expected in warmer environments. Prolonged half-lives in sediments and soil, where photodegradation is limited, demonstrate the importance of this mechanism in the breakdown of POPs.

LONG-RANGE TRANSPORT

Though a variety of global pathways have been identified, the relatively low volatility of POPs favors distribution to colder, higher latitudes through a process known as 'global distillation or fractionization'.² Oceans, fresh-water bodies, and land contain concentrations of POPs that are greater than that found in air. These reservoirs are in continuous equilibrium with the atmosphere. POPs enter and leave these reservoirs repeatedly as they move northward in a process described as the 'grasshopper effect'. Much of the re-deposition to the reservoirs following volatilization occurs via precipitation. More volatile compounds tend to migrate farther from their source than do less volatile ones; thus, less heavily chlorinated biphenyl compounds have greater transport due to higher volatility. Weather patterns dictate that most atmospheric transport to the Arctic occurs during the winter and spring. Similar patterns have been described for Antarctica. Deposition of contaminated river sediments into the Arctic seas provides a significant, but less important, mechanism of POP transport to Arctic regions. Because of this Arctic accumulation of POPs, populations indigenous to these regions are at risk for substantial exposure. This is especially true because their diets are heavily dependent on Arctic mammals in which POPs have already been heavily biomagnified.

Because of this dispersion process, reduction of POPs in the environment must be controlled on a global level. To this end, the United Nations Environmental Programme (UNEP) has identified 12 POPs in need of the most urgent attention.³ Nine organochlorine pesticides are cited including aldrin, chlordane, DDT, dieldrin, endrin, heptachlor, hexachlorobenzene (HCB), mirex, and toxaphene. Polychlorinated dibenzodioxins (dioxins or PCDDs), polychlorinated dibenzofurans (furans or PCDFs), and polychlorinated biphenyls (PCBs) are also included.

Additional work is being done to develop a consensus process for defining additional chemicals as POPs that warrant elimination. UNEP initiated negotiations on an international binding agreement that will reduce or eliminate the release of the 12 currently identified POPs into the environment. Over 120 countries were involved in this negotiative process, culminating in a treaty adopted in May 2001.

DIOXINS, FURANS, AND PCBS

Dioxins, furans, and coplanar 'dioxin-like' PCBs are the POPs that have received the most attention regarding environmental and human toxicity. Although there are some differences between the groups of compounds, research over the last decade has revealed a common mechanism of action that has led them to be assessed together in terms of their environmental impact.

Structure

While many isomeric forms exist, certain dioxins, furans, and PCBs are considered 'dioxin-like' compounds with the potential for behaving like 2,3,7,8-tetrachlorodibenzo-p-dioxin (2,3,7,8-TCDD), the most toxic molecule in this group and the one most often referred to as 'dioxin'. Current research suggests that all dioxin-like compounds have similar mechanisms of action and cause similar environmental and health effects. Like all POPs, they are hydrophobic and resistant to biodegradation and metabolism; therefore, they are environmentally persistent and accumulate in the fatty tissues of animals and humans. 2,3,7,8-TCDD has a human half-life of slightly over 7 years, and researchers use this value for mixtures of dioxin-like compounds in pharmacokinetic modeling. Individual dioxin-like compounds have half-lives ranging from less than 1 year to 10 years.

Dioxins, furans, and PCBs each have slightly different ringed structures with chlorine substituted at various locations on the rings (Fig. 45.1). The specific location of the chlorine molecules determines whether or not the compound is considered dioxin-like. The range of possible substitutions results in 75 chlorinated dioxin compounds (PCDDs), 135 chlorinated furan compounds (PCDFs), and 209 PCBs. Each of these individual compounds is referred to as a congener. To have dioxin-like activity, dioxins and furans must be, at a minimum, substituted with chlorine at all four lateral positions. Therefore, only seven PCDDs and 10 PCDFs are considered to have dioxin-like activity. Because PCBs must have four or more lateral chlorines with no more than a single substitution in the ortho (inner) positions to have dioxin-like activity, only 12 of these compounds are classified as such. This PCB configuration results in a flat, or coplanar, molecule that resembles the planar PCDDs and PCDFs.

Brominated dioxin and furan congeners, as well as polybrominated biphenyl congeners used as flame retardants, are grouped exactly the same as their chlorinated counterparts with similar biochemical properties. There are also mixed chlorinated and brominated congeners. All of these compounds are felt to have some dioxin-like activity, though less is known regarding their biologic effects.

Mechanisms

In 1976, it was shown that dioxin binds with high affinity to the aryl hydrocarbon receptor (AhR), an intracellular cytosolic protein that serves as a nuclear transcription factor. Once dioxin binds AhR, the complex enters the cell nucleus, where it combines with the AhR nuclear translocator (Arnt). This complex then attaches to enhancer/promoter regions of DNA to induce transcription. While the precise natural mechanism of the AhR has not been characterized, it appears to interact with a variety of

Figure 45.1: Structure of some polychlorinated dioxins, furans and biphenyl compounds.

ligands to produce effects; thus, it is less specific than most hormone receptors. The receptor's presence across both vertebrate and invertebrate species, along with the tremendous degree of interspecies homology, suggests an important evolutionary function. The best-studied interaction is dioxin's association with the promoter region of the CYP1A1 gene, which results in induction of cytochrome P4501A1 enzyme activity. This enzyme facilitates metabolism and excretion of lipophilic substrates, such as polycyclic aromatic hydrocarbons (PAHs), by oxidizing them to more water-soluble derivatives. Thus, the AhR and the biochemical pathways it induces may have a natural role that involves detoxification of these and other environmental and dietary carcinogens.⁴ However, prolonged activation of these pathways, and activation during developmentally critical periods, may be responsible for the adverse effects of dioxin-like chemicals.

While the AhR appears to be the dominant mechanism of action for dioxin-like compounds, it is worth noting that other modes of toxicity may be extant, especially for PCBs. In most PCB mixtures, dioxin-like PCBs comprise an extremely small fraction of the total, and health impacts from other congeners must be considered. For example, one animal study showed that carcinogenicity of Aroclor 1260 is not AhR dependent in rodents.⁵

The 'toxic equivalency factor' (TEF) concept

2,3,7,8-TCDD is the prototypical and most potent dioxin-like compound. The other congeners have a toxic potency that is less than that of 2,3,7,8-TCDD. Sources of dioxin often produce complex mixtures of the different congeners. Additionally, as dioxins persist and biomagnify, the congener make-up of the original environmental input changes due to different solubilities, volatilities, and rates of degradation/metabolism among the different congeners. Different ratios and types of dioxin-like compounds among different samples make comparisons of potency and adverse effects between cases very difficult. Therefore, the concept of toxic equivalency factors has been adopted. 2,3,7,8-TCDD has been assigned a TEF of 1.0, and the various other congeners have been assigned a TEF that is some fraction of 1.0 (Table 45.1). The total potency of any dioxin mixture can be determined by weighting the amount of each congener present in the mixture by its respective TEF. This gives a total amount (toxic equivalence, TEQ) of dioxin-like compounds in terms of 2,3,7,8-TCDD that is expressed in a variety of ways, including grams per year TEQ when referring to environmental inputs, or picograms per gram lipid TEQ when referring to serum levels.

The TEFs are derived both from in-vivo and in-vitro studies, and are felt to be conservative estimates that avoid underestimating risk of exposure to these compounds. Because of uncertainties in setting TEFs, they are to be considered 'an order of magnitude estimate' of potency, rather than a specific measure of toxicity. TEFs refer only to responses mediated via the AhR, and do not account for non-AhR-mediated effects. The most widely used TEF

Selected dioxin-like compounds	TEF
2,3,7,8-Tetrachlorodibenzo-p-dioxin (2,3,7,8-TCDD or 'dioxin')	1
2,3,7,8-Tetrachlorodibenzofuran (2,3,7,8-TCDF)	0.1
1,2,3,7,8-Pentachlorodibenzo-p-dioxin (1,2,3,7,8-PeCDD)	0.5
2,3,4,7,8-Pentachlorodibenzofuran (2,3,4,7,8-PeCDF)	0.5
3,3',4,4',5,5'-Hexachlorobiphenyl (PCB 169)	0.01
3,3',4,4',5-Pentachlorobiphenyl (PCB 126)	0.1

Table 45.1 Toxic equivalency factors (TEFs) for selected polychlorinated dibenzodioxins, polychlorinated dibenzofurans, and polychlorinated biphenyls (PCBs)

system was developed by the World Health Organization (WHO) and was reviewed and updated by consensus conference in 1997.⁶

Critics of the TEF approach cite excessive uncertainty in TEF estimates and the possibility of non-additive interactions among the various congeners as major limitations.^{7,8} Additionally, some studies show that natural AhR agonists (e.g., PAHs) found in dietary meat products and cigarette smoke result in much higher daily intake of TEQs and more readily elicit a biochemical response than TEQs derived from dioxin-like substances. This calls into question the relative significance of trace levels of dioxin-like TEQs compared to relatively high exposure to naturally occurring AhR agonists.⁸ Even with these potential limitations, TEFs are used as a risk assessment tool to approximate relative potencies of mixtures of dioxin-like compounds and show good correlation with health effects in peer-reviewed studies.⁷

Sources

Dioxins and furans are not intentionally produced for human use; rather, they are byproducts of manufacturing and incineration processes involving chlorinated compounds. Because of its high reactivity, chlorine reacts rapidly with any organic matter it encounters. Though this is an extremely beneficial property for chemical synthetic processes, it also means many unintended byproducts are created as contaminants.⁹ Thus, the production of pentachlorophenol (PCP; a pesticide previously used as a wood preservative), 2,4,5-trichloro-phenoxyacetic acid (a herbicide), polyvinyl chloride (PVC; a common plastic), and any other chlorinated organic material can result in byproducts containing dioxins. These waste products have been responsible for several instances of ambient environmental contamination and health concerns, as occurred at Love Canal and at Times Beach, Missouri.¹⁰

Other industrial waste sources include bleaching processes in the pulp and paper industry and dry-cleaning distillation residues. Point sources of combustion resulting in dioxin contaminants include municipal and hazardous waste incinerators, copper smelting, and sintering plants, while more diffuse sources include automobile exhaust and home heating emissions. Incineration of medical waste, which contains large amounts of organically bound

chlorine in the form of PVC plastic, has also been identified as a major source.¹¹ Accidents such as PCB fires and building fires can be a significant source of dioxin exposure. Finally, natural events such as forest fires and volcanic eruptions result in some dioxin formation.

PCBs are chemically stable, relatively inflammable compounds with good insulating properties that were produced commercially in the US from 1929 through 1976. Because of their chemical characteristics, they were used as coolants and lubricants in electrical transformers and capacitors, as flame retardants, and as weatherproofers. They have also been mixed with pesticides to prolong their residual activity. Aroclor is the most commonly referred to trade name for PCBs, and the various formulations are assigned a number (e.g., Aroclor-1221 or Aroclor-1232) depending on the relative amount of the various PCB congeners. Dioxin-like PCB congeners are only found in trace amounts in commercial PCB preparations. However, because approximately 1.2 million tons of PCBs have been produced worldwide, these commercial preparations serve as the largest source of dioxin-like PCB congeners and contaminate the environment when PCB-containing equipment and materials are improperly disposed of. Like dioxins, PCBs are formed and emitted during combustion of chlorinated material.¹² Finally, when PCBs accidentally burn or are significantly heated during use, dioxins and furans are created that add to the toxicity of any pre-existing dioxin-like PCB congeners in the mixture.

Elimination of PCP and PCB production, substitution of chlorine-free bleaching agents in the paper industry, and use of smokestack emission controls have decreased dioxin input into the environment.¹³ However, current environmental contaminants remain significant. The major environmental input sources are municipal waste incineration, copper smelting, medical waste incineration, coal combustion by utilities, sintering plants, industrial wood combustion, and sewage sludge incineration.

The 'endocrine disruption' hypothesis

Dioxin-like compounds and other organochlorines have been characterized as carcinogenic, developmental, endocrinologic, immunologic, and reproductive hazards. Multiple environmental observations of developmental and reproductive abnormalities in wildlife have been observed.¹⁴ Although the less persistent toxicants dibromochloropropane and ethylene dibromide have also been put forth as the etiologic agents responsible for alligator population decline in an ecologic habitat,¹⁵ the organochlorine pesticide DDT and other persistent pesticides are widely felt to be responsible. Following an accidental release of DDT into Lake Apopka, Florida, male juvenile alligators were shown to have diminished testosterone levels unresponsive to luteinizing hormone stimulation. Testes showed abnormal morphologic organization, and phalli were abnormally small. Normal sexual maturation did not occur, and reproductive capacity was diminished.¹⁶

Examples of endocrine abnormalities in wildlife have bolstered research on hormonally active agents in humans.

An endocrine disruptor has been defined by the Environmental Protection Agency (EPA) as an 'exogenous agent that interferes with the synthesis, secretion, transport, binding, action, or elimination of natural hormones in the body that are responsible for the maintenance of homeostasis, reproduction, development, and/or behavior'.¹⁷ A further discussion of this topic is provided in Chapter 27.1. Exogenous chemicals have been identified that mimic estrogen compounds; act as anti-estrogens, anti-androgens, and anti-progesterone compounds; and interfere with thyroid hormone function. Human health concerns are related to potential disruption of sex steroid axes, including abnormal sexual differentiation, diminished reproductive capacity, and endometriosis and breast cancer in females. Diminished sperm production and testicular cancer may be a result in males. Alteration in thyroid function related to PCB exposure in the prenatal period appears to adversely affect neurologic development.^{18,19} Additionally, as demonstrated by diethylstilbestrol (DES), compounds with estrogenic effects can result in transplacental effects after in-utero exposure. In the case of DES, clear-cell adenocarcinoma of the vagina, increased rates of cryptorchidism, and other reproductive abnormalities occurred in offspring of women administered DES during pregnancy.²⁰ Developmental exposure to endocrine disruptors is especially concerning because the absence of adult feedback mechanisms in the developing fetus may result in adverse effects at very low doses.¹⁷ In fact, a reverse dose-response curve may be in effect, where effects that occur at low doses are not seen at higher doses due to receptor saturation.

Because exposure to most hormonally active agents occurs at very low concentrations, and may depend on exposure during certain critical periods of development, current risk assessment methodologies relying on high-dose studies and classic dose-response curves may not be sensitive enough to detect effects of endocrine disruptors. The Safe Drinking Water Act Amendments of 1996 and the Food Quality Protection Act of 1996 have mandated that the US EPA develop testing methodologies that determine whether chemical compounds have endocrine effects in humans. Because previous multi-generation reproductive studies that focused on fertility, fecundity, and growth of offspring have been found to be relatively insensitive for endocrine disturbance, and fail to provide insight into underlying mechanisms of biologic disruption, new test batteries examining more sensitive parameters, such as female estrous cyclicity and sperm quality, are being designed to screen potential environmental contaminants for endocrine-disrupting effects. These test batteries will use in-vitro and in-vivo animal assays to evaluate interactions with estrogen, testosterone, and thyroid hormone.²¹ Accounting for the effect of complex mixtures of endocrine disruptors that are likely to occur in an exposed human population adds an additional level of complexity to the risk assessment process.

The 'endocrine disruption' hypothesis is consistent with the AhR mechanism of action for 2,3,7,8-TCDD. AhR agonists have been shown to disrupt thyroid homeostasis and induce teratogenicity. AhR-dependent effects of dioxin

also include diminished testosterone levels, disruption of pituitary feedback, and anti-estrogenic activity.⁴ Biochemical and animal assays, as well as environmental observations of wildlife, provide considerable evidence for endocrine disruption.^{22,23} However, studies of human health effects that may result from endocrine disruption remain conflicting and equivocal. This is likely a function of the limitations of epidemiologic research in detecting health effects in populations that result from a complex series of biochemical events, in response to varied exposures involving potentially dozens of endocrine-disrupting chemicals. A further discussion of endocrine disruption can be found in a National Academy of Sciences publication that addresses the current state of knowledge on this topic.²⁴

HEALTH EFFECTS OF DIOXIN-LIKE COMPOUNDS

High-dose exposures

Yusho and Yucheng²⁵

In 1968, 1866 people in southern Japan developed a severe clinical illness known as 'Yusho syndrome'. Similarly, 2061 people developed a similar constellation of signs and symptoms in Taiwan in 1979 that were labeled as 'Yucheng syndrome'. In both instances, it was determined that the syndrome developed following consumption of rice bran cooking oil that was contaminated during the cooking process with PCBs and PCDFs from heat exchangers. 'Yusho' and 'Yucheng' each mean oil disease in Japanese and Chinese, respectively. Symptoms included loss of appetite, nausea, pruritus, distal paresthesias, joint pain, headache, and bronchitic pulmonary symptoms. Signs included eyelid swelling, Meibomian gland hypersecretion, conjunctival changes, visual disturbances, chloracne (see below), pigmentation changes in the skin and nails, and liver function biochemical abnormalities. Follow-up has indicated increased cancer mortality in poisoning victims. Significant excess mortality was seen for malignant neoplasms at all sites in males, with considerably increased mortality for cancer of the liver in both males and females (statistically significant only in males). Offspring exposed in utero were born with grayish dark-brown skin, had nail and eyelid changes, and exhibited growth retardation. Cognitive delay has also been observed in these children.²⁶

Seveso

In 1976, thousands of people in the town of Seveso, Italy, were exposed to 2,3,7,8-TCDD that was released from a trichlorophenol production plant as a result of an accidental uncontrolled exothermic reaction. Immediately following the release, an excessive number of deaths were noted among animals, particularly poultry and rabbits. Chloracne (193 cases) was the most prominent acute manifestation among the exposed. Follow-up clinical studies revealed some evidence of neuropathy, immunologic changes, and a change in sex ratio, with an excess of female offspring in parents exposed to TCDD. Additional long-term

follow-up identified excess cardiovascular and respiratory mortality, increased incidence of diabetes, and an elevated occurrence of gastrointestinal, lymphatic, and hematopoietic malignancies.²⁷

Chloracne

Chloracne is a chronic, refractory dermatosis that is characterized by follicular hyperkeratosis (see Chapter 29.2). There is predominance of open over closed non-inflamed comedones. Milia develop and combine to form straw-colored cysts. In contradistinction to acne vulgaris, comedones and cysts concentrate over the malar crescent of the face, in the 'crow's foot' area lateral to the eyes, behind the ears, and in the axillae and scrotum. However, because the two conditions are often clinically and histologically indistinguishable, a history of exposure to dioxin-like compounds is frequently the only clue to the diagnosis of chloracne.²⁸ Chloracne results from exposure to a variety of halogenated organic compounds, and is a common feature of significant overexposure to dioxin-like compounds. Other symptoms consistent with exposure to the causative agent may be present concurrently with the skin condition. Chloracne occurs within 2 months of exposure and may persist for decades after exposure has ceased. As indicated in Table 45.2, the level of dioxin-like compounds required to develop chloracne is 30–60 times the background levels seen in the general population.²⁹ Neuberger et al. show that blood TCDD levels may remain elevated for many years in patients with chloracne.³⁰

Low-dose exposures

As noted above, assessment of the chronic health effects of POPs presents a clinical challenge. The following health effects summary focuses on human data that is inconclusive in many cases and will require further investigation. Hopefully, improvements in our ability to detect endocrine disruption and its outcomes in animal models will provide knowledge that will facilitate more conclusive epidemiologic evaluations.

Breast cancer

Human data addressing the association between dioxin-like compounds and breast cancer are limited. An occupational cohort of women exposed to TCDD demonstrated an approximately twofold increased risk of breast cancer mortality, with a standardized mortality ratio (SMR) of 2.15 (95% confidence interval [CI] 0.98–4.09).^{31,32} Seveso victims have shown a non-significant decrease in breast cancer risk. Nested case-control studies from 1994 and 1997 that examined the association between PCB levels and breast cancer found no significant relationship.^{33,34} Additionally, a 1998 study from Denmark noted that PCBs were not associated with increased breast cancer risk.³⁵

Other cancers

In a follow-up study of workers accidentally overexposed to 2,3,7,8-TCDD, there was no significant increase in overall

Exposure group	Years since exposure	Toxicant	Average levels (lipid basis)*	Range (lipid basis)*
9 Chlorophenoxy herbicide production workers with documented chloracne in 1972 and no further exposure ³⁰	18	2,3,7,8-TCDD	340 pg/g	98–659 pg/g
7 Chinese pentachlorophenol production workers with chloracne ²⁹	<1	Dioxins and furans	Not reported	1200–22,000 pg/g TEQ
9 Chinese pentachlorophenol production workers without chloracne ²⁹	<1	Dioxins and furans	Not reported	400–650 pg/g TEQ
228 members of German general population (1989) ⁵⁸	N/A	Dioxins and furans	43.74 pg/g TEQ	Not reported
69 members of German general population (1995) ⁵⁸	N/A	Dioxins and furans	24.06 pg/g TEQ	Not reported
50 young Japanese women 1993–1994 ⁶⁰	N/A	Dioxins and furans	21.0 pg/g TEQ	9.1–37.0 pg/g TEQ
85 members of German general population ⁵⁶	N/A	Dioxins and furans	42 ppt TEQ	Not reported
100 members of the US general population ⁵⁶	N/A	Dioxins and furans	41 ppt TEQ	Not reported
5 blood bank samples from Kansas City, MO ⁵⁷	N/A	Dioxins and furans	23 ppt TEQ	Not reported
	N/A	PCBs	46 ppt TEQ	Not reported
	N/A	Dioxins, furans, and PCBs	69 ppt TEQ	Not reported

*ppt equals pg/g
PCBs, polychlorinated biphenyls; TCDD, tetrachlorodibenzodioxin; TEQ, toxic equivalence

Table 45.2 Body burdens of dioxin-like compounds in selected populations (blood lipid basis)

or cancer-related mortality. Subgroup analyses revealed that the most highly exposed workers (those with chloracne) had an elevated SMR for malignant neoplasms only after 20 years of follow-up (SMR, 201; 90% CI, 122–315). No single tumor type showed a significant increase, but colorectal cancer (SMR, 344; 90% CI, 94–888) and tumors of the trachea, bronchus and lung (SMR, 252; 90% CI, 99–350) showed the strongest trends towards significance.³⁶

Another cohort study of workers with ongoing background exposure to TCDD showed a statistically significant increase in overall cancer mortality among the entire cohort, with an elevated risk of death from soft tissue sarcoma and respiratory cancers in the most highly exposed workers after 20 years of latency.³⁷ Workers in an herbicide plant contaminated with TCDD had an increase in overall cancer mortality, with increased death from cancers of the lung and hematopoietic system when compared to a similar non-exposed occupational referent group.³¹ Some association between soft tissue sarcomas and TCDD and higher chlorinated dioxins has also been noted.^{32,38}

In a 1997 case-control study, a dose-response relationship between serum PCB levels and non-Hodgkin's lymphoma was observed, with an odds ratio for the highest serum levels of 4.5 (95% CI, 1.7–12.0).³⁹ This was potentiated by seropositivity for Epstein-Barr virus (EBV), with an odds ratio of 22.3 (95% CI, 4.3–115.0) for elevated PCB levels with elevated EBV titers. The presence of elevated PCB levels in human populations has been proposed as an explanation for the worldwide increase in the incidence of this tumor in recent decades.³⁹ In 1997, the International Agency for Research on Cancer (IARC) characterized TCDD as a known human carcinogen (Group 1) based on the evidence in animals and human epidemiology.⁴⁰

Developmental abnormalities

Studies assessing cognitive development in children prenatally exposed to PCBs due to maternal fish consumption have demonstrated decrements in gross motor function

and visual recognition memory, as well as significant IQ decrements in more vulnerable children. Recent studies have confirmed these findings, suggesting particular sensitivity of the developing fetal brain.^{18,19} No relationship has been found between cognitive developments and breastfeeding with PCB-contaminated milk.

Thyroid dysfunction

A significantly increased rate of primary hypothyroidism has been seen in a cohort of workers exposed to polychlorinated biphenyls (PCBs).⁴¹ In another cohort, elevations in free thyroxine index were seen in workers with the highest body burdens of TCDD.⁴² There has been some correlation between elevated neonatal thyroid-stimulating hormone (TSH) levels and PCB exposure, but studies are conflicting.^{43,44} A further discussion of thyroid dysfunction is provided in Chapter 27.1.

Immune system dysfunction

Studies of adults occupationally exposed to PCDD/PCDFs have shown no consistent evidence of immune dysfunction, other than possible impairment of lymphocyte function with very high exposure.^{45,46} However, the developing immune system is likely more sensitive. Animal studies suggest prenatal exposure to these compounds may cause long-lasting immunologic incompetence. Additionally, prenatal 2,3,7,8-TCDD exposures may interfere with normal development of self-tolerance and predispose to autoimmune disease.⁴⁷ Recent work has shown an increased risk of chickenpox and ear infections in young children with higher exposure to PCBs.⁴⁸

Reproductive effects

As noted above, progeny of Seveso victims demonstrated a female-predominant altered sex ratio. Additional studies are underway to assess reproductive outcomes in this population.⁴⁹ Human studies have failed to demonstrate a consistent correlation between dioxin-like compounds and

endometriosis.⁴⁹ However, an animal model for dioxin-induced endometriosis has demonstrated that endometrial changes may be promoted by interference with progesterone action.⁵⁰

Although controversial, a recent meta-analysis confirmed that sperm density has been declining in Western countries.⁵¹ It has been speculated that hormonally active compounds may be contributing to this phenomenon. A further discussion of reproductive effects is provided in Chapter 27.2.

Diabetes

A study of Vietnam veterans has shown increased prevalence of type II diabetes in personnel exposed to Agent Orange.⁵² A potential mechanism includes estrogen-like effects, leading to hyperinsulinemia, with subsequent insulin resistance.⁵³

Other effects

In adults potentially exposed to 2,3,7,8-TCDD, elevation of gamma-glutamyltransferase (GGT), with normal levels of other hepatic enzymes, has been observed. Studies have also shown possible increases in cardiovascular disease⁵⁴ and abnormal lipid metabolism. Oxidative stress mediated by the AhR may be a potential mechanism for these and other effects, but requires confirmation.

RISK ASSESSMENT CONSIDERATIONS FOR DIOXIN-LIKE COMPOUNDS

As discussed above, most human exposure to dioxin-like compounds occurs via dietary intake. By analyzing dioxin and furan concentrations in food and considering American consumption rates, average daily adult intake for these compounds has been estimated to be 0.3–3.0 pg/kg body weight (bw)/day TEQ.⁵⁵ Because dioxin-like PCBs were not included in this analysis, and may make up 35% of the total daily intake of dioxin-like compounds, the actual adult consumption rate may be 0.5–5.0 pg/kg bw/day TEQ. Diets rich in fish, meat, and dairy products may increase consumption several fold, depending on background contamination levels. On a body weight basis, intake of dioxin-like compounds is greater for young children. Because these chemicals are concentrated in breast milk, breastfed infants are at higher risk of exposure and may have consumption rates 12–18 times higher than adults during the first year of life.

Body burdens of dioxin-like compounds have been evaluated and are usually reported on a lipid basis due to their lipophilic characteristics. The lipid fraction of blood or whole milk is separated from the non-lipid components, and lipid basis calculations are reported as amount of dioxin per gram of lipid, rather than amount per gram of tissue. Parts per trillion (ppt) calculated on a lipid basis is equivalent to picograms per gram of lipid. Schecter et al. noted that the body burden of PCDDs/PCDFs in Germany and the US is approximately 40 ppt TEQ on a blood lipid basis (Table 45.2).⁵⁶ Blood bank samples from Kansas City

found the PCDD/PCDF body burden to be only 23 ppt TEQ but also showed that dioxin-like PCBs contributed 46 ppt TEQ, for a total of 69 ppt TEQ on a blood lipid basis.⁵⁷ PCDD/PCDF levels reported by Wittsiepe et al. show that body burdens present in the German general population are decreasing.⁵⁸ Levels found in Japan are consistent with other observations.^{59,60}

Based on animal and epidemiologic data, several agencies have recommended exposure limits for dioxin-like compounds. In 1990, the WHO established a tolerable daily intake (TDI) for 2,3,7,8-TCDD of 10 pg/kg bw/day based on animal studies and kinetic modeling. In 1998, the WHO met again to evaluate new health effects evidence (particularly endocrine disruption) and incorporated the TEQ concept into the TDI. Based on the review, a daily intake of dioxin-like compounds of 1–4 pg/kg bw TEQ was recommended.⁶¹ The IARC classified 2,3,7,8-TCDD as carcinogenic to humans (IARC Group 1) in 1997, but noted that other dioxin-like compounds were not classifiable as to their carcinogenicity in humans (IARC Group 3) due to limited experimental and epidemiologic evidence.⁴⁰ The National Institute for Occupational Safety and Health (NIOSH) recognizes 2,3,7,8-TCDD as a potential occupational carcinogen and recommends that exposure be limited to the lowest concentration feasible. Both NIOSH and the Occupational Safety and Health Administration (OSHA) have established exposure limits for air-borne concentrations of PCBs.

In 1994, the US EPA issued a dioxin draft reassessment stating that the unit cancer risk for dioxin-like compounds is 1.0×10^{-4} (pg/kg-d)⁻¹ TEQ. In its 2000 reassessment, through accumulation of new data on cancer outcomes in occupationally exposed cohorts,^{31,36,37} the EPA has recommended a new value of 5.0×10^{-3} (pg/kg-d)⁻¹ that represents a 50-fold increase in its estimate of carcinogenic risk for dioxin-like compounds.^{62,63} Using an analytic format applied by Schecter and Olson,⁶⁴ the risk from dioxin exposure in the US population can be estimated. If the new EPA unit cancer risk is used in this calculation, a risk level several orders of magnitude greater than the EPA's usual acceptable risk level for environmental exposures is obtained, suggesting that potentially thousands of cancer cases per year may be directly linked to dioxin exposure. Like all risk assessment processes, the evaluation of dioxin's carcinogenicity has sparked tremendous criticism and controversy in the scientific and industrial communities, and the proposed risk level has not been formally accepted by the EPA for practical application. Further research will be required to characterize the risk of dioxin and other POPs.

OTHER PERSISTENT ORGANIC POLLUTANTS

The remaining POPs currently targeted for elimination are organochlorine pesticides, which are discussed in detail in Chapter 48. Generally, these agents act as central nervous system stimulants following acute exposure.

Compound	General comments	Current use and exposures	Ecologic considerations	Chronic health effects (carcinogenicity per IARC)	Exposure limits
Aldrin and dieldrin	Both used as insecticides in soil; aldrin metabolized to dieldrin in living systems	Banned in most developed countries; aldrin used as termiticide in parts of SE Asia, Africa, and S America; misapplications for indoor termite control occur; dermal and inhalational exposures from occupational application and indoor environment of treated homes	Binds soil, causing prolonged soil half-life; readily volatilized and redistributed	Not classifiable regarding human carcinogenicity (IARC Group 3), but 1998 study from Denmark showed possible dose-response in humans for breast cancer; ³⁵ neurologic changes include headache, dizziness, muscle twitches, abnormal ECGs, peripheral neuropathy, and psychologic illness; possible Parkinson's disease; may affect immune response; hepatotoxicity and renal toxicity in animals	Dieldrin: OSHA PEL 0.25 mg/m ³ air NIOSH – lowest feasible
Chlordane	Insecticide used in fire ant control and other broad-spectrum agricultural applications	Production ended in 1976 in US, 1997 worldwide; used extensively to control termites, and air-borne exposure after indoor spraying may be most significant source of current exposure; stockpiles still in use in some countries	Residues found in soil up to 20 years after application; transport to Arctic readily occurs	Possible human carcinogen (IARC Group 2b); exposure following indoor application may increase rates of bronchitis, sinusitis, and migraines and may cause neurobehavioral changes; exposed workers have shown increased rates of cerebrovascular disease	OSHA PEL 0.5 mg/m ³ air NIOSH REL 0.5 mg/m ³ air US EPA 0.002 mg/L water
DDT (dichlorodiphenyl-trichloroethane)	Insecticide used in agriculture and to control the mosquito vectors of malaria; readily metabolized in living systems to DDE, a stable and equally toxic compound	WHO endorses phasing out worldwide use, but still promotes limited governmental programs to control malaria; use banned in many countries, but some indoor and agricultural spraying still occurs	Concentrates in sediments; still found in US soil and sediments 20 years after use discontinued; highly concentrated in Arctic food chain	Possible human carcinogen (IARC Group 2b) based on liver tumors in rodents; commonly studied in relation to breast cancer, with conflicting results; in 1993, a nested case-control study in New York found a significant dose-response relationship between serum DDE and breast cancer; ⁶⁵ however, similar studies in 1994 and 1997 found no significant relationship; ³³ there was no association noted between DDT levels and lymphoma; ³⁹ case-control studies among farmers have shown no consistent correlation between DDT use and non-Hodgkin's lymphoma after adjustment for use of other pesticides; ⁶⁶ many examples of estrogenic endocrine disruptive effects in wildlife; diffuse nervous system abnormalities	OSHA PEL 1 mg/m ³ air NIOSH – lowest feasible
Endrin	Rodenticide; also an insecticide used on cotton, corn, and rice; related to aldrin and dieldrin, but more toxic; produces extremely toxic metabolites	Banned in most countries	Half-life in soil up to 12 years	Not classifiable as a human carcinogen (IARC Group 3); animal studies suggest that endrin may increase reactive oxygen species in the liver and brain and may lead to improper bone formation	
Heptachlor	Termiticide, insecticide used in agriculture and for fire ant control; found in chlordane preparations as an impurity; metabolized to heptachlor epoxide	Production ended in 1997, but use continues in many countries; exposure occurs via ingestion of treated foods contaminated with residues and via inhalation in the indoor environment of treated homes; most frequently detected organochlorine in US cattle	Long-range transport and atmospheric deposition via rainwater have been documented	Possible human carcinogen (IARC Group 2b) shown to inhibit breast epithelial cell communication; also may act as tumor promoter; occupational exposure may increase risk of bladder cancer; liver carcinomas in rats; increased risk of cerebrovascular disease in exposed workers	OSHA PEL 0.5 mg/m ³ air NIOSH – lowest feasible US EPA 0.0004 mg/L water

Table 45.3 Characteristics of nine organochlorine pesticides targeted as persistent organic pollutants³

Compound	General comments	Current use and exposures	Ecologic considerations	Chronic health effects (carcinogenicity per IARC)	Exposure limits
Hexachlorobenzene (HCB)	Used as a fungicide for seed treatment; produced as byproduct during chlorinated chemical production and municipal incineration of waste similar to dioxins	Minimal ongoing production and direct use; acute high exposure due to human consumption of HCB-treated seeds in Turkey during the late 1950s resulted in a porphyria cutanea tarda-like syndrome, and breastfed children of exposed mothers developed the dramatic 'pembe yara' syndrome (aka 'pink sore', a low-grade cellulitis that quickly deteriorates into a limb- or life-threatening soft tissue infection)	Deposition and bioaccumulation in Arctic regions has been documented	Known animal and possible human carcinogen (IARC Group 2b); CNS, liver, and spleen damage shown in animals; low doses in animals have been shown to alter adrenal cortex function	
Mirex	Insecticide used for fire ant control in SE US; previous use as fire retardant in plastics, paints, and electrical equipment largely banned; breaks down to more toxic photomirex in presence of sunlight	Ongoing insecticide use in some countries; food primary source of intake, but food levels generally below recognized tolerances	Very stable and persistent; resists biodegradation; half-life of up to 10 years in sediment; deposition and bioaccumulation in Arctic regions have been documented	Minimal human data; possible human carcinogen (IARC Group 2b) based on animal studies; immune suppression in animals; endocrine disruption in animals well documented	
Toxaphene	Insecticide and acaricide; used particularly on cotton crops	Most widely used insecticide in US by 1975; banned by the US EPA in 1982; stockpiles used through 1986; Argentina and Mexico continue to allow restricted use; very prominent residue on foods in 1980s, but current residue levels are generally below acceptable limits	One of most dominant freshwater organochlorine residues in US and Canada, with most transported via atmospheric deposition from C America and southern US; high Arctic concentrations	Limited human data; mutagenicity in mammalian cells and liver cancer in animals has resulted in classification as a possible human carcinogen (IARC Group 2b); has shown estrogenic and anti-estrogenic effects; may affect behavior and learning	Germany 0.1 mg/kg wet weight for fish US EPA 0.005 mg/L water

Table 45.3 (Cont'd) Characteristics of nine organochlorine pesticides targeted as persistent organic pollutants³

Headache, nausea and vomiting, dizziness, muscle weakness, ataxia, and seizures may occur. Coma, respiratory failure, and death may result from large overexposures. Some of the organochlorines may precipitate seizure at relatively low doses, even in the absence of other health effects. Though the evidence is stronger for some, many organochlorine pesticides are suspected of having hormonally active effects, raising concern over carcinogenic, developmental, endocrinologic, immunologic, and reproductive effects. Specific details for nine of the best-studied organochlorine compounds are shown in Table 45.3.

CLINICAL EVALUATION

In general, the appropriate clinical evaluation for patients concerned about exposures to PCBs, dioxins, and dibenzofurans focuses heavily on risk communication and avoidance of future exposures. History should emphasize sources of exposure, as well as health and reproductive function. Physical examination should be directed towards organ systems of concern, including skin, thyroid, lymphatic, breast, genitourinary, and hepatic systems. No special diagnostic tests or therapeutic regimen are recommended to avoid or prevent future health effects in most cases. While not specific, liver function tests, thyroid function, and complete blood count may be useful. Blood or lipid levels of these toxicants are occasionally helpful in etiologic assessment and as an aid to accurate risk communication. No therapeutic modality has been proven effective in reducing the half-life of these compounds in the human body. NIOSH provides excellent references for laboratory evaluation of persons exposed to PCBs, aldrin, dieldrin, chlordane, DDT, and endrin on their web page at www.cdc.gov/niosh/nmed/nmed0000.html. Local reference laboratories should be contacted for details regarding test specifications and interpretation, as well as specimen collection requirements.

Chapter 46

Mineral Dusts: Asbestos, Silica, Coal, Manufactured Fibers

Gregory R Wagner, Frank J Hearl

INTRODUCTION

Mineral is the term traditionally applied to naturally occurring inorganic substances having definable and consistent physical properties and chemical composition. By conventional contemporary usage, mineral also refers to similar substances of organic origin, such as coal, as well as manufactured materials of mineral origin, such as ceramic fibers or slag wool. Dusts generated in the mining, milling, manufacture, and use of minerals have long been recognized as causes of serious lung diseases. This chapter provides an overview of information useful in the recognition and prevention of diseases related to mineral dust exposure. As with any agents causing chronic disease, hazard recognition and environmental surveillance and control are key to disease prevention and are thus a primary focus of this section.

ASBESTOS

Exposure settings

Asbestos is a generic name used in referring to a group of fibrous minerals that have exceptional resistance to degradation by heat, acids, bases, or solvents. Asbestos is defined in US regulations as the minerals chrysotile, crocidolite, amosite, tremolite asbestos, actinolite asbestos, and anthophyllite asbestos, although there are other hazardous fibrous minerals such as erionite, richterite, and winchite with similar characteristics.

Asbestos fibers can be classified based on their physical and chemical structures as serpentine (curved) or amphiboles (straight and needle-like). The most commonly used asbestos fiber is chrysotile asbestos, which now comprises over 95% of worldwide production, and is the only serpentine asbestos of importance. Amphibole asbestos, used more in the past, includes commercially used amosite (mined in South Africa) and crocidolite, and non-commercially used anthophyllite, tremolite, and actinolite, which can potentially contaminate other mineral ores or cause environmental rather than occupational asbestos-related disease. The relative potency of the different forms of asbestos in causing both malignant and non-malignant asbestos-related conditions has been a source of controversy, complicated in part by the fact that each form is rarely pure, but may contain small amounts of other fiber types; anyone who has worked with asbestos for many

years likely was exposed to several fiber types. Chrysotile is generally considered less potent for mesothelioma induction than certain amphiboles, but still may be a cause. Crocidolite is considered the most potent fiber for mesothelioma.

The asbestos minerals are not combustible and have a high melting point and low thermal and electrical conductivity. These and other useful properties resulted in the development of thousands of commercial uses for asbestos. Asbestos has been in widespread use for more than a century. Before 1900, less than 10,000 metric tons per year were used in the US. The use of asbestos for products including clutch and brake linings, packing and gaskets, asbestos flooring, and thermal and electrical insulation, led to increased demand. By 1950, the annual US demand for asbestos grew to over 660,000 metric tons, and increased to over 801,000 metric tons by 1970.¹⁻³ Since the early 1970s, regulatory action and liability concerns have reduced or eliminated many uses in the US and elsewhere. Complete or partial asbestos bans are in place in at least 20 countries, and asbestos use will be banned throughout the European Union in 2005.

There are six classes of products in which the use of asbestos is currently banned by the US Environmental Protection Agency (EPA):

- corrugated paper;
- rollboard;
- commercial paper;
- specialty paper;
- flooring felt; and
- new uses of asbestos.

Since the 1970s, the US demand for asbestos products has dropped to the current levels of 14,600 metric tons in 2000.⁴

Recent total US production of asbestos fell from 9550 metric tons in 1996, to an estimated production of 5260 metric tons in 2000. Worldwide production and usage have been relatively stable, declining from 2.1 million metric tons in 1996 to 1.9 million metric tons in 2000. In 2000, the major continuing uses for asbestos were roofing products, gaskets, and friction products. Nevertheless, millions of tons of asbestos insulation remain installed, and removal and disposal create continuing exposure potential. In some situations, asbestos-bearing materials may be sealed with a coating to minimize release of inhalable fibers. This only defers the problem of exposure until

major renovation or demolition is required. Today, most domestic exposure occurs in construction workers exposed to installed asbestos products or during asbestos abatement and removal activities. Exposure may also occur when asbestos is found as a contaminant in other commercially useful minerals, including, talc, clays, vermiculite, magnetite, marble, and metal ores.

The Occupational Safety and Health Administration (OSHA) estimated in its 1994 Asbestos Standard that about 700,000 US workers were potentially exposed to asbestos in general industry and shipyards.⁵ Many more have been exposed in the past. Table 46.1 lists occupations where significant asbestos exposure has occurred and may continue to occur. Asbestos products have been so widely used that a complete list of potential exposure settings would include virtually all workplaces.

Acoustic product installers
Asbestos cement product makers and users
Asbestos grout makers and users
Asbestos millboard makers and users
Asbestos millers
Asbestos miners
Asbestos paper makers and users
Asbestos plaster makers and users
Asbestos insulators
Asbestos tile makers and installers
Asphalt mixers
Automobile repair workers
Boiler makers
Beer makers
Brake lining makers
Brake refabricators
Chemical workers
Clay workers
Construction workers
Demolition workers
Electric appliance workers
Electrical equipment workers
Electrical wire makers
Food processing workers
Gasket makers
Glass workers
Iron ore (taconite) miners and millers
Insulation workers
Loggers
Machinery makers
Maintenance and custodial workers
Nursery (agricultural) workers
Oil and gas extraction workers
Paint makers
Petroleum refinery workers
Primary metal industry workers
Plumbers and pipefitters
Railroad repair workers
Roofers
Rubber makers
Reinforced plastics makers
Shipyard workers
Stone workers
Talc miners and workers
Textile workers
Transportation equipment makers and repairers
Transportation workers
Vermiculite miners and workers

Table 46.1 Occupations with potential asbestos exposure

Environmental measurement

The techniques for environmental measurement of asbestos can be divided into two general categories. *Qualitative analysis* determines whether or not asbestos is present in a bulk material and estimates the relative amount and mineral type of asbestos present. Qualitative analysis can be done using polarized light microscopy, X-ray diffraction, or transmission electron microscopy. The results from qualitative analysis are usually given as percent asbestos on a projected area or a weight/weight basis. *Quantitative analysis* counts the number of fibers or structures present in a measured volume of air. Two principal techniques are generally used for quantitative analysis. Light microscopy with phase contrast enhancement is commonly used for the routine quantitative fiber measurements needed for comparison to occupational exposure limits. Transmission electron microscopy may be needed when thin fibers ($<0.25\ \mu\text{m}$) are present. Fibers smaller than $0.25\ \mu\text{m}$ are invisible using light microscopy techniques. When performing quantitative fiber analysis, the associated analytic capabilities of these microscopes limit the level of qualitative information (fiber-type identification) that can be gathered on individual fibers. Results from quantitative analysis are usually given as fibers per cubic centimeter or structures per cubic centimeter.^{6,7}

Clinical effects

Specific asbestos-related diseases are discussed in detail in Chapters 19.8 and 30.2.

Acute effects

Aside from a non-specific mild respiratory and skin irritant effect, no clinically observable acute effects of asbestos exposure have been documented. Asbestos warts or corns have been described within weeks or months of initial skin exposure to asbestos fibers. These are small nodular lesions, sometimes on an inflammatory base, resulting from a granulomatous reaction to the presence of a foreign body.

Chronic effects

Non-malignant diseases such as pulmonary fibrosis, pleural fibrosis, benign pleural effusion, and chronic bronchitis, as well as a variety of malignancies, including cancers of the respiratory tract, malignant mesothelioma of the pleura or peritoneum, and gastrointestinal cancers, can result from occupational or environmental asbestos exposure. All are chronic conditions of insidious onset occurring after latencies of one or more decades. Each of the non-malignant or malignant effects of asbestos exposure may occur independently of the others. With the exceptions noted below, none is pathognomonic for asbestos dust exposure. Clinical manifestations are non-specific.

Pulmonary fibrosis may be recognized as a result of mandated surveillance of current asbestos workers or through diagnostic evaluation of symptoms of persistent cough and exertional dyspnea of insidious onset. The chest

X-ray demonstrates small irregular opacities at the lung bases. Alternatively, fibrosis may be noted on pathologic examination of lung tissue removed during evaluation of a suspicious or malignant lung lesion, even when the preoperative chest X-ray shows no interstitial changes.⁸

Pleural fibrosis, in the form of discrete plaques or diffuse thickening of the pleura, can occur independently of pulmonary fibrosis. One or more discrete pleural plaques may be recognized along the diaphragm or along the lateral chest walls. Bilateral plaques and plaques with visible calcification seen in individuals with a credible history of asbestos exposure and sufficient latency are presumed to have resulted from the asbestos exposure, although unilateral plaques may result from asbestos exposure, and non-calcified plaques occur more commonly than calcified ones. Pleural plaques undetected by conventional radiographs are often visualized using computed tomography (CT). Diffuse pleural fibrosis often involving blunting or obliteration of the costo-phrenic angle on chest X-ray is also seen as a result of asbestos exposure. This may be associated with significant pulmonary function abnormality, although mild pulmonary dysfunction can also be associated with the presence of pleural plaques.⁹

Benign pleural effusions, lasting weeks to months before spontaneous resolution, occur in asbestos-exposed workers, often within the first two decades following first exposure. These are sterile and without malignant cells. Associated symptoms may be minimal. There are suggestive data associating the eventual development of extensive diffuse pleural fibrosis with antecedent pleural effusions. Chronic bronchitis, persistent cough with phlegm, in general occurs more often in people working in dust than in those who do not, when compared to others with similar smoking habits. This observation has been confirmed in some cohorts of asbestos workers.

Restrictive physiology with a reduced carbon monoxide diffusion capacity, characteristic of diffuse interstitial fibrosis, is typically seen in patients with asbestosis. Inflammation and fibrosis of the respiratory bronchioles can also occur as a manifestation of asbestos exposure, even in the absence of asbestosis visible on chest X-ray. Mild pure airflow obstruction from asbestos exposure (demonstrable as an increased loss of FEV₁ in the absence of other adverse exposures such as cigarette smoke) has been found in some asbestos-exposed workers. Some have observed FEV₁ deficits in asbestos workers with pleural fibrosis. Others have documented progressive loss of FEV₁ in asbestos-exposed workers as they develop symptoms.¹⁰ Higher degrees of lung function loss are associated with increasing pulmonary function deficits.¹¹

Respiratory tract cancers are the most common cancers associated with occupational asbestos exposure. These are pathologically indistinguishable from other respiratory tract cancers. Cancers of the lung and larynx are seen more frequently in workers occupationally exposed to asbestos than in others with comparable smoking habits. Latency averages about 25 years from first asbestos exposure. Combined exposure to asbestos and cigarette smoke puts workers at extremely high risk for

development of respiratory tract cancers. There is evidence that smoking cessation results in diminished lung cancer risk over time in individuals who have had prior asbestos exposure. Some have asserted that asbestos only causes lung cancer in workers who have already developed pulmonary fibrosis, although evidence for this is limited and increased risk of lung cancer with or without visible fibrosis is well documented in a number of occupational groups.¹² Since both the development of fibrosis and the development of lung cancer are dose-related phenomena, unambiguous resolution of this controversy is challenging.

Malignant mesothelioma of the pleura, peritoneum, or mediastinum in the presence of a credible history of asbestos exposure, occurring after a reasonable latency, are considered 'sentinel health events' presumptively resulting from exposure to the mineral fibers, most often asbestos. Mesothelial cells are thought to be transformed through direct interaction with asbestos fibers. Malignant mesothelioma has been reported with minimal exposure to asbestos; cohorts with high levels of exposure experience high rates of this cancer. Latency between first exposure and mesothelioma development is, on average, longer than that for bronchogenic cancer, averaging 30–35 years. The tumors grow rapidly and are virtually universally fatal, with no effective curative surgical or chemotherapeutic interventions found to date.

Cancers of the gastrointestinal tract, including cancer of the esophagus, stomach, pancreas, colon, and rectum, occur more frequently in most occupational cohorts heavily exposed to asbestos, although the risk is substantially less than for lung cancer.

Other cancers, including certain lymphomas and kidney cancer, have been observed more frequently in some, but not all, asbestos-exposed cohorts. Complex interrelationships between multiple adverse occupational exposures, including asbestos, may in part account for the diversity of malignancies associated with exposure.

Clinical evaluation and management

Clinical management of patients with a history of asbestos exposure requires a combination of medical screening, health counseling, appropriate and timely medical interventions, and emotional support based upon a realistic appraisal of the risks resulting from the exposure. If exposure is continuing, exposure control is critical, and health surveillance consistent with that mandated by the Occupational Safety and Health Administration (OSHA) is warranted. Given current restrictions on asbestos use, exposure has often ceased by the time healthcare is sought. Nevertheless, the biologic persistence of the fibers and the long latency between exposure and disease justify special attention to former asbestos-exposed workers. Also, individuals with asbestos-related diseases may be involved in litigation that may place certain responsibilities on the healthcare provider.

Medical screening involves the performance of tests directed toward the identification of significant diseases or conditions before the diseases become clinically apparent.

Effective treatments or interventions should be available which can improve the outcome of the disease. Screening for disease in an individual is a secondary prevention strategy, distinguishable from public health or workforce surveillance efforts that also involve medical testing. Also, tests done exclusively for screening purposes differ in intent from those performed for diagnostic purposes or to provide information useful in health counseling.¹³

Theoretically, any of the diseases for which asbestos-exposed individuals are at risk would be potential targets for screening in the course of routine medical care. However, most fail to justify the conduct of screening tests. For example, screening for malignant mesothelioma will not result in improved outcome until effective interventions are available. Respiratory tract cancer screening among high-risk groups, using periodic chest X-ray and sputum cytology, has failed to reduce significantly the number of cancer deaths in those screened compared to others receiving routine care. Newer approaches to lung cancer screening using low-dose spiral CT scanning are under evaluation and have demonstrated promising results in selected circumstances.¹⁴

No effective intervention has been identified to modify the course of pulmonary or pleural fibrosis resulting from asbestos exposures which are no longer continuing. However, the identification of one or more of these conditions combined with appropriate health counseling may help motivate patients to control or eliminate exposure to other pulmonary toxins, particularly tobacco smoke.

When exposure is continuing, however, the presence of abnormalities on chest X-ray justifies recommendations to increase the level of respiratory protection or eliminate the exposure altogether, since the development of fibrosis appears to be dose related and continuing exposure might cause more rapid deterioration. Thus, periodic chest X-rays are indicated for active asbestos workers. Also, when there is ongoing exposure, the ability to use respiratory protective equipment should be monitored closely by periodic examinations including pulmonary function testing.

Gastrointestinal cancer screening, using tests for occult blood in the stool and periodic sigmoidoscopy or colonoscopy, has been recommended by the US Preventive Services Task Force, the American Cancer Society, and others, as being effective in the general population. Given the increased risk of gastrointestinal cancer in asbestos-exposed individuals, this practice should be encouraged. No studies have yet shown benefit from either earlier initiation or more frequent performance of these screening procedures because of increased risk in this group.

Health counseling for patients currently or formerly exposed to asbestos must be directed toward control or elimination of exposure to all current pulmonary hazards, particularly asbestos dust and tobacco smoke. The importance of smoking cessation in asbestos-exposed patients, whether or not they have manifested any of the stigmata of asbestos-related diseases, cannot be overemphasized. The combination of asbestos exposure and tobacco smoke is far worse than either alone. During the decade following smoking cessation, lung cancer risk gradually drops but

remains significantly elevated as a result of the asbestos exposure. No healthcare encounter with a current or former asbestos worker should omit inquiry into tobacco use and reinforcement of a smoking cessation message to all current tobacco users.

To date, evidence that dietary modification may diminish cancer risk is unconvincing; however, research into this important question continues. Studies of former asbestos workers with X-ray abnormalities have failed to provide evidence justifying recommendations of specific dietary supplements or other dietary modifications for these patients. Given the risk status of exposed individuals and the limited number of interventions available, prudent advice based on the best available current recommendations from the National Cancer Institute should be offered.

Medical interventions depend upon the diseases manifested by the patient and do not differ appreciably from those that should be offered others with comparable diseases with other etiologies. For example, asbestos-associated malignancies have not been shown to respond any better or worse to conventional surgical techniques or chemotherapy than cancers of unknown or other etiologies. The course of pulmonary fibrosis caused by asbestos exposure is generally slowly progressive to indolent and has not been shown to be affected by any particular intervention. Some have tried decortication procedures to relieve restriction caused by the rare cases of massive diffuse pleural thickening. Such treatments must depend upon the particular circumstances of the individual patient.

Medical therapies should be directed toward early identification and treatment of infection and relief of any element of bronchoconstriction. Evidence of hypoxemia should be sought and treated in severely impaired patients. Desaturation with exercise or during sleep should stimulate consideration of intermittent or continuous oxygen therapy.

Comprehensive educational and support programs directed toward patients with chronic respiratory impairment and their families have been of benefit to some. These programs often direct attention toward significant changes resulting from the disease, such as the need for environmental controls, the onset of sexual dysfunction, or the discouragement resulting from involvement in protracted and incomprehensible litigation. Voluntary organizations such as the American Lung Association may offer referral to pulmonary rehabilitation programs and patient support groups.

Litigation seeking redress for injury from asbestos and finances to purchase necessary healthcare is common in the US among people with asbestos-associated diseases. Physicians caring for these patients must be prepared to provide timely reports when requested by the patient or the patient's representative. Standard diagnostic criteria may be useful in preparation of such reports.¹⁵ The fact that the patient is involved in litigation should not affect diagnostic or therapeutic decisions. Legal issues are considered in detail in Chapter 56.

Prevention

Control or elimination of exposure to asbestos-containing materials is the only absolutely effective strategy for prevention of asbestos-related diseases. Although substitute materials are being used in many current settings, the asbestos already in place will result in ongoing exposure to maintenance, mechanical, and construction workers for decades to come. Disease prevention in these workers will depend in great measure on recognition of the potential for exposure and strict compliance with health and safety regulations. Comprehensive regulations promulgated under the Occupational Safety and Health Act, intended to prevent asbestos-associated diseases, focus not only on exposure control but also on issues of training and surveillance.

Exposure limits

In the US, occupational exposure is limited to 0.1 fiber/cm³ as a time-weighted average (TWA) over an 8-hour workday for general industry. There is a 1.0 fiber/cm³ excursion limit averaged over a 30-minute sampling period. If exposure exceeds either the TWA or the excursion limit during the year, periodic exposure sampling, training, and surveillance are required.¹⁶

Monitoring

Initial personal sampling is required for all workers who may reasonably be expected to be exposed at or above the TWA and/or excursion exposure limits. Additional monitoring is required with a frequency such that the exposure of the worker is adequately described.

Regulated areas

Respiratory protection is required in areas where exposures exceed the TWA and/or excursion exposure limits. Hazard communications requirements, including the posting of warning signs and other restrictions on access, apply in any area with asbestos-containing materials or potentially asbestos-containing materials.

Control

Engineering and work practice controls are the preferred methods for maintaining exposure levels below the TWA and/or excursion exposure limits.

Respiratory protection

A strict program of respiratory protection using NIOSH-certified respirators, periodic fit testing, and training is mandated. The use of 'disposable' filtering facepiece respirators is not permitted. The employer must provide a tight-fitting positive-pressure respirator that provides adequate protection, instead of any negative-pressure respirator, if the employee chooses to use this type of respirator.

Training

All workers exposed above the TWA and/or excursion exposure limits must be trained initially and at least yearly thereafter. Items to include are:

- the health hazards of asbestos exposure;
- the relationship between asbestos and smoking in producing lung cancer;
- operations which could result in exposure;
- the importance of control procedures;
- proper use and limitations of respirators; and
- details of the medical surveillance program.

Medical surveillance

In the US employers must provide a medical surveillance program for all workers exposed above the TWA and/or excursion exposure limits, at no cost to the workers. A baseline pre-placement examination must include a medical and work history; a complete physical examination with emphasis on the respiratory, cardiovascular, and digestive tract systems; a standardized respiratory questionnaire; a full-sized PA chest radiograph; spirometry including FEV₁ and FVC; and any other tests deemed appropriate by the examining physician.

After the baseline examination, periodic examinations including an abbreviated questionnaire, periodic chest X-ray, and spirometry are mandated. The questionnaire is administered at baseline, then in an abbreviated form annually. Spirometry and a physical examination are performed at baseline, then annually. A chest radiograph must be offered:

- every 5 years for workers under 35 years and/or with less than 10 years since first asbestos exposure;
- every 2 years for workers aged 36–45 with over 10 years since first asbestos exposure; and
- every year for workers over age 45 with over 10 years since first exposure.

Medical examinations and testing are performed or conducted under the supervision of a licensed physician and at a 'reasonable time and place'. Chest X-ray interpretation is done according to the International Labour Office (ILO) classification system by a reader trained, tested, and certified by NIOSH (B reader), a board eligible or certified radiologist, or 'an experienced physician with known expertise in pneumoconioses'. The examining physician is responsible for making a determination as to whether the worker has any medical condition that would put him or her at increased risk of 'material health impairment'. There is mandatory worker and employer notification of the examining physician's opinion resulting from the overall assessment of the test results. Records of the interpretation of the examination along with supporting information must be kept by the employer for 30 years, whether or not the test results are abnormal.

There are no data reported which permit evaluation of the effectiveness of the current regulations for prevention of all asbestos-associated diseases. NIOSH has recommended that exposure to asbestos fibers be limited to 0.1 fibers/cm³ time-weighted averaged over a 100-minute sampling time, based on the technical limits of fiber monitoring rather than on absolute health protection.

Although compliance with current exposure standards should substantially diminish the burden of asbestos-associated disease in the future, there are still many settings

where significant asbestos exposure occurs before controls are put in place or where strict adherence to health protection programs is absent. When the possibility of asbestos exposure is determined after eliciting an occupational history, the healthcare provider should also inquire about the existence of a health protection program in the workplace.

SILICA
Exposure settings

Silicon is the second most common element in the earth's crust. The combination of silicon and oxygen, SiO₂, called silica, is found in amorphous or crystalline forms. Respirable crystalline silica causes silicosis. Heating can change amorphous silica into crystalline forms. The chief form of crystalline silica is α-quartz (hereafter simply 'quartz'). Quartz is a mineral found in most classes of rock, which is the principal source of exposure in many occupations (Table 46.2). Silica sand contains large amounts of quartz. Silica sand is used to produce glass, pottery, silica brick, mortar, and abrasives. Crystalline silica, as sand or aggregate, is added to cement to form concrete. Finely ground silica, also known as silica flour, is used in paints, porcelain, scouring soaps, and as wood filler. The clear rock crystal is of great value for electronic equipment. The colored varieties of crystalline silica are used as gems or ornamental materials.

Tridymite and cristobalite are chemically identical to quartz but differ in crystalline structure. These two minerals are used extensively as filtering and insulating media and as siliceous refractory materials for furnace linings and silica bricks. Flints contain crystalline silica and have been used for centuries because of their hardness and heat resistance.^{17,18}

Abrasive blasting
Abrasives
Boiler scaling

Ceramics
Coal mining and milling
Fillers (paint, rubber, etc.)
Foundry work (ferrous and non-ferrous)
Glass manufacture
Insulation production and installation
Metal mining and milling
Micaceous earth excavation
Mining, quarrying and tunneling
Non-metallic mining and milling
Plastic manufacturing
Pottery making
Refractory materials
Road working
Rubber manufacturing
Scouring soap manufacturing
Tile and clay production
Tunneling
Vitreous enameling

Table 46.2 Selected occupations and industries involving exposure to free crystalline silica

Description	Workers exposed
Masonry, plastering	13,800
Heavy construction	6300
Painting, paper hanging	3000
Iron and steel foundries	800
Metal services	400

Table 46.3 Estimation of workers exposed to at least 10 times the NIOSH REL for crystalline silica

In the US, occupational exposure to crystalline silica occurs in several large categories of industry. Using data from the National Occupational Exposure Survey (NOES) conducted from 1982 to 1983, and applying 1986 Bureau of the Census County Business Patterns, NIOSH estimated that 1.7 million workers are potentially exposed to one or more substances containing silica. Compliance data collected by OSHA inspectors indicate that within the exposed population, there are significant numbers of workers with continuing overexposures to crystalline silica. Table 46.3 lists the number of workers estimated to be exposed to at least 10 times the NIOSH recommended exposure limit (REL), which is approximately five times higher than the prevailing legal limit in the US, i.e., the permissible exposure limit or PEL.¹⁹

Occupational exposures to crystalline silica also occur throughout the mining industry. Over 300,000 coal, metal, and non-metal miners in stone or ground quarries are exposed to silica. Users of mined or quarried materials in activities such as road building, general construction, and railroad maintenance may be exposed to significant levels of quartz dust.

Environmental measurement

Silica often occurs in combination with other minerals whose composition may include silicon, aluminum, and varying amounts of magnesium, iron, calcium, and other elements. The term 'free silica' is sometimes used to describe SiO₂ that is not combined with other elements. Environmental measurement of silica involves two phases:

- collection of the sample using an appropriate sampling technique; and
- chemical analysis of the collected material.

Two types of samples are routinely collected: bulk dust and respirable dust. *Bulk samples* are collected to determine the average crystalline silica content of the dust in an environment. Once the average silica content is determined, an overall exposure limit for respirable dust can be computed in order to limit silica exposure. *Respirable dust samples* collect air-borne dust on a filter using a particle-size classifier such that the particle collection efficiency mimics the performance of the human respiratory system. It is possible to quantify individuals' exposure to low levels of silica using personal respirable dust samples.

Chemical analysis of both bulk dust and respirable dust samples may be done using X-ray diffraction (XRD) or infrared analysis (IR). A chemical technique involving acid digestion can also be used for bulk samples. The acid digestion technique was the basis for early (pre-1970) silica

analyses. Using phosphoric acid, the amorphous silica and silicate minerals from the bulk dust are digested, leaving the crystalline silica residue for quantification. The percent crystalline silica determined from the bulk analysis can be multiplied by air-borne respirable dust concentration to estimate worker exposure to air-borne crystalline silica. Using respirable dust personal samples, worker dust exposures are measured directly with subsequent crystalline silica analysis by IR or XRD on each individual respirable dust sample.²⁰

Clinical effects

The health effects of silica exposure are discussed more fully in Chapters 19.1 and 30.2.

Acute effects

No acute effects of silica exposure have been documented.

Chronic effects

Silicosis is the pneumoconiosis resulting from fibrotic reactions to lung deposition of inhaled crystalline quartz dust. Disease latency and time course depend on the intensity and duration of dust inhalation. Particle size distribution and surface characteristics, as well as the crystalline structure of the quartz particle, may affect toxicity. A characteristic pathologic entity, the silica nodule, results from pulmonary response to inhaled and retained silica. These nodules may coalesce with resulting tissue destruction and disruption of the normal thoracic architecture. This is known as progressive massive fibrosis. Silicosis that occurs within a few years of the initiation of exposure is sometimes referred to as accelerated silicosis. Disease with a more indolent time course, often not identified for one or more decades from first exposure, is sometimes referred to as chronic silicosis. Accelerated and chronic silicosis most likely result from the same disease mechanisms, differing only in time course. A distinct condition, referred to as acute silicosis, may result from a different mechanism. It is a rapidly progressive disease which develops after inhalation of high concentrations of fine silica particles. Acute silicosis has pathologic characteristics similar to alveolar proteinosis.²¹

All forms of silicosis can progress in the absence of ongoing silica dust exposure, and people with occupational silica exposure may not manifest chest X-ray abnormalities until well after retirement. Although silicosis is irreversible, the likelihood of progressive impairment from accelerated or chronic silicosis is presumably diminished through early identification of disease and cessation of exposure. Once acute silicosis is present, interventions have not been shown to favorably influence disease outcome. Experimental therapies or interventions which are not widely available, such as bronchoalveolar lavage and lung transplantation, have been attempted for workers with acute silicosis and for some with total pulmonary incapacity due to progressive massive fibrosis.

Silicosis was listed as an underlying or contributing cause of death on 187 death certificates in the US in 1999.

Surveillance data suggest that death certificate records significantly underestimate the extent of the problem.

The risk of tuberculosis is greater in workers with silicosis than in the general population. Tuberculosis is probably more common in silica-exposed workers even without diagnosed silicosis. Tuberculosis can cause significant morbidity and mortality, particularly if unrecognized and untreated. While effective treatments are available, treatment failures and relapses are reported to occur more commonly in people with silicosis.

Emphysema, bronchitis, and airways obstruction appear to occur more commonly in silica-exposed workers than in the general population. The risk is most likely dose dependent. In general, these conditions cause significant morbidity and can cause premature mortality. Early intervention with control or cessation of adverse pulmonary exposures (including dust and tobacco smoke) may result in reversal of bronchitis symptoms and presumably diminish the rate of progression of airways obstruction.

Lung cancer as a result of silica exposure is the subject of ongoing scientific investigation. After intensive review, the International Agency for Research on Cancer (IARC) has stated that there is sufficient evidence to conclude that inhaled crystalline silica from occupational sources is a human carcinogen,¹⁸ and NIOSH has recommended control of exposure based on the importance of reducing silicosis risk and the conclusion that crystalline silica should be considered a potential occupational carcinogen.¹⁷ Some investigators suggest that silicosis rather than silica exposure is the key risk factor. In any event, as with lung cancer from asbestos exposure, there is no indication that silica dust-associated lung cancers differ from other lung cancers. No effective methods of early identification leading to successful intervention have been identified. Because both silica exposure and lung cancer are so common, even a small increase in relative risk of disease resulting from the exposure could result in a significant number of excess cases.

Clinical evaluation and management

A silica-exposed worker with chest symptoms should be evaluated in the normal fashion with a comprehensive history, focused physical examination, and a logical sequence of medical testing. Medical history should concentrate on adverse pulmonary exposures, including occupational exposure to dusts and fumes and tobacco use. A history of significant chest trauma, pulmonary infections, and cardiovascular disease is relevant. The extent to which current pulmonary problems interfere with normal levels of functioning should be documented. In general, a diagnosis of silicosis is made on the basis of an abnormal chest radiograph along with a credible history of silica exposure.

General clinical management issues for treatment of silicosis are no different than for other chronic pulmonary diseases. Elimination of adverse exposures, patient and family support and education, and interventions directed at optimization of the level of function and minimizing

time lost to infection are appropriate. Because of the increased risk of mycobacterial infection in patients with silicosis, tuberculin skin testing and evaluation of risks and potential benefits of treatment should be pursued (see also Chapter 19.9).

Silicosis can progress in the absence of additional exposures, presumably through an iterative process of macrophage ingestion of retained silica particles followed by cell death (liberating inflammatory and fibrogenic mediators), and reingestion. In order to interrupt this process, some have suggested that bronchoalveolar lavage could diminish the body burden of silica. At this time, such therapies should be considered experimental and be performed only in the context of a clinical trial. Lung transplantation has also been attempted for far-advanced disease.

Prevention

Primary prevention

Although the effects of exposure to free silica have been known for many years, silicosis continues to prevail among workers in the dusty trades. The critical strategy for prevention of silicosis is prevention of exposure. The OSHA PEL for general industry is based on the measurement of respirable dust (including silica and non-silica components) and comparing that measurement to the following formula:

$$\text{PEL} = 10 \text{ mg/m}^3 / (\% \text{ quartz} + 2)$$

The effect of the formula is to limit respirable dust containing 100% quartz below 0.1 mg/m^3 , and to limit respirable dust below 5.0 mg/m^3 for quartz-free dusts. The OSHA limit for the two other forms of crystalline silica, cristobalite and tridymite, is half the limit allowed for quartz.²² Both NIOSH and the American Conference of Governmental Industrial Hygienists (ACGIH) recommend exposure limits of 0.05 mg/m^3 for all crystalline forms of silica.^{23,24} Complicating the situation, OSHA uses a different and older standard for the construction industry, nominally requiring a count of the number of particles collected. Today, few laboratories are equipped or trained to do the microscopic particle counting that is required, consequently respirable mass measurements are sometimes used in conjunction with mass-to-count conversion factors to compare measurements to the exposure limits. The exposure limit for all forms of crystalline silica in the construction industry is determined from the following formula:

$$\text{PEL} = 250 \text{ mppcf} / (\% \text{ quartz} + 5)$$

where mppcf stands for million particles per cubic foot of air sampled.

The Mine Safety and Health Administration (MSHA) uses a crystalline silica standard equivalent to the OSHA standard for metal and non-metal mines. For underground coal mines, the respirable dust standard is 2.0 mg/m^3

for coal mine dust with less than 5% crystalline silica. When coal mine dust exceeds 5% quartz, the respirable dust standard (RDS) is calculated using the formula:

$$\text{RDS} = 10 \text{ mg/m}^3 / (\% \text{ quartz})$$

Silica dust is generated when silica-bearing soil, rock, or ore is drilled, blasted, cut, dug, or otherwise disturbed. There is no obvious way to determine if the material being processed contains silica other than to perform chemical analyses described earlier in this chapter. As a result, many exposures to crystalline silica go undetected simply because the exposure is not sampled and analyzed for silica. In mine settings, veins of silica may intertwine with veins of desirable ore. Crushed rock and gravel may have varying degrees of silica based on the specific location where the material originated. The best approach for protecting workers health is to sample and analyze the materials being mined or processed frequently.

Once the potential for exposure to silica is established, effective preventative measures are almost always available. These measures include substitution of materials and engineering controls. OSHA and MSHA have established legal standards for compliance, setting exposure limits at approximately $100 \text{ }\mu\text{g/m}^3$ described by the PEL and RDS formulae above; and a REL has been established by NIOSH at $50 \text{ }\mu\text{g/m}^3$. Any measure to control exposure should use these limits to determine the need for engineering controls and their adequacy. The selection of a specific control strategy that maintains exposures below these limits will be determined by the economic and technical feasibility of that particular strategy in each situation.

In abrasive blasting, where risk is high because of the generation of fine particles of 'freshly fractured' silica, it is often possible to replace the silica being used with a less toxic substitute. When using silica, even when the abrasive blaster operator is protected with an air-supplied respirator, blaster helpers and other process workers in the area may be exposed. There are alternative materials available that can be used as an abrasive agent in lieu of silica sand. Although those materials may also be hazardous, and the material liberated during blasting is often toxic, appropriate substitution combined with personal protective equipment can reduce the health risks for the blaster and other nearby workers.

The most common engineering control available in most settings is ventilation. In non-mining industries, ventilation is usually subdivided as blowing and exhausting ventilation and dilution ventilation. Particularly harmful dusts are often removed from the exhaust stream using bag-house filters to prevent general environmental contamination. Industrial applications where these controls have been successfully applied include, among others, foundries, ceramic industries, crushing, grinding, and screening.

In mining environments, the dust control problems are different. Drilling and grinding operations present high exposure potential at surface mines. Since these operations are typically open to the environment, ventilation is not a

practical solution. There are two alternative strategies that can be applied: enclosure and dust suppression. The operator's cab in equipment used at surface mines can be enclosed and designed to deliver air-conditioned filtered air to the operator; however, other workers who are not machine operators may continue to be exposed. It may be possible to enclose the point of dust generation. Water injection, water spraying, and the use of wetting agents are means of dust suppression which have been used at both surface and underground mines.

At underground mines, dust control can be achieved through forced ventilation systems. Underground operations may also use high-pressure water sprays, water injection drilling, and other wetting methods to suppress the generation of dust at its source.

Finally, there are a number of ways to do most jobs. Redesigning task performance, utilizing engineering equipment to reduce dust exposure, or altering work practices can be effective. Educational efforts, labeling of quartz-containing materials, and posting of hazardous work sites can assist workers in recognizing the dangers of exposure to dust and the benefits to be gained by altering work practices to reduce exposure to the minimum achievable level.

Secondary prevention

Workplace-based medical screening of silica-exposed workers is generally recommended, using periodic questionnaires, chest X-rays, and lung function tests. The effectiveness of screening efforts has not yet been published. Chest radiographs may detect silicosis in some workers at a point when the disease is asymptomatic, but X-rays may be insensitive to other silica effects. In most exposure settings, a PA chest radiograph repeated every 3 years for asymptomatic workers should be sufficient. More frequent examinations should be conducted if an abnormality is demonstrated and exposure continues. Spirometry is another tool for screening and surveillance. Spirometry is inexpensive, acceptable, and readily available. Lung function testing should be performed using equipment and methods meeting American Thoracic Society-recommended standards (see Chapter 19.1). Spirometry can demonstrate restrictive or obstructive abnormalities, either of which may result from silica dust exposure. Once patients test below population-based 'normal' values, disease is generally well established. Using the patient's own baseline spirometry values for comparison may provide an earlier indication of the development of a problem. In this case, a drop of 15 percentage points from the baseline 'percent predicted' value for either FEV₁ or FVC (e.g., from 105% of predicted FEV₁ to 90% of predicted) should suggest the need for additional evaluation.

A number of state health departments require reporting of cases of silicosis as 'sentinel events'. Investigations of reported cases can identify new cases and lead to prevention of disease in workers not yet affected. Case identification and reporting are no substitute for primary disease prevention through exposure control; they are, however, critical components of an overall program of prevention requiring the cooperation of primary healthcare professionals.

Although silicosis is often thought to be a disease of primarily historical interest, current exposure conditions continue to produce significant disease and even death from silicosis. Exposure is so widespread that workers, employers, and healthcare providers must maintain a high index of suspicion that any work in a dusty trade may result in the development of this serious pulmonary disease.

COAL

Exposure settings

Coal is organic material that has been fossilized after millions of years of pressure and temperature extremes. Coal is used as a basic fuel for numerous industries requiring a source of heat; some coal is also used for residential heating. A relatively small amount of coal is used for production of gaseous and liquid fuels.

The primary occupations that are exposed to coal dust are those associated with the actual mining and processing of coal. Other workers may have significant exposures through coal handling operations. The method of mining has an effect on the dust concentration level in which a miner may work. Usually, coal miners who are employed at the working face (the area of the mine where the actual extraction of coal occurs) of underground mines have the highest coal mine dust exposures. In 2000, there were approximately 76,000 workers in the coal mining industry in the US.

Environmental measurement

Coal dust health standards

In the US, respirable dust levels in both underground and above-ground coal mines have been regulated since 1969. The current US exposure limit for respirable coal mine dust is 2.0 mg/m³.²⁵ A lower limit is applicable if more than 5% of the dust is quartz. Exposures to coal mine dust in general industry occur primarily in the steam generation of electricity.

The basic sampling unit used in the US for measuring respirable dust consists of a battery-powered personal sampling pump which draws dust-laden air through a particle pre-separator (generally a cyclone) and onto a pre-weighed filter at a controlled flow rate for an 8-hour shift. The large particles are removed by the pre-separator, and the smaller respirable dust is collected on the filter. Because the exposure limit is for 'respirable coal mine dust', no special chemical analysis is needed; the filters are weighed and the measured mass collected is divided by the volume of air sampled, to calculate the worker's daily exposure.

Coal dust particle size distributions and regional effects

The current coal mine dust standard was intended to prevent deposition of fine particles in the non-ciliated alveolar air spaces. A study of particle size distributions in

underground coal mines found that a substantial fraction of mine dust consists of larger particles capable of deposition in the upper airways. Chronic bronchitis is also prevalent in coal miners and may be related in part to the deposition of larger particles in the ciliated, conducting airways. Dust control techniques designed to obtain compliance with the respirable dust standard do not necessarily reduce the thoracic dust exposures.

Clinical effects

The health effects of coal mining are discussed further in Chapter 19.10.

Acute effects

A few studies have identified a relatively acute drop in FEV₁ among some, but not all, miners during the first months to years following first exposure to coal mine dust. The clinical and prognostic significance of this drop is unclear and is the subject of ongoing investigations.

Chronic effects

Coal workers' pneumoconiosis (CWP) is one of the lung diseases arising from inhalation and deposition of coal dust in the lungs and the reaction of the lungs to the dust. CWP is a chronic, irreversible disease of insidious onset, usually requiring 10 or more years of dust exposure before becoming apparent on routine chest radiographs. It is characterized by macular and nodular pigmented lesions in the lungs, which may be visible radiographically as small or large opacities. When only small opacities are present, the condition is called simple CWP or chronic CWP. Progressive massive fibrosis (PMF) or complicated CWP are terms used when radiographic shadows greater than 1 cm, attributable to coal dust exposure, are present. CWP, particularly in advanced stages or when PMF is present, has been associated with pulmonary incapacity and increased morbidity and mortality. The occurrence of CWP is dependent on the intensity and duration of coal mine dust exposure. CWP, in some instances, progresses after cessation of exposure, although this seems to be less common and the progression less aggressive than that resulting from retained silica dust.

CWP was listed as an underlying or contributing cause of death on over 1417 death certificates in the US in 1996. As exposure conditions have improved, the average age at death among men with CWP has increased and approximates the average age at death of all men in the US. Since chest X-ray abnormalities may be visible in the absence of clinical disease in some individuals, there may be a 'preclinical' stage during which CWP can be identified. Although reduction or elimination of exposure to coal mine dust in workers with chest X-rays showing category 1 abnormalities, by ILO criteria, would presumably result in decreased progression of disease and in fewer cases of PMF, statistical modeling based on large data sets in the UK and the US suggests that this benefit may not prove very great.

Dust control strategies in the US, initiated in the early 1970s, were directed at preventing miners from developing

ILO category 2 CWP. Miners with category 1 CWP were offered work in jobs with a maximum dust exposure of 1 mg/m³. It was anticipated that this would result in the virtual elimination of PMF. This strategy has not been completely successful, in part because PMF can appear on a background of category 1 CWP or, rarely, category 0.

Chronic bronchitis, emphysema, and airways obstruction (accelerated loss of FEV₁) are more common in workers exposed to coal mine dust than in others with comparable tobacco use habits. All of these conditions appear to be dose related. Chronic bronchitis symptoms may be reversible if adverse exposures are controlled early. Presumably, the rate of loss of FEV₁ could be diminished through reduction or elimination of dust exposure, although the rate of loss that should trigger intervention and the optimal timing for intervention remain the subject of investigation. Chronic bronchitis, emphysema, airways obstruction, and CWP all result from exposure to coal mine dust and may occur in various combinations. The chest X-ray is not a reliable predictor of the likelihood of airways obstruction associated with dust exposure.²⁶ In general, diminished FEV₁ is associated with morbidity and premature mortality. Dust exposure unlikely to result in the development of CWP or PMF may still cause or contribute to clinically significant airways obstruction.²⁷

Coal mine dust may contain varying proportions of crystalline quartz. CWP may be indistinguishable from silicosis on chest X-ray.

Excess risk of stomach cancer has been reported with coal mine dust exposure, although the level of increased risk is not great and the population prevalence of this condition is generally low (see Chapter 30.5).

Clinical evaluation and management

Miners with lung disease generally present for evaluation either of progressive dyspnea or an acute chest illness. Because a federal benefits program compensates miners with severe impairment, some miners present for consultation or evaluation of their qualification for these benefits. In other instances, the possibility of disease from coal mine dust exposure is an incidental finding in a routine health evaluation.

A clinical evaluation should include a comprehensive medical and occupational history, with a focus on the pulmonary and cardiovascular systems. Since miners with lung disease often become involved in benefits applications and significant weight is given to the assessment of the primary care physician, the history should be carefully taken and well documented. The onset and evolving course of symptoms such as dyspnea, cough, and sputum production should be described. Any changes in normal life activities should be explored in detail. For example, many miners describe the need to abandon hobbies such as hunting, or may report the modification of sexual activity as a result of increasing pulmonary impairment. Work decisions, such as a job transfer from a strenuous or dusty job to one that is less demanding physically, are significant. Since disease development is frequently insidious,

it is often helpful to ask about the abilities of the patient in comparison with non-exposed contemporaries. Careful inquiry should also be made into adverse pulmonary exposures on and off the job, including tobacco use.

A comprehensive physical examination is appropriate, although findings are not specific. It is, however, often helpful to determine if other conditions associated with work exposures are present, such as noise-induced hearing loss or musculoskeletal disorders, which should be evaluated and treated.

Testing may include chest radiography, which should be interpreted by someone skilled in recognition of the pneumoconioses, preferably a certified B-reader. Spirometry should be performed using methods and equipment meeting American Thoracic Society recommendations. Other measures of lung function may be helpful in certain clinical settings but do not need to be performed routinely.

Care for miners with chronic lung disease should attempt to maximize their level of functioning and minimize life disruption. Ongoing dust exposure should be controlled to the extent possible, with transfer to a low-dust job recommended for working miners. Where other adverse exposures such as tobacco smoke can be identified, they should be eliminated. Bronchodilators provide symptomatic relief for some. Infections should be treated early and monitored carefully. Immunization against influenza and pneumococcal disease should be encouraged. Tuberculosis does not complicate CWP as it does silicosis.

In coal mining areas, the US Department of Labor has assisted in the development of clinic- or hospital-based respiratory disease treatment programs for miners and their families. Patient and family education can reinforce the therapeutic interventions of the primary care provider and provide emotional support.

Prevention

Primary prevention

The primary means of preventing dust-related illnesses is to limit the exposure of all workers through the use of engineering controls.²⁸ These include dilution ventilation and dust suppression. The MSHA prescribes minimum ventilation requirements for face operations, primarily to control the emission of methane from freshly fractured coal. The fresh air also reduces the dust concentration through mixing with the dust-laden air exhausting out of the return air tunnels. Dust suppression usually involves a system of water sprays near the cutting head of continuous mining machines or longwall shears. Dust exposures can also be reduced on an individual basis through the use of approved particulate air-purifying respirators. Respirator usage is usually voluntary and is not considered by MSHA to be an acceptable means for the operator to reduce exposures to respirable dust. However, many miners choose to wear respirators, particularly during the dust-producing mining operations. There is some evidence that use of respirators is associated with preservation of lung function.

Exposure limits in the US for coal mine dust are enforced by MSHA. Mine operators must take periodic dust samples during normal working conditions and send them to MSHA for weighing and analysis. The integrity of this program has been brought into question after MSHA's allegations of widespread tampering with dust sampling. The mandatory operator sampling program is supplemented by periodic inspections by MSHA personnel. Recent information suggests that the current dust exposure limit might not be fully protective, and NIOSH has recommended a lowering of the dust limit along with changes in the program of inspection and enforcement.²⁹

Secondary prevention

Medical surveillance, directed toward the early identification of CWP through periodic radiographic examinations, is available for all underground coal miners in the US through the Coal Workers' X-ray Surveillance Program administered by NIOSH. Miners with CWP may exercise a right to work in a reduced dust environment of 1 mg/m³ and have their exposures sampled more frequently. There is currently no screening or surveillance program directed toward the prevention of airways obstruction, which can cause significant morbidity among miners. Primary healthcare providers should consider performing periodic spirometry using techniques and equipment meeting the American Thoracic Society recommendations as a guide to care and education of patients exposed to coal mine dust. A drop of 15 percentage points or more from baseline 'percent predicted' values of FEV₁ should suggest the need for more intensive investigation and additional preventive interventions.

In the years following adoption of the current coal mine dust exposure regulations, an average of over 2000 former miners have continued to die each year in the US with CWP as an underlying or contributing cause of death. Thousands of others suffer from significant airways disease caused, at least in part, by their coal mine dust exposure. There must be continued attention to early disease identification and preventive intervention in order to supplement dust control efforts and prevent the continuing progression of these diseases.

MAN-MADE MINERAL FIBERS

Exposure settings

Man-made mineral fibers (MMMF), also called synthetic or man-made vitreous fibers, include a variety of manufactured materials with excellent insulating properties. Not true minerals, they are amorphous silicates manufactured into a fibrous form. MMMF are grouped according to their origin into glass fiber (from glass), ceramic fiber (from kaolin clay), and mineral wool (from rock or slag). Increasingly used as asbestos substitutes, they have thousands of applications in industrial and non-industrial settings. They are used for thermal and acoustic insulation and plastic reinforcement in everything from buildings, ships, and automobiles, to home appliances, industrial kilns, and furnaces.

Managers and administrators
 Civil engineers
 Mechanical engineers
 Chemists (except biochemists)
 Electrical and electronic technicians
 Chemical and science technicians
 Production coordinators
 Warehouse clerks (receiving, recording, and issuing)
 Janitors and cleaners
 Supervisors (mechanics and repairers)
 Engine mechanics (aircraft, bus, truck, and stationary)
 Heavy equipment mechanics
 Industrial machinery repairers
 Mechanics (heating, air conditioning, and refrigeration)
 Brick masons and stonemasons
 Tile setters
 Carpenters
 Drywall installers
 Painters (construction and maintenance)
 Plasterers
 Plumbers (pipe fitters and steam fitters)
 Insulation workers
 Roofers
 Sheet metal duct installers
 Structural metal workers
 Boilermakers
 Sheet metal workers
 Plant and system operators
 Machine operators (grinding, abrading, buffing/polishing)
 Machine operators (metal, plastic, stone, and glass working)
 Packing and filling machine operators
 Slicing and cutting machine operators
 Crushing and grinding operators
 Oven operators (furnace and kiln)
 Assemblers
 Production manager (inspectors, checkers, and examiners)
 Production testers, samplers, weighers, and helpers
 Truck drivers (heavy and light)
 Crane and tower operators
 Industrial truck and tractor equipment operators
 Material moving equipment operators
 Construction laborers
 Stock handlers and baggers
 Vehicle washers and equipment cleaners
 Hand packers and packagers

Table 46.4 Workers potentially exposed to man-made fibers

Exposure to MMMF occurs during production, fabrication, and application of materials. Over 500,000 US workers are potentially exposed to MMMF (Table 46.4), and that number is likely to increase.

Environmental measurement

The sampling protocol for MMMF is virtually identical to that for asbestos. The sample is collected on a filter for microscopic examination. The current literature indicates that in addition to biopersistence and durability, health effects relate to the length and diameter of the fibers; therefore, some size selectivity must be employed in either the sampling or analysis. The technique for asbestos sampling, as described earlier in this chapter, is the most common measurement technique.

Clinical effects

The health effects of MMMF are discussed in greater detail in Chapters 19.11 and 30.2.

Acute effects

Acute respiratory and skin irritation occur frequently among workers newly exposed to mineral fibers. Irritation has been reported most often in glass wool workers, but it can result from contact with other fibers. Although usually self-limited, these problems may cause workers to leave employment.

Chronic effects

Some studies have shown excess lung cancer risk in glass fiber and mineral wool production workers. Synthetic fibers vary widely in their physicochemical characteristics, and carcinogenic potential most likely relates to the biopersistence and solubility of inhaled fibers, with the most persistent and durable fibers – those most like asbestos – posing the greatest risk. IARC has recently reviewed the relevant scientific literature and concluded that the more biopersistent materials such as refractory ceramic fibers and some special-purpose glass wools are possible human carcinogens (IARC Group 2B). IARC has reclassified the more commonly used vitreous fiber glass wool and slag wool as not classifiable as to their carcinogenicity (IARC Group 3).³⁰ The US National Toxicology Program classifies ceramic fibers of respirable size as reasonably anticipated to be a human carcinogen.³¹

Epidemiologic investigations have suggested that exposure to mineral fibers may be associated with the development of low profusions of chest X-ray opacities consistent with a diagnosis of pneumoconiosis in some workers. In addition, refractory ceramic fiber production workers have been found to develop pleural plaques and pleural thickening which increases with increased latency.³² These asbestos-like effects suggest the possibility that other asbestos-like health effects, particularly lung cancer, could result from refractory ceramic fibers. Mineral fiber exposure may also increase the risk of chronic bronchitis.

Clinical evaluation and management

When workers newly exposed to MMMF complain of intense pruritus with a minimum of visible dermatologic changes, the etiology is readily apparent. At times, fibers can be seen microscopically after cellophane tape is pressed against exposed skin. Workers presenting with skin irritation from mineral fiber exposure should be encouraged to minimize exposure through use of appropriate protective equipment and should be reassured that the acutely troublesome symptoms are generally self-limited. Anti-pruritic medications may be of benefit to some.

The approach to evaluation for chronic conditions associated with mineral fiber exposure is similar to the assessment of these conditions where there is no occupational exposure. A careful medical history, including a history of occupational and environmental exposures, forms the basis for care. Chest imaging to exclude other acute or reversible disease processes is indicated. Spirometry and possibly other measures of pulmonary function provide diagnostic and prognostic information.

There are no specific interventions uniquely beneficial for individuals with cancers that may be associated with mineral fiber exposure. Chronic bronchitis and airways obstruction should be approached in the usual fashion. Management should include reduction or elimination of adverse pulmonary exposures, including workplace dusts and tobacco smoke. Symptomatic treatment, reversal of reversible or intermittent airways obstruction, and infection control are also important. In the case of moderate-to-severe disease, referral to patient and family support and education programs may be helpful.

Disease prevention

Primary prevention

Given the classification of MMMF as potential human carcinogens by IARC, mineral fiber exposure should be limited to the extent feasible by technology. This can be done by several standard techniques. Where possible, substitutes should be used in place of the MMMF. This is often difficult since these products were, in many cases, replacements for asbestos. Lacking alternative materials, engineering controls to contain the source of exposure become the next best approach. When the process cannot be fully controlled, the worker must be isolated from the process generating the dust. Finally, the worker may be isolated by use of respiratory protection equipment. For uncontrolled exposures to RCF, as with asbestos, the appropriate type of respirator could be an air purifying or self-contained breathing apparatus (SCBA) with a full facepiece, operated in a pressure demand or other positive pressure mode. Respirators should be used with a complete respiratory protection plan. Administrative controls can also be used to reduce exposures by limiting the amount of time a worker spends in a contaminated environment. Administrative controls need to be coupled with personal samplers on the workers to closely monitor exposures and assure the maximum level of exposure is not surpassed.

Secondary prevention

There is no consensus approach to screening or surveillance of MMMF-exposed workers. However, in light of concern about asbestos-like effects, it would be prudent to closely monitor these workers for pulmonary health effects. The level of health risk from MMMF exposure most likely varies depending on the intensity and duration of exposure as well as with the specific physical and chemical characteristics of the fiber. Until the specific risks are better defined, a generic approach to surveillance of 'fiber-exposed' workers is reasonable. Baseline and periodic respiratory symptom questionnaires, spirometry, and chest radiographs should be offered. Since the diseases of concern have long latency, the frequency of observation should increase in each decade following first exposure. Careful collection and retention of exposure data should make future screening more productive as new knowledge from ongoing systematic observation of occupational cohorts becomes available.

Chapter 47

Toxic Gases

Akshay Sood

GENERAL CONSIDERATIONS

Specific toxic gases are discussed here. The clinical effects and management of acute-inhalation injury are discussed further in Chapter 19.5, and the effects of outdoor air pollutants in Chapter 51.

The circumstances of exposure to toxic gases and knowledge of their properties are useful in estimating the dose of exposure and anticipating the severity of injury.¹ Gases with potent odors or sensory irritant properties (e.g., hydrogen sulfide or sulfur dioxide) will motivate the exposed individual to flee the area, thus limiting the duration of exposure; whereas exposure to gases without these properties (e.g., carbon monoxide or phosgene) may be more prolonged and, thus, more deadly.

Any gas may act as an asphyxiant by physically displacing oxygen from the inhaled ambient air and subsequently lowering the alveolar oxygen tension. Some gases, such as carbon monoxide, cyanide, and hydrogen sulfide, may act as chemical asphyxiants by interfering with the oxygen transport system. Irritant gases, on the other hand, may directly injure the respiratory system, which may compromise the gas-exchanging function of the lung.

The dose of an inorganic gas delivered to the respiratory system is determined by several factors outlined in Table 47.1. The most important physicochemical determinant of the dose delivered is the solubility of the gas in water.² Because the respiratory system is lined with mucus in a watery solution, a more soluble gas (for example sulfur dioxide, ammonia and acid mists) will be predominantly taken up by the mucous lining of the nose and upper airway; and the smaller airways and alveoli are relatively spared. This is more likely to result in upper airway irritation and asthma-like symptomatology. However, under conditions of high concentrations of exposure, even highly soluble gases will penetrate the alveoli to cause acute alveolar lung injury. On the other hand, less soluble gases (for example, oxides of nitrogen, ozone, phosgene) are more likely to penetrate to these more distal airways even in conditions of exposure at relatively lower concentrations, and are thus more likely to produce a clinical picture of bronchiolitis or acute alveolar injury (see Chapter 19.5). Chlorine and hydrogen sulfide have intermediate solubility and can produce a full spectrum of pulmonary irritant effects involving both upper and lower airways. The solubility of a gas in the liquid lining of the respiratory system is described by Henry's law, and quantified by the Henry's law coefficient of the gas. US Standards for selected irritant and asphyxiant gases are listed in Table 47.2.

CARBON MONOXIDE

Carbon monoxide is a colorless, odorless, and non-irritant gas and is believed to be one of the most frequent causes of acute fatal poisoning in the United States, with an estimated 40,000 emergency department visits annually.³ Normal non-smoking adults will have approximately 0.5% saturation with carboxyhemoglobin in the absence of any environmental exposure, and American adults commonly have about 1% carboxyhemoglobinemia with typical environmental exposures.

Exposure setting

Carbon monoxide is a product of the incomplete combustion of hydrocarbons. Tobacco smoke is the most important source. The concentration of carbon monoxide in mainstream cigarette smoke, though variable, averages approximately 400 ppm (0.04%), or eight times the current Occupational Safety and Health Administration (OSHA) permissible exposure limit (PEL). Among regular cigarette smokers, carboxyhemoglobin levels usually range from 3% to 8%, with levels up to and higher than 15% occurring in some very heavy smokers.

After cigarette smoke, the most common source of exposure to carbon monoxide is faulty or inadequately ventilated combustion sources. Automobile engine exhaust is the most important source of such exposure for American non-smokers and also accounts for the majority of deaths from carbon monoxide poisoning in the United States. Lethal concentrations of carboxyhemoglobin can be achieved within 10 minutes in the confines of a closed garage. Carbon monoxide toxicity can also occur in semi-enclosed spaces, working or living quarters adjacent to garages, and structural fires.

Improperly functioning or poorly ventilated home combustion appliances (such as gas clothes dryers with kinked exhaust hoses, heating furnaces, stoves, and ovens with continuously burning pilot lights) may produce carbon monoxide air concentrations exceeding 100 ppm, which may lead to levels of carboxyhemoglobin in the blood of 10% after 8 hours of exposure. An often overlooked source of carbon monoxide is methylene chloride, a common component of solvents like paint removers and furniture strippers. Once absorbed, methylene chloride is metabolized in the liver to carbon monoxide.

Environmental measurement

Colorimetric devices are available that can estimate individual exposure over a prolonged period. Instantaneous point

Physical and chemical characteristics of the gas
 Inhaled concentration of gas
 Duration of exposure
 Minute ventilation (tidal volume \times respiratory rate)
 Physical and chemical characteristics of the gas

Table 47.1 Factors affecting the dose of an inorganic gas delivered to the respiratory system

air measurements may also be made with real-time instruments. When investigating homes for sources of carbon monoxide, indoor measurements of carbon dioxide as an indicator of unventilated combustion products are commonly used.

Biologic monitoring

Coburn and Forster developed a dose-response relationship model, between the partial pressure of carbon monoxide inhaled and the percent of carboxyhemoglobin saturation in blood. At normal body temperature and pH, carbon monoxide has approximately 220 times the affinity for hemoglobin as oxygen. Thus, when the partial pressure of carbon monoxide is 1/220th that of oxygen (or 0.1% carbon monoxide in air or approximately 1000 ppm),

blood at equilibrium will be 50% saturated by carbon monoxide and 50% saturated with oxygen. At low concentrations under conditions of rest, the percent of carboxyhemoglobin rises gradually over a period of hours to a plateau or steady state.^{4,5} For concentrations of inhaled carbon monoxide greater than 100 ppm, the percent of carboxyhemoglobin can be related to the inhaled carbon monoxide concentration, the duration of exposure, and minute ventilation by the following equation:

$$\%COHb = [CO]_{air} \times KT$$

where COHb is carboxyhemoglobin, [CO] is the air concentration of carbon monoxide in parts per million, K is a constant that varies with minute ventilation, and T is the time in hours.

In a patient who presents with carbon monoxide poisoning of unknown concentration and duration who has been removed from exposure for a known period of time, it is possible to estimate the exposure concentration or earlier peak carboxyhemoglobin levels using the known carboxyhemoglobin levels and the duration since exposure. The time for the half reduction of blood carboxyhemoglobin levels is 320 minutes while breathing room air.

Substance	Type of standard	Level
Carbon monoxide	OSHA Permissible exposure limit: 8 hr TWA	50 ppm
	NIOSH Recommended exposure limit: 10 hr TWA	35 ppm
	NIOSH Recommended exposure limit: Ceiling Value	200 ppm
	NIOSH Immediately dangerous to life and health level	1200 ppm
Sulfur dioxide	OSHA Permissible exposure limit: 8 hr TWA	5 ppm
	NIOSH Recommended exposure limit: 10 hr TWA	2 ppm
	NIOSH 15 min. Short term exposure limit	5 ppm
	NIOSH Immediately dangerous to life and health level	100 ppm
Chlorine	OSHA Permissible exposure limit: ceiling value	1 ppm
	NIOSH Recommended exposure limit: 15 min ceiling value	0.5 ppm
	NIOSH Immediately dangerous to life and health level	10 ppm
Nitrogen dioxide	OSHA Permissible exposure limit: ceiling value	5 ppm
	NIOSH 15 min. Short term exposure limit	1 ppm
	NIOSH Immediately dangerous to life and health level	20 ppm
Cyanide	OSHA Permissible exposure limit: 8 hr TWA	10 ppm
	NIOSH 15 min. Short term exposure limit	4.7 ppm
	NIOSH Immediately dangerous to life and health level	50 ppm
Hydrogen sulfide	OSHA Permissible exposure limit: ceiling concentration	20 ppm
	OSHA Permissible exposure limit: acceptable maximum peak above ceiling concentration for an 8 hr shift*	50 ppm
	NIOSH Recommended Exposure limit: 10 min ceiling value	10 ppm
	NIOSH Immediately dangerous to life and health level	100 ppm
Ozone	OSHA Permissible exposure limit: 8 hr TWA	0.1 ppm
	NIOSH Recommended exposure limit: ceiling value	0.1 ppm
	NIOSH Immediately dangerous to life and health level	5 ppm
Phosgene	OSHA Permissible exposure limit: 8 hr TWA	0.1 ppm
	NIOSH Recommended exposure limit: 10 hr TWA	0.1 ppm
	NIOSH Recommended exposure limit: 15 min ceiling value	0.2 ppm
Ammonia	OSHA Permissible exposure limit: 8 hr TWA	50 ppm
	NIOSH Recommended exposure limit: 10 hr TWA	25 ppm
	NIOSH 15 min. Short term exposure limit:	35 ppm
	NIOSH Immediately dangerous to life and health level	300 ppm

*Acceptable maximum peak above ceiling concentration for an 8-hour shift, maximum duration 10 minutes, once, only if no other measured exposure occurs
 OSHA: Occupational Safety and Health Administration
 NIOSH: National Institute for Occupational Safety and Health. These standards are recommended, not legally mandated.
 TWA: Time weighted average
 ppm: parts per million

Table 47.2 United States occupational safety standards for selected irritant gases

Figure 47.1: Increase in the percent of carboxyhemoglobin in the blood of resting subjects exposed by inhalation in relation to the concentration of carbon monoxide in the air and hours of exposure. Increasing the level of physical activity will increase the percent change in carboxyhemoglobin levels for a given air concentration and duration. (Adapted from Forbes W, Sargent F, Roughton F. The rate of carbon monoxide uptake by normal men. *Am J Physiol* 1945; 143:594–608.⁵)

Therefore, for example, a patient brought to the emergency room with a carboxyhemoglobin level of 20%, 2 hours after rescue from a building in which the patient was found unconscious, may have had a peak carboxyhemoglobin level of about 25% (assuming that the interval elapsed is 0.375 half times of dissociation and that the current carboxyhemoglobin level is about 81% of the level 2 hours ago). A patient with a 50% carboxyhemoglobin level immediately on cessation of exposure has come into equilibrium with an inhaled carbon monoxide concentration of 0.1% in air or may have been exposed to an even higher concentration for a short duration, insufficient to reach steady-state equilibrium. The relationship among air concentration of carbon monoxide, hours of exposure, and the increase in the percent of carboxyhemoglobin is shown in Figure 47.1.

Pathophysiology

The major effect of carbon monoxide is to reduce the oxygen-carrying capacity of hemoglobin in the blood; hemoglobin bound to carbon monoxide is unavailable for binding with oxygen. In addition, carbon monoxide alters the relationship between arterial oxygen tension and hemoglobin saturation, making hemoglobin more avid for oxygen (a left shift of the oxygen–hemoglobin saturation curve) and making less oxygen available for release from hemoglobin in the vascular periphery (Fig. 47.2). The result is that the amount of available oxygen for tissues with a 60% carboxyhemoglobin level is substantially less than with a 60% loss of hemoglobin in cases of severe anemia. Other heme-containing enzyme systems like cytochrome a_3 may also be poisoned by carbon monoxide. These alterations result in cellular hypoxia.

Figure 47.2: Oxygen–hemoglobin dissociation curve. The presence of carboxyhemoglobin shifts the curve to the left and changes it to a more hyperbolic shape. This results in a decrease in the oxygen-carrying capacity and impaired release of oxygen at the tissue level. (From: Ernst A, Zibrak JZ. Carbon monoxide poisoning. *N Engl J Med* 1998; 339: 1603–8. © 1998 Massachusetts Medical Society. All rights reserved.⁹)

Recent investigations suggest other mechanisms of carbon monoxide-mediated toxicity. These include reoxygenation injury to the central nervous system by oxygen radicals⁶ and lipid peroxidation resulting in demyelination of lipids in the central nervous system.⁷ These mechanisms are believed to be responsible for the delayed neuropsychiatric sequelae described with carbon monoxide. The toxic effects of carbon monoxide are manifest earlier in those with diseases or circumstances associated with limited or impaired oxygen delivery such as hemoglobin abnormalities (including anemia), high altitude, heavy cigarette smoking, critical degree of vascular stenosis, and heart and lung disease. Carbon monoxide exposure has an especially deleterious effect on the fetus in pregnant women.⁸

Acute clinical effects

The clinical symptoms of carbon monoxide poisoning are non-specific and often mistaken for a viral illness. These symptoms include headache, weakness, nausea, and dizziness.^{4,9} Subtle alterations in visual perception and other central nervous system functions can be detected at carboxyhemoglobin levels above 5%. As the percent of carboxyhemoglobin in the blood rises, aortic and carotid oxygen chemoreceptors, which respond primarily to PaO₂ and not to oxygen saturation, will not increase the rate of firing, and hypoxia-driven hyperventilation and the accompanying symptom of dyspnea may not occur. Above 5% carboxyhemoglobinemia, a compensatory vasodilation to supply more blood to hypoxic tissues may occur with a resultant increase in cardiac output. If the ability to increase cardiac output in relation to vasodilation is exceeded, syncope may occur. Hyperventilation will finally occur when lactic acidosis develops. When the tissue hypoxia becomes more severe, seizures, coma, cardiac arrhythmias, myocardial infarction, or sudden death may supervene.¹⁰

The classic findings of cherry-red lips, cyanosis and retinal hemorrhages occur rarely.¹¹ Erythematous lesions with bullae over bony prominences have been described but are non-specific for carbon monoxide poisoning.⁹ Necrosis of sweat glands is a characteristic histologic feature.

It is important to recognize that carboxyhemoglobin levels often do not correspond well to severity of symptoms, and the duration of exposure is an important factor mediating toxicity.⁹ Further, the oxygen tension in plasma (measured as the PaO₂ on blood gas measurements) may be unaffected in carbon monoxide toxicity. Pulse oximetry cannot distinguish between oxyhemoglobin and carboxyhemoglobin at the commonly employed wavelengths and may therefore give a falsely normal reading of oxygen saturation. The percent of carboxyhemoglobin can be measured by co-oximetry (available on most blood gas machines used in hospitals).

Delayed effects

Of patients surviving acute carbon monoxide poisoning, 10–30% may have delayed neuropsychiatric sequelae that appear only after an interval (2–40 days) after an apparent

complete recovery from the initial intoxication.¹² These include symptoms of mental deterioration, mood disorders, unusual behavior, irrational speech content, gait and other movement disturbances, parkinsonian deficits, and other focal neurologic signs. Abnormalities were seen on computed tomographic brain scans in about 50% in one series, commonly involving the globus pallidus. With prolonged follow-up, many but not all of the patients had complete resolution of these delayed sequelae.¹²

Chronic effects

Relatively little is known about chronic adaptation to low levels of carbon monoxide, other than that some heavy cigarette smokers have a secondary erythrocytosis, at least in part as a result of chronically elevated carboxyhemoglobin levels. In carefully controlled chamber-exposure studies, patients with ischemic heart disease experienced a decrease in time to the onset of angina during exercise following carbon monoxide exposure. However, the available evidence fails to support a causal relationship between exposure to carbon monoxide and atherosclerosis.¹³ Current evidence on an arrhythmogenic effect is inconclusive.

Clinical evaluation strategy

A high index of clinical suspicion is essential for making the diagnosis of carbon monoxide toxicity. Measurement of blood carboxyhemoglobin levels is mandatory but alone may be insufficient to rule out the diagnosis. Since serum levels of carboxyhemoglobin may have already fallen by the time the patient reaches the emergency room, measurements of carbon monoxide levels in the exhaled air of patients, or measurement of carbon monoxide levels in the ambient air, or measurement of carboxyhemoglobin levels in the blood drawn at the scene of the event by the fire department or the paramedics may be helpful in confirming the diagnosis. Application of the half-time of dissociation of carbon monoxide can be used to extrapolate back to the carboxyhemoglobin levels that may have been present before the patient's arrival at the hospital.

Attention to clinical indicators, particularly a detailed neurologic examination and neuropsychologic testing, is important. Patients with current known overexposure, as indicated by carboxyhemoglobin levels of 25% or more, or a consistent clinical picture should be observed closely for rapidly evolving or delayed sequelae.

Management

The carbon monoxide-intoxicated patient should be first removed from the source of exposure. In addition to close monitoring and general supportive measures, increasing the arterial oxygen tension by administering 100% oxygen will improve tissue oxygenation, while increasing the rate of excretion of hemoglobin-bound carbon monoxide. The time for the half reduction of blood carboxyhemoglobin levels is 320 minutes breathing room air at 1 atmosphere, 80 minutes for 100% oxygen at 1 atmosphere, and 23 minutes using hyperbaric oxygen at 3 atmospheres. Increase in mechanical ventilation can also increase the

Coma
 Any period of unconsciousness
 Any abnormal score on the Carbon Monoxide Neuropsychologic Screening Battery
 Carboxyhemoglobin level > 40%
 Pregnancy and carboxyhemoglobin level > 15% or evidence of fetal distress
 Signs of cardiac ischemia and arrhythmia
 History of ischemic heart disease and carboxyhemoglobin level \geq 20%
 Recurrent symptoms for up to 3 weeks after the original treatment
 Symptoms that do not resolve with normobaric oxygen after 4–6 hours

Data from Meyers RAM, Thom SR. Carbon monoxide and cyanide poisoning. In: Kindwall EP, ed. Hyperbaric medicine practice. Flagstaff, Arizona: Best Publishing, 1994, 357.¹⁶

Table 47.3 Suggested indications for hyperbaric oxygen therapy in patients with carbon monoxide poisoning.

excretion rate of carbon monoxide. Isocapnic hyperpnea in mechanically ventilated patients by providing very high minute ventilation while adding carbon dioxide to the respiratory circuit has been described to accelerate the elimination of carbon monoxide.¹⁴

The delivery of 100% oxygen at pressures greater than atmospheric in a high-pressure chamber (hyperbaric oxygen therapy) hastens the resolution of symptoms. However, it is unclear whether hyperbaric oxygen therapy influences the late sequelae and mortality.¹⁵ The commonly suggested indications for hyperbaric oxygen therapy are summarized in Table 47.3.¹⁶ Other than coma, there is disagreement about the absolute indications for instituting this therapy. Hyperbaric oxygen may carry the potential risk for central nervous system oxygen toxicity. In most cases, the therapy is unavailable within the critical first few hours after recognition of carbon monoxide poisoning.

Prevention

Most cases can be prevented by routine attention to proper function and ventilation of combustion sources. Heating oil or gas companies will often perform safety inspections and environmental measurements when a faulty furnace is suspected. Catalytic converters reduce the carbon monoxide content of car exhaust fumes. In evaluating indoor sources of combustion, measurements of carbon monoxide itself (or sometimes carbon dioxide as an index of unvented combustion products) are made during operation of the combustion source with maximal draft applied to the indoor area of interest. Electronic carbon monoxide alarms, designed like residential smoke detectors, are being increasingly used in residential and commercial buildings.

SULFUR DIOXIDE

Exposure settings

Sulfur dioxide gas is generated by the combustion of fossil fuels, as occurs in coal- and oil-fired power plants and in industrial processes such as petroleum refining, and smelt-

ing of metal ores. It is also used as a bleaching agent in the textile, paper pulp, wool and fresh produce industries and as a fumigant for grain. Exposure at lower concentration occurs as an ambient outdoor air pollutant (see Chapter 51).

Environmental measurement

Commercially available sampling devices can continuously measure the ambient sulfur dioxide concentrations with a rapid response time to change in concentration. These devices provide early warning of rising levels of sulfur dioxide. They are therefore very useful in environmental air-monitoring stations and can also be adapted to industrial settings. Current occupational safety standards in the US are listed in Table 47.2.

Acute clinical effects

Being both soluble and a potent mucous membrane irritant, sulfur dioxide predominantly causes immediate symptoms of eye, nasal and upper airway irritation. Those acutely exposed to this irritant gas seek immediate escape. Those chronically exposed may develop sensory tolerance to its irritant properties and may be less aware of its presence.

Studies have shown impaired small airways mucosal clearance after exposure to aerosolized sulfuric acid. Asthmatic patients are more sensitive to the bronchoconstricting action of sulfur dioxide. Cases of single, acute, high-level exposures followed by development of reactive airways dysfunction (RADS) have been reported (see Chapter 19.2). Severe inhalation cases are often complicated by acute lung injury and secondary bacterial pneumonia.

Chronic clinical effects.

After adjustment for levels of particulate matter less than 10 microns in aerodynamic diameter (PM_{10}) and ozone, there is little evidence that ambient environmental sulfur dioxide levels have a significant effect on mortality.^{17–20} SO_2 levels may be associated with the frequency of respiratory symptoms,²¹ though the association is stronger with particulate exposure.²²

Clinical evaluation strategy

In the acutely exposed and symptomatic worker, management should be directed to detect and treat acute bronchospasm. Acute parenchymal lung injury is infrequent and occurs with heavy exposure. Lung examination, spirometry and pulse oximetry may be more useful than chest X-ray studies in detecting the airway abnormalities. Patients who appear stable after acute exposure should undergo follow-up evaluations of symptoms and pulmonary function testing.

Management

Treatment of inhalation injury due to sulfur dioxide is supportive. Early institution of bronchodilators with or without steroids is recommended, further discussed in Chapter 19.5.

Prevention

The education of those at risk in appropriate evacuation measures when a leak of sulfur dioxide is detected by odor may reduce subsequent higher-dose exposures. Continuous air monitoring in high-risk areas is available, using commercially available devices. Containment vessels of the gas should be properly stored, in well-ventilated areas, away from workers.

CHLORINE

Exposure settings

Molecular chlorine is a yellowish green gas used widely in many industrial processes such as making paper. Many occupational groups have a potential for exposure to chlorine in manufacture, transport, and utilization processes. The generation of chlorine gas by the inadvertent mixing of bleach (sodium hypochlorite) and phosphoric acid containing cleaning powders used for janitorial cleaning tasks has become a frequent cause of domestic and industrial exposure to chlorine.²³ Common settings for chlorine exposure include transportation or industrial accidents or spills, and accidents at swimming pools and sewage treatment facilities. Chlorine and phosgene gases were also used during World War I as chemical weapons.

Environmental measurement

Determination of exposure to airborne chlorine is made using a glass bubbler containing sulfamic acid, followed by analysis using an ion-specific electrode. Another method for determining exposure to airborne chlorine involves analysis using ion-chromatography. The current occupational safety standards in the US are listed in Table 47.2.

Acute clinical effects

Chlorine has strong odor, and sensory irritant properties. Slight irritation can be noted at 1–3 ppm, and easily noticeable irritation becomes evident with even brief exposure to 3–6 ppm. Chlorine inhalation may manifest any of the full spectrum of pulmonary irritant effects, from minor mucosal responses of the eyes, nose, throat, upper airway, nausea and vomiting to acute chemical tracheobronchitis, bronchospasm and non-cardiogenic pulmonary edema (see Chapter 19.5).^{24,25}

Chronic clinical effects

Some survivors of short-term, uncontrolled, high-level chlorine exposures may develop RADS. Studies on residual effects of acute chlorine exposure on pulp mill workers also demonstrate a greater prevalence of respiratory symptoms and airflow obstruction.²⁶ However, data on the effect of chronic low-level chlorine exposures are inconclusive.^{25,27,28}

Clinical evaluation strategy

Recently exposed patients should be observed for progressive airway and lung injury. Initial indicators of the sever-

ity of response include spirometry, arterial blood gas levels, and chest roentgenographic studies.

Management

Treatment is primarily supportive and can include use of antitussive agents, aerosolized bronchodilators, oxygen, maintenance of a patent airway, and (if necessary) intubation with positive pressure ventilation. The role of inhaled sodium bicarbonate and systemic corticosteroids remains unproven.

Prevention

Where chlorine gas is manufactured, transported, or used, good industrial hygiene practices and worker education regarding handling chlorine gas should prevent most acute high-level exposures. Rapid evacuation plans and the availability of emergency self-contained breathing devices can be life saving in the event of accidental release of the gas.

NITROGEN OXIDES

During high temperature combustion, oxygen reacts with nitrogen to generate oxides of nitrogen. Nitrogen dioxide is the major oxide of nitrogen causing inhalation respiratory disease in the workplace. The toxicity of nitrogen dioxide is attributed to its oxidative capabilities.

Exposure settings

Common sources of occupational exposure are the fermentation of freshly stored hay or corn in silos (causing silo filler's disease), pickling or etching of metal with nitric acid, cutting and burning flames or welding arcs, fuel combustion (for example, from ice skating rink resurfacing machines), the exposure of miners to products of underground blasting, and firefighters' exposure to the combustion of nitrogen-containing materials (as in the tragic results of the burning of nitrocellulose x-ray films during the Cleveland Clinic fire of 1929). The principal source of lower level environmental exposures is outdoor air pollution from motor vehicle emissions, and indoor air pollution from gas cooking ranges and kerosene space heaters (see Chapter 50 and 51).

Environmental measurement

A variety of methods are available for measuring nitrogen oxides. These include continuous sampling devices accurate at concentrations below the occupational standard. Current US occupational safety standards are listed in Table 47.2.

Acute clinical effects

Because of the relatively mild odor, minimal mucous membrane irritant properties and relatively low tissue solubility, these gases lack warning properties and have potential for causing damage to the small airways and alveoli. The onset of effects is characteristically delayed 1–30 hours after the acute exposure and may include reversible bronchitis, acute, and sometimes irreversible, bronchiolitis

obliterans alone or with organizing pneumonia (BOOP), and non-cardiogenic pulmonary edema. Toxicity of oxides of nitrogen may be complicated by systemic absorption of nitrates and nitrites, producing hypotension or methemoglobinemia.

Survivors of massive acute exposures may experience the onset of chronic pulmonary disease up to 1 month following exposure, with progressive worsening of lung function, usually attributed to bronchiolitis obliterans.

Chronic clinical effects

While individual epidemiologic studies of ambient environmental exposures have shown inconsistent results,^{29,30} a meta-analysis in 1992 showed a slightly increased risk for respiratory tract infections in children with indoor nitrogen dioxide exposures.³¹ Studies involving controlled exposures of asthmatic volunteers to nitrogen dioxide have also yielded conflicting results.^{29,30} There is little evidence that ambient nitrogen dioxide levels have a significant effect on mortality.¹⁷

Evaluation strategy

Because of the possibility of severe delayed respiratory toxicity following high acute exposures, careful serial examination is essential. Close inpatient monitoring during the first 24–48 hours after exposure may be warranted. After the initial period, regular follow-up evaluation during the first month is warranted.

Management

Systemic corticosteroid therapy may be useful in modulating the sequelae of acute exposure, and should be considered early in the course after a known massive exposure and in patients with spirometric abnormalities. Supportive treatment includes supplemental oxygen and ventilatory support.

Prevention

Engineering controls, including limitations on production, use of closed systems, and local ventilation, can avert exposure under routine workplace conditions. Welders working in enclosed spaces require appropriate respiratory protection in addition to local exhaust ventilation. Before entry, filled silos should be thoroughly vented with fresh air. When effective flushing of nitrogen dioxide cannot be verified, farmers should enter silos with self-containing breathing apparatus or clean air-supplied respirators under direct observation of a companion similarly equipped.

CYANIDE (HYDROGEN CYANIDE)

Exposure setting

Prussic acid (hydrogen cyanide) and cyanide salts are used as fumigating agents for killing insects and rodents in agricultural buildings and ships, in electroplating and metal cleaning,³² and in the manufacture of nylon. Exposure may occur through inhalation of dust, combustion products of some plastics, by skin absorption (when liquid) or

ingestion. Clinically relevant cyanide toxicity may also be present in smoke-exposed firefighters and other smoke inhalation victims (see Chapter 41).³³

Environmental measurement

Cyanide compounds can be unstable in collection media, and often several forms must be assayed to develop an accurate profile of exposure. In workplace air, cyanide is commonly collected in an impinger containing sodium hydroxide. Biologic monitoring or exposure may be accomplished by measuring thiocyanate levels in the urine or blood (although care must be taken not to misinterpret low blood levels because toxicity is more closely related to levels in tissue than in blood). US current occupational safety standards for cyanide are listed in Table 47.2.

Acute clinical effects

Cyanide rapidly causes asphyxia in the mitochondria by binding to the enzyme cytochrome oxidase, preventing the utilization of oxygen in affected cells, and halting aerobic metabolism. Symptoms of toxicity may be non-specific. In cases of mild poisoning, these may include a bitter almond taste, irritation of mucous membranes, dyspnea, headache, dizziness, nausea or vomiting, and agitation. In more severe cases, hypotension, arrhythmias, cardiogenic and non-cardiogenic pulmonary edema, lactic acidosis, seizures and coma may also occur. The cardiovascular collapse is associated with a characteristic cherry-red skin color and a relatively normal heart rate. Acute cyanide exposure directly affects aortic and carotid chemoreceptors, causing hyperpnea, and respiratory arrest, resulting from the direct effects on the central nervous respiratory control system, soon follows. Death may occur within minutes. A delayed cyanide leukoencephalopathy, similar to that seen in survivors of carbon monoxide intoxication, occurs in a minority of those who recover from an acute episode of severe cyanide intoxication.

Chronic clinical effects

Cyanide salts are skin and mucous membrane irritants. Strong cyanide solution may produce skin ulcerations after direct contact with skin. Chronic cyanide exposure, particularly when dietary iodide levels are low, has also been reported to cause thyroid gland enlargement in workers. Goiter has also been associated with dietary intake of cassavas, which contain cyanide precursors. In those who have had chronic workplace exposure to cyanide at levels sufficient to produce symptoms without overt intoxication, residual symptoms of rash, bitter or almond taste, and headache have been reported as chronic sequelae up to 7 months after cessation of exposure.

Similar to acute cyanide intoxication, several neurologic deficits have been proposed following chronic cyanide exposure from cigarette smoke or from a diet rich in unprocessed cassava. These include a neuro-ophthalmologic syndrome, smoker's amblyopia, reportedly responsive to hydroxycobalamin, and a chronic demyelinating neurotoxic syndrome.

Sodium nitrite	10 ml of 3% solution (300 mg) IV over 5–20 minutes
Amyl nitrite	0.3 ml ampoule crushed every minute, via inhalation
Sodium thiosulfate	50 ml of 25% solution (12.5 g) IV over 10 min
Hydroxycobalamin	10 ml of 40% solution (4 g) IV over 20 min

*Recommended initial doses may be higher for children

Table 47.4 Recommended cyanide antidote dosage* regimens

Clinical evaluation strategy

In acute exposure, including smoke inhalation victims, little time is available for diagnostic efforts; the diagnosis should be made on clinical grounds and the antidote administered immediately,^{33,34} further described below. In suspected subacute or chronic toxicity, the measurement of elevated blood or urine thiocyanate levels (commonly available in clinical laboratories in the monitoring of nitroprusside therapy) may confirm cyanide exposure. A blood level of cyanide greater than 0.2 µg/ml may indicate a toxic exposure, although adverse effects may occur at lower blood levels.

Management

Current treatment of cyanide poisoning consists of initiating basic support measures (removal from exposure, skin decontamination, and the administration of 100% normobaric oxygen) followed by the administration of antidotes outlined in Table 47.4. The objective is to bind and convert cyanide before it has saturated tissue cytochrome oxidase. Because irreversible poisoning and death may occur within minutes of exposure, antidotes must be administered without delay, usually available as a cyanide antidote kit, containing sodium nitrite, sodium thiosulfate, and amyl nitrite. The first step is rapid administration of nitrates. If the victim is breathing, amyl nitrite may be administered by inhalation until the intravenous infusion is started and intravenous sodium nitrite is administered to generate methemoglobin from hemoglobin, which is more avid for cyanide than is cytochrome oxidase. Next, sodium thiosulfate is administered, which stimulates the conversion of cyanmethemoglobin to thiocyanate, a less toxic product that is rapidly excreted in urine. If concomitant carboxyhemoglobinemia is also present, the induction of methemoglobinemia may be harmful. In such a case, thiosulfate can be given alone or additional nitrites can be given cautiously, aiming to keep the sum of methemoglobin and carboxyhemoglobin below 40%.

Intravenous administration of a preparation of hydroxycobalamin (vitamin B_{12a}) to form a renally excreted cyanocobalamin complex is a safe and effective alternative therapy used in Europe but not available in the United States in the necessary concentration.

Prevention

A high index of suspicion is needed to detect symptomatic exposure before a fatal event occurs. Because the symp-

toms of intoxication are non-specific, the removal of workers from the exposure area and measurement of blood or urine thiocyanate levels while engineering controls are re-evaluated may be life saving. Where a risk of skin exposure occurs, protective gloves, aprons, face shields, and other gear are indicated. The availability of eye-wash and emergency shower facilities is mandatory.

HYDROGEN SULFIDE

In addition to its irritant properties, hydrogen sulfide is an asphyxiant at the cellular level, acting in much the same way as cyanide, binding to and inactivating cytochrome c oxidase.³⁵ Hydrogen sulfide has a strong smell of sulfur or rotten eggs, with an odor threshold at about 5 parts per billion, well below the irritant threshold (>10 ppm) but at high concentrations (>100 ppm) the gas can inactivate the sense of smell by a toxic effect on the olfactory nerve. In cases of acute exposures, would-be rescuers without proper protective equipment may themselves become victims.

Exposure settings

Hydrogen sulfide is formed naturally from the decay of organic sulfur-containing material and may thus be encountered as an unwanted byproduct in human and animal waste water disposal systems (and hence the name sewer gas), farm manure containment areas, in processes using animal products (such as glue factories, tanneries, and felt-making operations), or from the decomposition of fish (such as in the holds of fishing vessels). It may also be formed in mineral deposits of sulfur and encountered in mining and blasting operations, particularly in the recovery and processing of petroleum containing high sulfur content. Hydrogen sulfide is denser than air and accumulates in low-lying areas.

Environmental measurement

Hydrogen sulfide may be measured in air by monitoring instruments using several techniques. Current US occupational safety standards are outlined in Table 47.2.

Acute clinical effects

The presenting symptoms relate to the inability of metabolizing cells to utilize oxygen, with central nervous system abnormalities which may include rapid loss of consciousness (termed as 'knockdown' in oil and natural gas workers) and respiratory paralysis.^{35,36} Initial tachycardia and hyperpnea can lead to cardiovascular collapse and death. Hydrogen sulfide also has acute irritant effects ranging from mucosal irritation to pulmonary edema. The survivors of acute intoxication may have persistent central nervous system deficits.

Chronic clinical effects

Exposures to prolonged periods of low concentrations of hydrogen sulfide may cause conjunctival irritation, reduction in threshold for odor detection or complete anosmia. The latter may leave the worker less able to detect the warning properties of subsequent exposures. Chronic CNS

effects may be cumulative over several 'knockdowns' and may be associated with changes in cognitive function, affect and personality.

Clinical evaluation strategy

Awareness of the circumstances or industries of exposure may help to identify hydrogen sulfide gas exposure. A smell of rotten eggs from a patient's breath, clothing or freshly drawn blood may be helpful. Time does not usually permit a more definitive assessment of the cause of a severe toxic event. Other than air monitoring instruments, urinary thiosulfate determination is the only practical test to monitor hydrogen sulfide exposure in workers.³⁵ However, ingestion of sulfur-rich food or water can dramatically influence these results. Increased lactic acid and anion gap acidosis suggest chemical asphyxia but there is no specific test to confirm hydrogen sulfide intoxication.

Management

In addition to the administration of 100% oxygen, the use of only the first step of the cyanide antidote listed in Table 47.4 – sodium nitrite – may be helpful. The rationale is to generate methemoglobin, which can successfully compete for hydrogen sulfide by forming sulfhemoglobin, thus freeing and reactivating cytochrome oxidase. Animal studies indicate a beneficial effect, although human efficacy is not well established. A potential toxicity of this therapy is a reduction in the oxygen-carrying capacity of the blood with the formation of sulfhemoglobin.

Prevention

The great potency and potential for irreversible and fatal outcomes of hydrogen sulfide mandate rigorous control technology and air monitoring wherever this gas is known to occur as a product of industrial processes. Education concerning risks and the need for evacuation and the availability of escape equipment (self-contained breathing devices) may be life saving in circumstances in which the gas may be encountered suddenly and without warning.

OZONE

Based on concentration per volume of air, ozone is one of the more toxic gases to the respiratory system. Because it is relatively insoluble, its effect is greatest at the level of distal airways and alveoli. The cytotoxicity of ozone is largely due to generation of free radicals and peroxygenation of unsaturated lipids. The toxicity of ozone, as discussed here, refers to the effects of low altitude or tropospheric ozone. At higher altitudes (stratospheric) ozone is in fact beneficial, as it blocks the harmful effects of cosmic waves.

Exposure setting

Ozone is generated intentionally as a bactericidal gas for purification of drinking water and for hot tubs and also as an unintentional byproduct of ultraviolet light within a certain range of wavelengths. Toxic concentrations of

ozone have been described to occur in poorly ventilated areas from arc welding (particularly tungsten-inert gas shielded welding) operations³⁷ and from malfunctioning coronas of photocopy machines.

Automobiles are major environmental contributors of the compounds which produce ozone, one of the air pollutants regulated by the EPA.³⁸ Widespread environmental exposure to low concentrations of ozone occurs during air pollution episodes (see Chapter 51). Concentrations of ozone sufficient to cause symptoms and reversible respiratory effects have been described in the past within high-altitude commercial aircraft flying certain routes during certain seasons. However, in more modern aircraft, removal of ozone from cabin air by conditioning is readily accomplished.

Environmental measurement

The concentration of ozone in the air may drop off rapidly within inches from a point source. The measurement of ozone in air is most reliably accomplished with the use of real-time instruments with photochemical cells. The expense of these instruments and their requirement for recalibration make constant workplace monitoring uncommon. US occupational safety standards are listed in Table 47.2.

Acute clinical effects

Ozone has a characteristic odor reminiscent of chlorine bleach (hypochlorous acid), but olfactory adaptation occurs within minutes. There is a striking individual gradient in the threshold to respiratory system response. The more sensitive subjects in the normal population will demonstrate symptoms (cough or chest tightness on deep inspiration) and reversible obstructive pulmonary function effects with sustained aerobic exercise within minutes of exposure to ozone levels of 0.2 ppm. As the concentration rises, a greater proportion of the healthy population will experience acute symptoms. Higher acute concentrations may result in respiratory distress from airway narrowing and from acute lung injury or non-cardiogenic pulmonary edema. Systemic toxicity other than that secondary to acute lung injury has not been described.

Chronic clinical effects

Experimental exposures to ozone cause reversible decrements in lung function.³⁹ Several epidemiologic studies also suggest that ambient ozone exposure of asthmatics is associated with increased hospitalizations and emergency room visits. Whether repeated low level ozone exposures cause irreversible pulmonary changes remains unclear.¹⁹ The mortality rate from all causes and from cardiovascular and respiratory illnesses is only weakly associated with increases in ozone levels.¹⁷

Clinical evaluation strategy

The clinician must try to determine whether the exposure was sufficient to require close monitoring and support. Similar to other potent pulmonary irritants, the presence of adventitious lung sounds, abnormalities on chest

roentgenographs, arterial hypoxemia or oxygen desaturation may indicate an early or evolving acute pneumonitis requiring close monitoring.

Management

Although there is no specific therapy for ozone toxicity, the symptomatic worker may need supportive treatment, which may involve cough suppression and bronchodilator use. Acute lung injury may require supplementary oxygen and ventilatory support.

Prevention

When ozone production is anticipated, control technology is relatively straightforward. The gas is reactive with most surfaces (exceptions include glass, stainless steel, and Teflon) and can be largely converted back to molecular oxygen while piping it to the outdoors through local exhaust ventilation ducts. Real-time monitoring of the air concentration is easily achieved with commercially available instruments. Awareness of the potential for generating ozone when ultraviolet light of certain frequencies passes through oxygen can, in most instances, prevent generation of harmful concentrations of ozone in the air.

PHOSGENE

Also known by the synonyms carbonic acid dichloride, carbonyl chloride, chloroformyl chloride, and carbon oxychloride, phosgene is a colorless, oxidant gas, with low solubility, and odor of new-mown hay or rotting vegetable material. It is one of the most acutely toxic of all gases used in industry. Part of its extreme danger lies in its potency and lack of warning properties. The pathogenesis of phosgene poisoning is not clearly understood.⁴⁰

Exposure setting

It is used as a synthesizing agent for manufacture of industrial chemicals such as isocyanates, urea, coal tar, dyes, pharmaceuticals and insecticides. Clinically significant acute inhalation exposure may also occur when chlorinated hydrocarbons are heated by flame or contact with a hot metal. The best described industrial instances of this type have been the welding of metals 'degassed' with solvents (trichloroethylene and 1,1,1-trichloroethane),^{41,42} and the use of carbon tetrachloride as a fire-fighting agent in poorly ventilated areas. Phosgene was also used as a rapidly fatal gas on the battlefields of World War I (Fig. 47.3).

Environmental measurement

For continuous air monitoring of phosgene, infrared spectrophotometry, gas chromatography, and a paper-tape method have been proposed.⁴³ Exposed workers should be encouraged to wear phosgene indicator badges, which act as dose-dependent colorimeters. The current occupational safety standards in the US are listed in Table 47.2.

Acute clinical effects

Initial symptoms and signs relate to irritation of eyes and upper airway. The severity of these early irritant effects is

no guide to the severity of poisoning. Further, because of its relatively low solubility, a lethal dose may be inhaled without the victim's knowledge. This may result in direct alveolar injury, leading to acute pneumonitis and non-cardiogenic pulmonary edema, which may be fatal. Similar to nitrogen dioxide, the onset of non-cardiogenic pulmonary edema may be delayed for several hours (up to 12 or more) after the acute exposure.

Chronic clinical effects

Persisting pulmonary function abnormalities have been noted with long-term follow-up of those who survived acute phosgene lung injury. The nature of the chronic injury has not been well characterized.⁴⁴

Clinical evaluation strategy

Any patient with phosgene exposure should be admitted for observation for at least 24 hours.⁴⁰ Immediately following exposure, patients with life-threatening exposure may be clinically indistinguishable from those with relatively mild exposure. Knowledge of the potential concentrations and the circumstances of the exposure may be one guide to determining risk. The presence of eye, nasal, or tracheal irritation may indicate the potential for life-threatening sequelae. Acute pneumonitis and pulmonary edema can progress to adult respiratory distress syndrome (ARDS).

Management

The treatment is primarily supportive, including maintenance of a patent airway and support of arterial oxygenation, if necessary, by positive pressure ventilation. Close observation of the asymptomatic or mildly symptomatic patient is the key to recognizing the delayed onset of ARDS. There is no known antidote to phosgene. However, particularly when administered early after a heavy exposure, systemic corticosteroids may have some benefit.⁴⁵ Intravenous theophylline and beta-adrenergic agonists have potential utility in reducing the development of pulmonary edema, based on animal models.⁴⁶

Prevention

Use of phosgene requires the most thorough precautions against acute exposures. Industrial practices are needed to minimize the possibility of exposure, including isolation of the material, education of workers, use of phosgene indicator badges, the development of evacuation plans, and the availability of self-contained breathing devices for rapid escape.

AMMONIA

Ammonia is a soluble, colorless, irritant gas with a well-recognized pungent odor. High atmospheric concentration of this gas usually forces the exposed individual to attempt escape before significant pulmonary injury occurs. Ammonia reacts with water present in moist mucosal surfaces to form ammonium hydroxide, a potent alkali. This causes liquefactive necrosis of the mucosal surface, which in turn exposes more ammonia to the watery surface and results in further necrosis.

Exposure settings

Common exposure settings involve release of 'fumes' from a variety of household cleaning agents at home. Accidents involving the commercial use of refrigeration equipment and in the plastics, explosives and fertilizer industries are other exposure settings. Ammonia is also present in swine confinement buildings and is used as a soil fertilizer on farms.

Environmental monitoring

Ammonia levels in air can be monitored by collecting air through a glass tube containing sulfuric acid-impregnated carbon beads followed by analysis with ion chromatography. The current US occupational safety standards for ammonia are listed in Table 47.2.

Acute clinical effects

Ammonia is markedly irritating to the eyes, skin and mucous membranes of upper respiratory tracts and may cause severe edema of the larynx, resulting in upper airway obstruction. Higher exposures may result in the sloughing of the upper airway mucosa with extensive edema. Chemical bronchitis, bronchospasm, and non-cardiogenic pulmonary edema are also described. Furthermore, while the strong odor of the gas would tend to drive an individual away from the scene, blindness resulting from burn injuries to the eyes may trap the worker in the area, resulting in more severe respiratory injury. Complete recovery is usual with lesser exposures. Persistent effects following high exposures include reactive airways dysfunction syndrome (RADS), bronchopneumonia due to bacterial super-infection, bronchiectasis, airway stenosis, and bronchiolitis obliterans.

Chronic clinical effects

Chronic exposures are associated with reversible eye, nose and throat irritation.

Clinical evaluation strategy

Individuals with orofacial lesions may be at higher risk of developing acute laryngeal obstruction; however, this early complication can develop even in patients without visible injury. Patients with postexposure abnormalities clinically or on chest radiograph, pulmonary function test or increased arterial alveolar gradient on blood gas analysis should be observed in the hospital for at least 24 hours.

Management

Treatment is primarily supportive and aimed at maintenance of airway patency. Oxygen, bronchodilators, and assisted ventilation should be implemented as needed. Steroids and antibiotics are usually not effective.

Prevention

In addition to engineering controls, workers involved in handling of ammonia gas should be instructed to follow proper procedures, use personal protective equipment and have access to plenty of clean water for first aid.

Chapter 48

Pesticides and Related Compounds

Matthew C Keifer, Catharina Wesseling, Rob McConnell

Pesticides are defined broadly in the United States under the Food, Insecticide, Fungicide, and Rodenticide Act (FIFRA) as substances intended for preventing, destroying, repelling, or mitigating a pest (e.g., insect, rodent, nematode, fungus, weed) or substances intended for use as plant regulators, defoliants, or desiccants. This definition includes materials such as hypochlorites, alcohols, aldehydes, hexachlorophene, and pinene-containing substances used as disinfectants. This chapter will focus principally on chemicals more commonly understood as pesticides, such as insecticides, herbicides, fungicides, and fumigants. Pesticides include a large group of diverse chemical substances with different functions and toxicities. The single characteristic in common is that of being dispersed purposefully into the environment with the intention of adversely affecting the health or behavior of a pest species.

HISTORIC AND CURRENT USE

Pesticides have a rich, though poorly documented history, with an intimate overlap between materials used to destroy or mitigate pests and those used as agents to poison humans. Some of the history of man's early use of chemicals to battle 'pests' survives in documentation in the ancient writings of the Egyptians and Chinese. Chinese writings refer to the use of sulfur as a fumigant. Odysseus, after slaying his wife's suitors, used sulfur to purify 'hall, house and courtyard'. Achilles in the *Iliad* also used sulfur in the cleansing of a chalice before offering a libation to Zeus during the siege of Troy. Leonardo da Vinci (1500) described the injection of arsenic into apple trees, not to control insect pests but as a means of assassination.

While many potions and other mixtures were recommended in an attempt to control pests prior to the 19th century, few were carefully tested, and most proved ineffective in larger scale agricultural use. One of the first pesticides to find broad use, and the first successful arsenical compound, was Paris green (copper acetoarsenate). Originally used as a paint pigment, Paris green was discovered to be insecticidal, and in 1867 found its first wide use in the control of the Colorado potato beetle. It was later used to control many other insect pests. Paris green was supplemented by several other arsenic-containing materials, such as London purple, which was a toxic waste product of the English dye industry. While easier to apply due to its higher water solubility, and having the advantage of visibility once applied, it proved nearly as damaging to the plants it protected as the insects it controlled. The most important product in the latter half of the 19th and early

20th century was lead arsenate. This was first introduced to replace Paris green, to which the gypsy moth was resistant. Lead arsenate became one of the most important and widely used pesticides and found use in many aspects of agriculture. Relatively safer for the applicator, due to its low volatility and skin absorption, it resulted in lead poisoning among fruit consumers, and even led to protests in England against use on imported apples. Despite objections to its use, lead arsenate remained the major insecticidal tool for the control of apple pests until the mid 1940s. It should be noted that despite their virtual replacement by synthetic organic pesticides, arsenical pesticides remained a source of poisoning even as late as the 1970s, when a national study of hospitalized pesticide poisonings estimated that 23 out of 770 poisonings were due to arsenic.¹

Pyrethrum was an early effective botanic insecticide. The insecticidal qualities of chrysanthemums, from which pyrethrum derives, had been a secret closely guarded by merchants in the Caucasus, where pyrethrum flowers were grown, dried, and powdered. The secret was discovered and marketed widely in the Middle East in the early 1800s, making its way to US markets by the 1850s. An attempt to establish pyrethrum cultivation in the US by the Department of Agriculture failed in the early 1880s, and even in California, where the cultivation was successful, it did not prove economic for agricultural production.²

Historically, fungicide development paralleled that of insecticides, and at times overlapped, as many products were both insecticidal and fungicidal. Sulfur was the first effective fungicide, and it remains useful today. The use of copper sulfate to control bunt, a fungal disease, dates to 1761. The combination of copper sulfate and lime was initially used to deter pedestrians from disturbing grapes along vineyard paths. Its fungicidal value was recognized by an astute botanist, Alexis Millardet, when *Plasmopara viticola*, the fungus responsible for downy mildew, swept across the French countryside. Millardet noticed that only the roadside plants appeared resistant. After testing the mixture, Millardet promoted the use of copper sulfate and lime, which became known as Bordeaux mixture. In doing so, he helped save the French wine crop from devastation. Organic mercurial agents, initially used by Erlich in the treatment of syphilis, were introduced in the early 1910s and remained an important mainstay of seed treatment until recent times.

Modern organic chemistry led to the development of new pesticidal products in great abundance in the mid 1930s. The modern era of synthetic organic chemical control of

pests dates to the discoveries of the fungicidal effects of the dithiocarbamates in 1934, the insecticidal effects of the organophosphates in 1936, and 1,1-bis-(*p*-chlorophenyl)-2,2,2-trichloroethane (DDT) in 1939.

Dithiocarbamates found use both as fungicides and as rubber polymerization accelerators. They were first patented as fungicides by chemists in 1934, but were little used or publicized until the introduction of thiram in 1949. At that time two other dithiocarbamates, the iron-containing ferbam and the zinc-containing ziram, were introduced. These were eventually joined by an expanding array of other effective organic fungicides.

Organophosphates were observed to have potent insecticidal qualities by a German scientist, Gerhard Shrader, who between 1935 and 1937 developed hundreds of compounds in search of new pesticidal chemicals. He developed several insecticides, including parathion, TEPP, and shraden. He also developed tabun, also known as GA, and along with his lab assistant was the first person in history to suffer an acute intoxication with a nerve agent. His work on insecticides led to development of several other war gases under the Nazi regime, though his original work appears to have been directed towards insecticides.

While looking for potential insecticides among thousands of chemical products, Paul Mueller discovered the insecticidal qualities of a long known but seemingly inert compound, dichloro-diphenyl trichloroethane (DDT), originally synthesized by Othmar Zeidler in 1873. Mueller, then working at the Ciba-Geigy facilities in Switzerland, discovered its remarkable potency, revolutionizing insect control. Its persistence, effectiveness, broad spectrum, and relative low acute mammalian toxicity made it appear to be a virtually perfect insecticide. DDT, used in the control of louse-borne typhus, malaria, yellow fever and dengue fever, also revolutionized warfare. Due to the control of these diseases for the first time in history, fewer combatants died of infection than inflicted wounds. Mueller was subsequently awarded the Nobel Prize in Medicine for this discovery and its benefits in controlling vector-borne infectious diseases.³

Many other new insecticides, herbicides, fungicides, and fumigants were discovered during the decade surrounding World War I. Lindane's insecticidal activity was described by Van Linden, and applied as both a general use insecticide and a scabicide. After the war, surplus tear gas (chloropicrin) was adapted as a soil fumigant, but was eventually replaced by products such as dibromo-chloropropane, 1,2 dibromo-propane, and methyl bromide.

DDT and other insecticides in the organochlorine family began to lose effectiveness due to insect resistance, and were restricted in the 1970s because of their environmental persistence and related ecologic damage. This resulted in increased use of the organophosphate and N-methyl carbamate insecticides. The use of these compounds in the agricultural workplace in the early 1950s resulted in frequent intoxications among workers more familiar with the less toxic DDT and lead arsenate. Recently the organophosphates have come under stricter scrutiny, due to their very high toxicity and frequent

human intoxications. Several organophosphates have been removed from registration or have had significant restrictions included in their registered uses, including phosdrin, ethyl-parathion, chlorpyrifos and diazinon. An important class of insecticides included synthetic analogs of the natural pyrethrum molecule, leading to the many variants of synthetic pyrethroids, which today are widely used in both agriculture and non-agricultural insect control activities. However, the pyrethroids have encountered increasing resistance among target pests, reducing their usefulness and economic viability.

As organophosphates are increasingly more restricted, pyrethroids are encountering greater resistance and organochlorines are quickly vanishing, with new compounds being developed to fill their place. The mechanisms of action in many are sufficiently pest specific that toxicity in humans is less likely. Chitin inhibitors and insect pheromones are examples of these. The toxicity of these compounds for humans is likely to be low, except when dosed in large quantities, when allergic or idiopathic responses may be encountered, or if they are carcinogenic.

In the United States, with few exceptions, data are not available by state or region on the amounts of specific pesticides used in applications. California is the primary exception, where pesticide application information is reported and centrally available. New York also recently began to require that commercial applicators file application records annually. The amount of pesticides used worldwide exceeded 5.6 billion pounds in 1998 and 1999, of which 1.2 billion were used in the US. California alone reported 184,000,000 pounds of pesticides applied to agricultural crops in 2000.⁴ Information for most other states can only be estimated by use of national surveys such as the National Agricultural Survey Service database.

While pesticides have contributed to a substantial increase in agricultural productivity worldwide, the associated environmental costs are less well documented. Pest control with insecticides has also played an important role in the control of malaria and other vector-borne diseases in most of the developed world. However, this advantage in developing countries has been ephemeral. In some endemic areas, the incidence of malaria has increased in recent years, partly as a result of insect resistance to DDT and other insecticides. The overuse of insecticides in agriculture has facilitated the development of resistance in insect vectors and made their control even more difficult.³

There are approximately 900 active ingredients currently registered for use in the United States. This number is in constant flux as pesticides lose registration or new agents are added. These chemicals are mixed with many other compounds, termed 'inert ingredients,' without pesticidal properties but not necessarily without health effects that can be found in more than 35,000 commercial products.

Pesticides are classified by function according to the class of pest they are active against, chemical class, and by toxicity (e.g., World Health Organization and US EPA). As demonstrated in Table 48.1, the EPA toxicity categories correspond to acute effects.

Parameter	Category			
	I	II	III	IV
Oral LD ₅₀	50 mg/kg	50–500 mg/kg	500–5000 mg/kg	> 5000 mg/kg
Inhalation LD ₅₀	0.2 mg/l	0.2–2 mg/l	2–20 mg/l	> 20 mg/l
Dermal LD ₅₀	200 mg/kg	200–2000 mg/kg	2000–20,000 mg/kg	> 20,000 mg/kg
Eye effects	Corrosive; corneal opacity not reversible within 7 days	Corneal opacity reversible within 7 days; irritation persisting for 7 days	No corneal opacity; irritation reversible within 7 days	No irritation
Skin effects	Corrosive	Severe irritation at 72 hours	Moderate irritation at 72 hours	Mild or slight irritation at 72 hours
Signal word	Danger	Warning	Caution	Caution
LD ₅₀ , lethal dose for 50% of animals tested.				

Table 48.1 Environmental Protection Agency toxicity categories for pesticides

EXPOSURE

In occupational settings, dermal exposure is commonly the primary source of overexposure; however, exposure by inhalation, ingestion, or a combination of routes may be important. The conjunctival membranes of the eye and other mucous membranes are sometimes included as a distinct route of systemic exposure. Many fumigants, which are often released as gases into enclosed spaces, are easily and efficiently absorbed by inhalation. Aerosols, fine mists, and powders may have particle sizes small enough to be inhaled deep into the lungs and absorbed. Larger particle fractions often deposit on upper and lower airway surfaces, where they are readily absorbed, and even coarse mists may deposit in the oropharynx and be swallowed. Many sprays and granules have particle sizes larger than 30 microns and do not reach the lungs effectively through inhalation.

While most pesticides have low odor thresholds and are often identifiable at low concentrations, many pesticides are of relatively low volatility, with dermal exposure being more significant than the inhalation route. It is important to emphasize that exposure to even low-volatility pesticides in enclosed spaces over significant durations, or exposure to highly volatile pesticides, including fumigants, may result in substantial exposure by the inhalation route. Though rarely of occupational import, many pesticides are efficiently absorbed from the gastrointestinal tract. Accidental splashes with pesticides expose mucous membranes of the eye, nose, and gut, and so represent an efficient route of absorption. Exposure route should be discerned and described clearly in the process of making the diagnosis of pesticide-related illness, and reporting overexposures.

Acute toxicity from dermal exposure depends on both the toxicity of the pesticide and on the ease with which it is absorbed (bioavailability). Absorption of pesticides, like absorption of medications through the skin, depends on the concentration and lipid solubility of the active ingredient, the absorptive potential of the solvent in which the product is formulated, the frequency and promptness with which skin is washed after contact. The integrity of the skin barrier can also influence the rate of absorption; abraded or highly vascularized inflamed skin surfaces enhance absorption. The part of the body exposed is also

very important in the ease of absorption.^{5,6} Experiments with volunteers, for example, have shown that little as 8.6% of applied parathion may be absorbed through skin of the forearm, but as much as 100% may be absorbed through scrotal skin. Important in the first aid of overexposed victims is prompt decontamination. One study demonstrated that as much as 92% of applied parathion could be washed free 30 minutes after application, but as much as 70% could still be washed free after 300 minutes.

Some organophosphate agents can have potent interactions with other pesticides or with chemical contaminants within the same preparation. Malathion, for example, is much more toxic if administered with ethyl-p-nitrophenyl thionobenzenephosphorothioate (EPN). Isomalathion, present as a contaminant to malathion, resulted in epidemic poisoning among vector control spray operators in Pakistan.⁷ Paraoxon and malaoxon, which are the principal toxic metabolites of parathion and malathion, have been reported to cause epidemic poisoning. Hot, dry conditions, perhaps in combination with contaminants in air pollution, enhance the environmental formation and persistence of paraoxon from parathion.⁸ Alteration in toxicity through contaminants and storage conditions is not well characterized for most pesticides, and is generally not part of the toxicity studies required for pesticide registration.⁹ The clinician should thus consider the possibility of toxicity enhancement through mixed applications, through more highly toxic contaminants, or through environmental activation, when the presenting toxicity is not fully explained by the estimated dose based on known pesticide characteristics.

Occupational exposure to pesticides occurs among manufacturers and formulators; during transport and storage; among mixers, loaders, and applicators working in fields, greenhouses, parks, and residential buildings (Fig. 48.1); among vector control and structural (especially termite control) applicators; and among farm workers entering fields or greenhouse workers handling foliage previously sprayed by pesticides (Table 48.2). Crop duster aviation mechanics have been reported to be at high risk for pesticide poisoning.¹⁰ Other groups occasionally exposed include emergency crews or sewer workers involved in cleanup procedures. Perhaps the largest exposed group in developed countries is building maintenance workers, who apply household insecticides and disinfectants. Non-occupational environmental

Figure 48.1: Nicaraguan child pouring pesticide. (Courtesy of Aurora Aragon MD, National University of Nicaragua, Leon)

exposure occurs from drift,^{11,12} contaminated water, residues in indoor air or food, or from exposure to hazardous waste that is improperly disposed of. Although non-occupational exposure is often low level, there have been numerous episodes of acute illness resulting from drift from nearby fields or from consumption of contaminated food. In the United States, an epidemic of more than 1300 poisonings (and possibly eight deaths) was associated with the consumption of California watermelons contaminated with aldicarb.¹³ Intentional ingestion of pesticides is a frequent means of suicide, particularly in developing countries.¹⁴

EPIDEMIOLOGY

United States

No single surveillance system tracks pesticide poisonings in the US. In 1976, a national study of hospital admissions for pesticide poisonings noted that there was no system for recording pesticide poisonings in the United States. More than a quarter of a century later this remains the case. The majority of pesticide poisonings go unreported to any specific registry. Several states, including California, Washington, and New York (Table 48.3), have reporting systems that specifically identify pesticide poisonings. Other states require occupational intoxications to be reported, but many states have no reporting requirements.

Occupational exposure	Non-occupational exposure
Research chemistry	Residues from household and lawn applications
Manufacturing active ingredient	Termite control
Formulating end product	Accidental or intentional ingestion
Transportation	Food residues
Storage/warehouse work	Water residues
Mixing and loading	Hazardous waste sites
Agricultural application	Traffic accidents
Flaggers	Industrial spills
Structural application	
Building maintenance work	
Crop duster maintenance	
Farm work	
Greenhouse, nursery, mushroom house workers	
Livestock dippers	
Veterinarians	
Landscapers	
Park workers	
Forestry workers	
Entomologists	
Work on highways, railroads or rights of way	
Wood treatment workers	
Vector control workers	
Emergency workers	
Firefighters	
Sewer workers	
Hazardous waste workers	
Medical personnel	
Treating contaminated workers	

Table 48.2 Workplace and non-workplace exposures to pesticides

The Environmental Protection Agency has estimated that some 10,000–20,000 medically treated pesticide poisonings occur annually in the US.¹⁵ The mortality rate from unintentional acute pesticide poisoning in the United States in 1983 was estimated to be 2.7 per 10 million men (compared with 0.5 per 10 million women). The rate was three times higher among blacks than among whites. The mortality rate of pesticide poisoning related to suicide was 2.3 per 10 million for blacks and 2.6 per 10 million for whites. In California, which accounts for about one-third of the United States agricultural work force, 2001 registry data indicate that there were 979 reports of poisoning, 626 (63%) of which were judged after investigation to be potentially related to pesticides; 66% of poisonings were occupational. The largest group affected in agricultural settings was residue-exposed field workers (57 cases). Forty-two percent of these were identified as handlers, meaning that they were involved in some portion of the application process.

A significant drop in reports of pesticide-related illness has occurred in the past 10 years. In 1987, there were 2897 reported poisonings in California, 1754 (61%) of which were judged after investigation to be potentially related to pesticides. More than 80% of these were occupational poisonings. While some of this change may be related to reporting patterns, some is undoubtedly due to the elimination of several very toxic pesticides, such as phosdrin and ethyl parathion. The management of acute poisoning presented in this chapter will focus primarily on those pesticides that account for the most common and severe poisonings.

Table 48.3 States with established pesticide-related illness and injury surveillance systems

Under-reporting of pesticide poisonings, even in locations where reporting is mandatory, is likely to be a significant problem.¹⁶ A study from Nicaragua, with results consistently observed for most of Central America (see also section on Developing Countries below) found reporting percentages as high as 30% in some regions⁹ but as low as 2% in others.¹⁷ Reporting is probably even less accurate for non-occupational compared to occupational poisonings. In one study, less than 1% of poison center referrals (most of which were non-occupational) were actually reported. Approximately 4% of poison control center consultations in the United States involve pesticide exposure (34% of consultations for children under 6 years of age).

Developing countries

While consumption of pesticides in developed countries has tended to decrease or remain stable, pesticide use has increased, and indeed been promoted, in developing countries. In Latin America, a high proportion of farmers use pesticides heavily, approaching 100% in some groups such as subsistence farmers. Recently, the widespread production of ornamental plants, tropical fruits, and vegetables for export has relied heavily on pesticide application.

In the early 1980s, based on data from Asian countries, it was projected that 90% of the estimated 3 million annual pesticide poisonings worldwide, and more than 99% of the 220,000 pesticide-related deaths, occurred in developing countries.¹⁸ It was also estimated, based on extrapolation of interviews of several thousand agricultural workers in Asian countries, that 25 million occupational poisonings have occurred among agricultural workers in developing countries worldwide. These figures have not been updated and no new global estimates have been produced since their publication. In Costa Rica, it has been estimated that at least 4.5% of agricultural workers experience a pesticide-related illness each year.¹⁹ In surveys of agricultural workers in several Asian countries, and of cotton workers in Mexico, 3–7% and 13–15%, respectively, reported poisoning in the previous year. In addition, pesticide poisoning may be more likely to be underdiagnosed than in the developed countries. In one ecologic study of mortality trends in the Philippines, a dramatic increase in diagnosed medical conditions that might be confused with pesticide poisoning was observed among men of working age in rural areas. The increase was not seen among those less likely to be exposed to pesticides, namely women or older or younger men. The increased mortality rate among men corresponded to the

introduction of organochlorine pesticides into common agricultural practice in the 1970s, and was seen in a seasonal pattern that corresponded to the use of pesticides.²⁰ In Nicaragua, in 2000 it was estimated that among those persons with either domestic or occupational exposure to pesticides, 5% suffered a symptomatic poisoning episode.²¹

In general, large volumes of highly toxic pesticides are applied in the United States by relatively few workers loading crop dusters or tractor-drawn booms for application to large areas of land. Engineering controls, such as closed-system mixing and loading units, personal protective equipment, and medical supervision, are often available. By contrast, the small farmer in a developing country is likely to mix and load a backpack sprayer that may be poorly maintained, and to apply highly toxic insecticides without gloves, coveralls, or shoes.^{22–24} Of concern, some 30% of the pesticide exports to other countries from the United States are of pesticides prohibited or restricted in the United States. Warning labels are often not in the language of the receiving country, with limited literacy among many farmers. In one epidemic, hungry victims washed seed grain treated with alkyl-mercury before eating it, in the mistaken belief that this would remove the toxin, with resulting widespread intoxication (see below). Severe malnutrition, especially protein deficiency, may markedly potentiate the toxicity of certain pesticides, such as captan and several acutely toxic organophosphates and carbamates.

Many of the most serious epidemics of pesticide poisoning have occurred in the developing world. Methyl mercury seed treatment has led to poisoning epidemics in Latin America and the Middle East. An estimated 60,000 illnesses and 2000–2500 deaths from exposure to methyl isocyanate, used as an intermediary in insecticide manufacture, occurred in Bhopal, India during an uncontrolled release. More recently, in 1999, 24 children died in the Anduvian village of Taucamarca in Peru, after the milk supply at school was accidentally contaminated with methylparathion.

Increasingly, suicides have become an important pesticide-related health problem in developing countries.²⁵ While responsibility for this has been attributed to the person committing suicide,²⁶ suicides in agricultural workers can be viewed as an occupational disease (defined by WHO as “type IV”) due to easy availability of the poisoning agent.²⁷ In Costa Rica, non-occupational accidental and suicidal pesticide poisonings were 11 times more frequent among agricultural workers than among the general population.¹⁹ In Surinam, the incidence of paraquat suicides correlated closely with amounts of paraquat imported and distributed for agricultural use.²⁸ It is important to recognize that exposure to organophosphate pesticides may in itself cause psychiatric disorders including depression, leading to increased risk of suicides among farming populations.²⁹ In Serra Gaucha, Brazil, a high proportion of farm workers presented with minor psychiatric disorders,³⁰ which were strongly associated with pesticide exposures. In Ecuador, the suicide rate with pesticides was extremely high in a potato farming population;³¹ suicidal ideation was four times more frequent among previously poisoned banana plantation workers than among workers who had never been poisoned.

GENERAL APPROACH TO THE PATIENT EXPOSED TO PESTICIDES

A pesticide-exposed patient, like a patient with a severely contagious disease, presents a risk for healthcare workers. Given the potential toxicity of some agricultural chemicals, management of a poisoning includes careful attention to the safety of the receiving healthcare professionals. Contaminated clothing, gastric, or bowel contents and secretions should be carefully handled and disposed of with great caution.

After (and sometimes during) support of respiration and circulation, decontamination is essential to curtail further dosing of the affected subject from skin or gut contamination. Among the first tasks of a healthcare worker presented with a patient overexposed to pesticides is to determine the chemical involved. In many countries, if the label on the container is available, it will list the active ingredients and their acute toxicity. In the United States, the label must list the EPA registration number and the EPA signal word, which indicates the relative acute toxicity (Table 48.1). The *Farm Chemicals Handbook*³² is an index of most of the brand names available in the United States, and indicates the common chemical name of each active ingredient and the manufacturer. After the chemical name is known, useful resources for identifying the hazards of individual or groups of pesticides, and the management of related acute (and chronic) effects are listed in Table 48.4. In the United States, other resources include local poison control centers for the treatment of acute poisoning. An excellent resource, *Recognition and Management of Pesticide Poisoning*,³³ that is periodically updated and available through the EPA, is a detailed guide to treating acute poisoning.

Prompt induction of vomiting (or gastric lavage through a large-bore orogastric tube) is indicated to treat poisoning by ingestion. If consciousness is impaired or a petroleum distillate or corrosive was swallowed, gastric lavage should be performed. Caution must be exercised to avoid aspiration of petroleum distillates (producing a chemical pneumonitis), and use of a cuffed endotracheal tube in place before the stomach undergoes lavage should be considered. A chest x-ray study is indicated within a few hours after gastric lavage if aspiration of petroleum distillates is a possibility. Lavage should be followed by activated charcoal (50–100 g in 300 to 800 ml of water) to slow absorption and by a cathartic (e.g., sorbitol 1–2 g/kg of body weight to a maximum of 250 g per dose) to hasten transit time. Diazepam (Valium) 5–10 mg given slowly intravenously (not faster than 2 mg/minute) may be useful in controlling seizures.

If there is dermal exposure, the skin, hair, and nails should be bathed thoroughly with a mild detergent (or soap) and abundant water. The skin should not be scrubbed vigorously because damage to the superficial layers may enhance absorption. Further bathing with 70% alcohol may be helpful in removing additional residue. Skin, secretions, and clothing contaminated with pesticides should be

*Throughout this chapter, the numbers in parentheses after the names of insecticides and other chemicals are the EPA toxicity category (described in Table 48.1).

Acute clinical effects

Although there are important differences in the treatment of acute poisoning with the organophosphate and N-methyl carbamate insecticides, their clinical presentations are similar. Acute poisoning with these two classes of pesticides accounts for the majority of systemic poisoning cases seen by clinicians in the United States. Both inhibit neuronal acetylcholinesterase, as shown schematically in Figure 48.2. Normal function of the cholinergic nervous system is modulated by this enzyme, which cleaves the principal neurotransmitter, acetylcholine, into choline and acetic acid. The inhibition of acetylcholinesterase results in an increase in acetylcholine and in overstimulation of the postsynaptic receptors in the cholinergic nervous system. These effects can be differentiated toxicologically into stimulation of the central nervous system, of the nicotinic receptors (skeletal muscle and autonomic ganglia) and the muscarinic receptors (secretory glands and postganglionic fibers in the parasympathetic nervous system) (Table 48.5). The nicotinic effects generally appear later, and usually in moderate to severe poisoning cases. Headache, anxiety, and sleep disturbance, often accompanied by salivation and anorexia, are common early symptoms of mild overexposure to cholinesterase inhibitors. Chest tightness is a symptom of moderately severe poisoning after dermal exposure, but it can be an early symptom if there is significant exposure to the respiratory tract. Seizures and impaired consciousness occur in more severe poisoning cases. Other reported acute effects include myopathy (including myocardiopathy), hypothermia, liver dysfunction, brady- or tachyarrhythmias, leukocytosis, and acute psychosis. Clinical findings may be variable, with postganglionic sympathetic stimulation dominating over parasympathetic findings. For example, varying degrees of miosis or even mydriasis may be observed following organophosphate poisoning.

Delayed or chronic effects of exposure to organophosphates

Chronic low-level exposure to organophosphates may result in weakness and malaise, often accompanied by headache and light-headedness, but without other specific

symptoms. The etiologic relationship to pesticides of such non-specific symptoms may pose a clinical challenge (see section on Evaluation).

Several complications may occur in patients poisoned with organophosphates as follows.

1. There have been case reports of acute and persistent psychotic illness associated with poisoning by organophosphates.³⁴
2. QT prolongation and torsade de pointes, a life-threatening ventricular tachycardia, have been reported to occur for up to several days after severe poisoning.³⁵
3. The so-called intermediate syndrome, characterized by the paralysis of the proximal musculature and muscles of respiration and of cranial motor nerves, occurs 1–4 days

after poisoning (after recovery from the life-threatening manifestations of acute poisoning). Supportive mechanical ventilation for up to 2 weeks typically results in recovery without specific treatment. The mechanism of the intermediate syndrome is not fully known, but may be related to either involution of acetylcholine receptors or continued severe cholinesterase inhibition.³⁶

4. Organophosphate-induced delayed polyneuropathy (OPIDP), a distal dying-back axonopathy, is characterized clinically by cramping muscle pain in the legs, often followed by paresthesias and motor weakness. The onset occurs 10 days to 3 weeks following a severe poisoning episode. There may be marked foot drop and weakness of the distal upper extremities. In some patients pyramidal signs may develop. The best example of this problem was the epidemic of “Jake Leg”, which resulted from widespread ingestion of tri-ortho-cresyl-pyrophosphate (TOCP) in adulterated ginger extract. TOCP is an organophosphate that is not an acetylcholinesterase inhibitor, and is used principally as a plasticizer and in hydraulic lubricants. The prognosis for complete recovery of victims with long tract signs is poor. Although objective evidence of sensory loss is often lacking, decreased vibration sense has been reported on examination almost 50 years after the onset of disease.³⁷ Neurophysiologic studies in humans and animals have demonstrated relatively normal nerve conduction velocities, with markedly decreased sensory amplitudes and muscle action potentials. The pathophysiology of the disease appears to involve the inhibition and subsequent aging of a poorly characterized esterase known as neuropathy target esterase (NTE), which is distinct from acetylcholinesterase. Although the assay for NTE activity is not available clinically, high levels of inhibition and aging of NTE activity in human lymphocytes have been shown to predict the onset of OPIDP in a patient poisoned with chlorpyrifos.³⁸ Most reported cases occurring after insecticide poisoning have involved methamidophos. In humans, OPIDP also has been reported to occur after poisoning with merphos, mipafox, leptophos, trichlorphon, trichloronat, chlorpyrifos, and fenthion.

Table 48.5 Symptoms and signs of poisoning with anticholinesterases

5. In addition, persistent visual disturbances, difficulty concentrating, impaired memory, irritability, fatigue, and headache have been reported by individuals following poisoning with organophosphates. In large case series in the developed world, between 4% and 9% of poisoned individuals were reported to have clinically significant chronic neuropsychologic sequelae. In epidemiologic studies, even single episodes of severe organophosphate poisoning were associated with a persistent decrement in neuropsychologic function, including auditory attention, visual memory, visuomotor speed, sequencing and problem solving, motor steadiness, reaction time, and dexterity. Differences in the range of normal function, depending on cultural and, perhaps, socioeconomic factors are a challenge in clinical assessment; few tests are standardized for worker populations. In addition, there is large interindividual variability within the range of normal. An individual may have significant deterioration in neuropsychologic function and still remain within the interindividual normal range, if their premorbid function was high. Neuropsychologic evaluation should include an assessment of premorbid functioning, though previous neuropsychologic testing is rarely available. Chronic electroencephalographic disturbances, especially an increase in beta activity, have been reported among previously poisoned individuals.^{39–41}

Evaluation

Although not always present, especially in mild poisoning, fasciculations with miosis are virtually diagnostic of poisoning with these agents. In cases of mild acute poisoning, a cautious diagnostic trial of atropine sulfate (0.4–1 mg intravenously slowly) will usually result in a prompt improvement of symptoms. In poisoning resulting from dermal exposure, the onset of symptoms is rarely delayed longer than 12 hours and almost never longer than 24 hours after the exposure ends. The symptoms usually occur within 2–3 hours of ingestion and more rapidly after exposure by inhalation. Although considerable variability exists, if the onset of symptoms is delayed longer, the clinician must reconsider the diagnosis or consider the possibility of continued occult exposure (to contaminated clothing, for example).^{42,43} Although the results often are not available immediately, the measurement of cholinesterase levels in erythrocytes or in plasma is a useful confirmatory test.

Baseline cholinesterase levels are essential in interpreting values. Even mild depression of cholinesterase activity may result in symptoms, especially if the depression is sudden. Because there is a wide interindividual variation in normal cholinesterase activity, a low level is useful diagnostically, but a low normal level in an individual with symptoms of mild poisoning does not exclude the diagnosis. Rising cholinesterase for weeks to months after exposure may be useful in confirming the diagnosis. Most important is a comparison with baseline values, when available. Removal from exposure and serial measurements of cholinesterase activity are helpful diagnostic exercises in the setting of

subtle non-specific symptoms (e.g., headache, malaise, and fatigue) and chronic low-level exposure to organophosphates. Cholinesterase inhibition in blood samples may rapidly reverse in the case of carbamate poisoning. Samples collected for cholinesterase testing should be chilled and tested as soon as possible after venepuncture. The use and interpretation of cholinesterase results are discussed further in a later section on monitoring pesticide-exposed workers. The evaluation of persistent neuropsychologic complaints after overexposure to organophosphates includes neurologic and neurobehavioral testing.^{11,12,39}

Treatment

In addition to measures taken for all pesticide-intoxicated patients, the specific initial treatment of poisoning is the same for N-methyl carbamates and for organophosphates. The mainstay of treatment is atropine sulfate, which may be administered intravenously or intramuscularly. In mild to moderately severe poisoning, 1 mg is often enough to control symptoms, but may require further doses. The patient should be re-evaluated before each administration. Atropine toxicity (flushed, hot and dry skin, fever, and delirium) is a complication of overzealous treatment of mild cases of poisoning with cholinesterase inhibitors. In general, patients who are ill enough to require pharmacologic treatment (either with atropine or cholinesterase reactivators) should be observed for 12–24 hours after treatment.

Treatment temporarily may mask the symptoms as further absorption occurs or as insecticides are mobilized from temporary deposition in the fat stores.⁴⁴ In more severe poisoning, an initial dose of atropine sulfate (2.0 mg in adults or 0.05 mg/kg in children younger than 12 years old) should be administered. Treatment may be repeated at 10–15-minute intervals or titrated by an intravenous drip to achieve adequate atropinization (pulse 140/minute, mydriasis, and dry axillae).^{33,45} A decreasing level of rales in the pulmonary fields is reported to be a useful crude guide to the efficacy of treatment. If necessary, tachycardia may be controlled with small doses of propranolol (Inderal). In one severely poisoned patient, 31 g of atropine sulfate were administered (during a 5-week period).

The pulmonary system fails first in fatal poisonings. Respiratory failure is multifactorial due to bronchorrhea resulting in airway compromise; stimulation of smooth muscle resulting in bronchospasm; cholinergic blockade of skeletal muscle resulting in diaphragmatic paralysis; and depression of respiratory centers. In patients requiring mechanical ventilation, frequent suctioning of copious pulmonary secretions is fundamental for effective treatment.

Atropine sulfate acts by blocking the postsynaptic receptors for acetylcholine. Another important treatment modality for organophosphate insecticide poisoning (but not for N-methyl carbamate poisoning) is the reactivation of acetylcholinesterase, for example, with pralidoxime (Protopam, 2-PAM; Fig. 48.2). Because atropine does not antagonize the nicotinic effects of acetylcholine on skeletal muscle, cholinesterase reactivation is critical in the treatment of respiratory muscle paralysis. In addition, oxime reactivators and atropine may each potentiate

synergistically the therapeutic effect of the other. Treatment with 1 g of 2-PAM intravenously (in 5% glucose over several minutes; 20–50 mg/kg in children younger than age 12 years) can be repeated in 1 hour, if necessary. The half-life of pralidoxime is 0.9 hours in humans. Administration should be discontinued in cases of dangerous increases in blood pressure. Administration at a rate greater than 500 mg/minute can cause weakness, visual blurring, diplopia, dizziness, headache, tachycardia, and nausea. In one severe poisoning, 92 g was given over 23 days. However, because the acetylcholinesterase-phosphoryl bond strengthens (ages) with the loss of an additional alkyl group with time, treatment with 2-PAM is more effective the earlier it is given and, in some cases, becomes ineffective after 36–48 hours from the onset of poisoning. Blood should be drawn for the assay of cholinesterase activity before treatment with cholinesterase reactivators. Diazepam or barbiturates may be useful, but should be used with caution to manage seizures caused by cholinesterase inhibitors. The cause of seizures is often anoxia, and the delivery of oxygen to tissues should be a priority in treatment. Drugs that are contraindicated in the treatment of cholinesterase inhibitors include morphine, phenothiazines, reserpine, and theophylline.

Glycopyrolate, a potential substitute for atropine, has been under study in organophosphate pesticide poisonings. There may be some advantages such as reduced respiratory infections, but relatively little information is presently available in peer-reviewed journals.³³

Because mild or subclinical cases of OPIDP following severe cholinergic poisoning may be much more common than previously suspected, patients poisoned with these or structurally similar organophosphates (Fig. 48.3) deserve a careful clinical evaluation of symptoms, motor strength, and vibration threshold. Electrophysiologic study of sensory amplitudes and muscle action potentials is indicated if the symptoms or examination suggest neuropathy. Rehabilitative treatment may be helpful, but there is no specific antidotal treatment to OPIDP.

Treatment of poisoning with N-methyl carbamates

Carbamate insecticides are reversible inhibitors of cholinesterase, and aggressive treatment with atropine will support life as the N-methyl carbamate is gradually metabolized and excreted. Even life-threatening cases generally recover within 12 hours. Cholinesterase reactivators, such as 2-PAM, generally are ineffective or only marginally effective in the treatment of N-methyl carbamate-poisoned patients. In animals, oxime reactivators have been shown to potentiate the toxicity of one N-methyl carbamate, carbaryl. Therefore, 2-PAM is not indicated in the treatment of N-methyl carbamate poisoning. However, if an organophosphate may also have been involved in a severe poisoning or if doubt exists as to whether an organophosphate or N-methyl carbamate caused the poisoning, 2-PAM should be administered, with the primary objective being to avoid respiratory paralysis from organophosphate poisoning.

Figure 48.3: Organophosphates that have been associated with neurotoxicity. (From: Raffle P, Lee W, McCallum R, Murray R, eds. *Hunter's diseases of occupations*. Boston: Little, Brown, and Company, 1988.)

Pyrethrum and pyrethroids

Cismethrin (3)
Cypermethrin (2)
Cyfluthrin (2)
Deltamethrin (4)
Fenvalerate (2)
Flucythrinate (1)
Fluvalinate (2)
Pyrethrin (3)
Resmethrin (3)

In the mid-1800s, pyrethrum extracts of chrysanthemum flowers (containing pyrethrin and other active ingredients) were found to be effective insecticides. Although they are absorbed across the gut and through the lungs, they are minimally absorbed across intact skin, and they are relatively less toxic than other commonly used insecticides. Pyrethrum may cause asthma or allergic rhinitis, and contact dermatitis is frequent through allergic mechanisms. The mainstay of treatment for these conditions is avoidance of exposure. Acute allergic rhinitis may be treated with antihistamines, and severe asthmatic reactions should be treated similarly to asthma of other causes, and through strict avoidance of further exposures.

The many synthetic pyrethroid insecticides, which are closely related chemically to the naturally occurring pyrethrins, are more stable in the natural environment and are used in agriculture and in household pest control, although toxicity to non-target aquatic and terrestrial invertebrates is high. Ingestion of large doses of pyrethroids causes

salivation, nausea, vomiting, diarrhea, irritability, tremor, inco-ordination, seizures, and death. Toxicity is thought to be mediated through functional changes in sodium channels. Treatment of acute poisoning is non-specific and supportive, including administration of activated charcoal and a cathartic following gastric aspiration and lavage.

Allergic responses to synthetic pyrethroids are uncommon. However, a high proportion of exposed workers report annoying itching and tingling of exposed skin, especially of the face, without visible inflammatory response. Symptoms resolve slowly (within 1 day) after exposure is discontinued. The mechanism of this seemingly local neurotoxic effect is not well understood, but application of vitamin E oil prior to exposure may be preventive. Caution should be taken to avoid eye contact, especially with fluvalinate, which is corrosive as formulated. Prolonged flushing of contaminated eyes with water or saline should be followed by referral to an ophthalmologist.

Organochlorine insecticides

Cyclodienes

Aldrin (1)

Chlordane (2)

Dieldrin (1)

Endosulfan (1)

Endrin (1)

Heptachlor (2)

Chlordecone (4)

DDT (2)

Lindane (Kwell) (2)

Toxaphene (1 or 2)

Many of these chemically diverse insecticides have been banned or restricted in the developed world because they persist in the environment and concentrate in the food chain, damaging wildlife. Fat levels of DDT in human surveys have decreased markedly since DDT was banned in the United States in 1973. In the developing world, DDT (for vector control in malaria-endemic areas) and toxaphene (in cotton cultivation) are still used, though movements to restrict the use of these persistent organic pollutants have had some effect at limiting their use in some countries (see Chapter 45). High concentrations of DDT in the fat and milk from humans and cows continue to be found in developing countries. Chlordane was, until recently, the agent of choice for termite control in most of the United States, and lindane still is used widely as an ectoparasiticide. Endosulfan is still registered and used in the US. Interestingly, the new pesticide fipronil has a similar but much more potent effect on the GABA receptor than do lindane, dieldrin, and endosulfan. The relative safety of the chemical appears to be due to its greater specificity for insect GABA A receptors than for those in mammals.^{46,47}

Acute effects

Dermal absorption of the cyclodienes, chlordecone, and lindane is good. Because acute toxicity is high for chlorde-

cone, endrin, aldrin, and dieldrin, these account for most occupational poisonings. Most other acute poisonings result from ingestion. Acute toxicity reflects influence on neuronal membrane stability through interaction with either sodium channels or GABA receptors, resulting in hyperactivity in the central nervous system. Sudden seizures (especially from aldrin, dieldrin, endrin, lindane, and toxaphene) may occur up to 48 hours after exposure, and may be relatively intractable. Headache, nausea, dizziness, inco-ordination, confusion, tremor, and paresthesias are common. Tremor is characteristic of poisoning with DDT and chlordecone. Abnormal liver enzyme levels and renal tubular abnormalities may be seen.

Chronic effects

A very important historic event related to pesticide overexposure was epidemic occupational chlordecone (Kepone) poisoning in a manufacturing facility, characterized by anxiety, tremor, opsochonus, personality changes, pleuritic and joint pains, weight loss, liver disease, and oligospermia. Indirect exposure was an important factor, with two family members of workers also poisoned by contaminated work clothes. A portion of the Chesapeake Bay in the United States was polluted by discharge from the plant. Almost all organochlorine insecticides have been found to be carcinogenic in at least one species of rodent. Idiosyncratic cases of aplastic anemia have been reported anecdotally in association with exposure to organochlorines, especially to chlordane and lindane.

Evaluation and treatment

The diagnosis of acute poisoning is made by a history of exposure in the appropriate clinical setting. Although the tests are not routinely available, organochlorines and their metabolites may be found in the blood or in fat. Treatment is supportive. Diazepam 5–10 mg by slow intravenous injection may be repeated at 10–15-minute intervals up to a total dose of 30 mg for the control of intractable seizures. Pentobarbital (100 mg by slow intravenous administration) is useful, not only for controlling seizures but also because it induces hepatic enzymes that may accelerate the metabolism of organochlorines. Additional doses may be given up to 500 mg. In studies of animals poisoned by aldrin and dieldrin, doses of pentobarbital that would otherwise cause anesthesia (20 mg/kg in dogs followed by 5 mg/kg twice daily) were required for periods of more than 2 weeks to control intractable seizures. Atropine and adrenergic amines are contraindicated because the organochlorines may potentiate myocardial irritability. Cholestyramine (Questran) was found to be effective in increasing elimination and ameliorating hepatic effects in chlordecone-poisoned patients. It has been recommended for treatment of poisoning by other organochlorines.

ANTICOAGULANT RODENTICIDES

Brodifacoum (1)

Diphacinone (1)

Warfarin (1, 2, or 3)

Since the synthesis of dicumarol in 1940, non-intentional ingestion of related anticoagulant baits has been common among children. Occupational poisoning by dermally absorbed warfarin has been reported. Some coumarin derivatives are used in medicine for the treatment of thromboembolic disease.

Acute effects

Increased capillary permeability and the antagonism of hepatic synthesis of vitamin K-dependent clotting factors II, VII, IX, and X produce bleeding gums and nose, ecchymoses, hematuria, and melena. Some, but not all, anticoagulant rodenticides produce diarrhea, small intestinal necrosis, urticaria, dermatitis, leukopenia, alopecia, and abnormal liver enzymes.

Evaluation and treatment

Diagnosis in the appropriate clinical setting is confirmed by an increased prothrombin time, which reaches a maximum 36–72 hours after ingestion. Treatment with the naturally occurring form of vitamin K₁ (phytonadione [aquamephyton]) is preferred. If ingestion is doubtful, the treatment may be oral, i.e., 15–25 mg (5–10 mg in children younger than 12 years old). If more than 1 mg/kg of coumarin or its related anticoagulant is ingested, vomiting should be induced with syrup of ipecac (within the first few hours, as bleeding may later become a complication of vomiting), or the stomach should undergo lavage. Treatment with vitamin K₁ 5–10 mg intramuscularly (1–5 mg if younger than 12 years) is provided and repeated after 24 hours if the prothrombin time remains increased. If there is evidence of bleeding, phytonadione (in dextrose or saline) may be administered intravenously over 20 minutes (up to 10 mg; 5 mg if younger than 12 years old). If the bleeding is severe, treatment with fresh blood may be required. Prothrombin time and hemoglobin level should be monitored every 6–12 hours. Patients receiving intravenous vitamin K₁ should be monitored carefully, and treatment discontinued in the case of dyspnea, dizziness, flushing, decreased blood pressure, or cyanosis. Poisonings with diphacinone and brodifacoum may require larger doses of vitamin K₁ for more prolonged periods.

HERBICIDES

Alachlor (3)
Atrazine (3)
2,4-D (1 or 3)
2,4,5-T (3)
Butylate (3)
Cyanazine (2 or 3)
Glyphosate (2)
Metolachlor (3)
Metribuzin (3)
Paraquat (diquat) (2)
Trifluralin (3 or 4)

A broad and extensively used group of chemicals, herbicides include some chemicals with well-understood mechanisms of toxicity and others about which little is known. With some exceptions, most herbicides are generally of low acute toxicity. Herbicides make up the largest portion of the pesticidal chemicals used in the US. Some herbicides are important ground water contaminants and are animal carcinogens, including, for example, alachlor and atrazine.

Bipyridils (diquat and paraquat)

Among the most acutely toxic of the herbicidal chemicals is the bipyridil herbicide paraquat (Fig. 48.4). This extremely effective contact herbicide is widely used in both developing and developed countries. It is a restricted-use pesticide in the US. As a non-selective herbicide, paraquat is a desiccant and defoliant, and is widely used for control of broadleaf weeds and grasses. It is generally distributed as a liquid (e.g., 20% concentrate), and can be applied by aerial, tractor-based or backpack applications. Paraquat is sold under many trade names, sometimes combined with another bipyridil, diquat.

Paraquat has extremely low volatility with a slight amine-like odor. It is very soluble in water and poorly soluble in lipids. It is quickly destroyed by ultraviolet light. It does not generally leach from soil into ground water, as it binds quickly to or reacts with soil constituents.

The minimum lethal dose for human beings is thought to be approximately 35 mg/kg for paraquat. It has been involved in occupational and, more commonly, non-occupational self-induced deaths.^{18,48} In Japan, where intentional ingestion is common, there are 2000 deaths each year attributable to paraquat. Occupational systemic poisoning in the United States is uncommon, but data from the Agricultural Health Study indicate that paraquat may be among several pesticides contributing to respiratory symptoms in farmers.⁴⁹ Severe occupational poisonings are rare in the US, but have been reported in Central America.⁴⁸ Dermal contact is an important exposure route.

Acute effects

Skin and ocular burns from splashes of the concentrate are among the most common consequences of overexposure to paraquat. A somewhat unique outcome among workers is loss of fingernails. Epistaxis is also reported among workers using the chemical. Painful burns and bleeding of the

Figure 48.4: Chemical structures of MPTP and paraquat.

gastrointestinal tract are common with ingestion. Approximately 20% of ingested paraquat is absorbed systemically, where it may cause acute hepatic necrosis and renal failure. Paraquat is concentrated from the systemic circulation into the lungs, where prominent pulmonary injury may occur; pulmonary edema may develop 2–4 days following ingestion, leading to pulmonary fibrosis in survivors.⁵⁰ Pneumothorax and pneumomediastinum are also common in the acute exposure setting.⁵¹ Damage to muscle, including myocardium, and to the central nervous system have been reported. The mortality rate is greater than 50% in most case series of suicidal ingestion.

Paraquat is not well absorbed from intact skin; however, damaged skin is much more permeable to paraquat.⁵² There are several reports of fatal paraquat poisoning caused by dermal absorption.²⁷ The lethal dose in 50% of rabbits repeatedly dermally dosed is only 4.5 mg/kg/day under occlusion. Occupational poisoning resulting from dermal absorption is more likely to occur in developing countries, where applicators may carry and mix concentrated paraquat in leaky backpack sprayers.

Chronic effects

Pulmonary fibrosis has been reported among survivors of paraquat poisoning.⁵³ Paraquat is structurally similar to 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), an illicit drug that caused an outbreak of acute-onset Parkinson's disease. Although it has been argued that paraquat does not cross the blood–brain barrier, ecologic studies and one case-control study suggest an association between herbicide exposure and Parkinson's disease.⁵⁴ In contrast, animal studies have failed to demonstrate a connection between paraquat and parkinsonism.

Evaluation and treatment

Contaminated skin should be washed thoroughly. Subsequent avoidance of exposure will usually result in resolution of rash and damage to the nails. If paraquat is splashed on to the eyes, they should be irrigated thoroughly with clean water, with referral to an ophthalmologist.

Paraquat absorption may be confirmed at the bedside by observing the colorimetric urinary reaction with sodium dithionite, performed by mixing the urine 2:1 with freshly prepared 1% sodium hydrosulfate in 1 N sodium hydroxide. Development of a blue color over a 60-second period indicates paraquat in excess of 0.5 mg/liter. The diagnosis should be confirmed by measuring plasma paraquat levels, which have been found to be useful prognostically in identifying those individuals likely to survive after ingestion. Those with plasma concentrations at 4, 6, 10, 16, and 24 hours after ingestion that are less than 2, 6, 0.3, 0.16, and 0.1 mg/liter, respectively, were likely to survive.

Unfortunately, there is no adequate specific antidote for paraquat poisoning. If paraquat ingestion is suspected, the stomach should be lavaged immediately with a slurry of Fuller's earth (100–150 g in 30% suspension; 2 g/kg in children). Lavage should be repeated every 2–4 hours until the slurry appears in the stool. A cathartic should be administered, unless intestinal ileus (a common complication of

poisoning) is present. Diuresis with isotonic saline, Ringer's solution, and 5% glucose in water is indicated to promote the excretion of paraquat and to correct dehydration and electrolyte imbalances, as long as the urinary output is adequate. Because paraquat-induced pulmonary toxicity is thought to arise from the generation of free radicals, which is enhanced by high oxygen concentrations, oxygen use should be minimized to the amount necessary to correct hypoxemia. One case report describes complete recovery from a combined paraquat-diquat ingestion with therapy including forced diuresis, hemofiltration with n-acetylcysteine, methylprednisolone, cyclophosphamide, vitamin E, cholchicine, and delayed continuous nitric oxide inhalation.⁵⁵

Diquat

Poisoning with diquat is less common and generally less lethal than paraquat. The clinical presentation is similar to that of paraquat poisoning, except that central nervous system symptoms are more likely, including disorientation, psychotic behavior, and seizures. Renal failure is more prominent, as diquat does not concentrate in the lungs, with less severe pulmonary injury. Management is similar to that for paraquat poisoning.

Chlorophenoxy herbicides

2,4-D

2,4-DP,

2,4-DB,

2,4,5-T,

MCPA

Polychlorinated dibenzo-dioxins (PCDD) contaminants

Chlorophenoxy herbicides have been used widely in the United States and elsewhere against broad-leaved plants. During the American involvement in the Vietnam War, 2,4-D and 2,4,5-T were applied together for deforestation in a formulation known as Agent Orange. Chlorophenoxy herbicides are absorbed dermally, by inhalation, and by ingestion. Symptoms of irritant effects on the skin and mucous membranes are common. While acute systemic toxicity is generally low, after ingestion of large doses multiple organ systems may be affected, with resulting nausea, vomiting, diarrhea, myotonia, fever, confusion, leukocytosis, abnormal liver enzyme levels, elevated creatinine phosphokinase concentrations, myoglobinuria, T-wave flattening and inversion, and coma in severe poisonings. Treatment includes decontamination and forced alkaline diuresis with intravenous saline and dextrose with 44–88 mEq of sodium bicarbonate per liter, to maintain the urine pH at 7.6–8.8. Renal function and fluid balance should be carefully monitored. Heavy exposure to 2,4-D has been reported to cause peripheral neuropathy. In case-control studies, a history of exposure to 2,4-D has been associated epidemiologically with non-Hodgkin's lymphoma.

The chemical 2,4,5-T, which is no longer marketed in many of the industrialized countries, is contaminated with PCDD, of which the most toxic is 2,3,7,8-tetrachlorodibenzodioxin (TCDD). TCDD bioaccumulates, and most

of the low-level body burden for the general population comes from food, especially, fish, meat, and dairy products. In workers chronically and heavily exposed to TCDD, an increased overall incidence of cancer has been observed. The largest published cohort study of heavily exposed workers demonstrated an association between 2,4,5-T exposures and non-Hodgkin's lymphoma and soft tissue sarcoma – associations previously seen in some case-control studies. In animals, there are great differences in the interspecies toxicity of TCDD. In some animals, TCDD is an exceedingly potent carcinogen and teratogen, with acute hepatotoxic, immunotoxic, peripheral neuropathic, hematopoietic, and dermal effects. In accidents in which people have been highly exposed, TCDD has been reported in clinical series to be associated with chloracne, porphyria cutanea tarda, hepatic and renal disease, peripheral neuropathy, increased lipid levels, and possible accelerated atherosclerosis and neuropsychiatric disease.

The hallmark of TCDD exposure is the pale, small cyst characteristic of chloracne. However, among populations with environmental exposure to TCDD, such as veterans of the Vietnam War, individuals exposed to industrial waste in Seveso (Italy), Niagara Falls (New York), and Newark (New Jersey) or to TCDD-contaminated waste oil applied for dust control at Times Beach and other sites in Missouri, chloracne has been relatively uncommon. In epidemiologic studies of environmentally and occupationally exposed populations, subclinical depression of cell-mediated immunity, elevation of liver enzyme levels, and subclinical evidence for peripheral neuropathy have been observed variably.

Current or previous exposure to TCDD should be considered in the differential diagnosis of lesions compatible with chloracne, non-Hodgkin's lymphoma, and soft tissue sarcoma. If there is reason to suspect exposure to TCDD in these clinical settings, serum or adipose TCDD levels, although expensive, may be useful in helping to establish prior exposure. The mean half-life of TCDD in adipose tissue is approximately 7 years, and generally does not to exceed 15–20 parts per trillion in the general population.

The Veterans Administration has adopted regulations to compensate veterans exposed to Agent Orange during the Vietnam War for soft tissue sarcoma, non-Hodgkin's lymphoma, Hodgkin's disease, respiratory cancers, chloracne, peripheral neuropathy, and Type 2 diabetes.

Nitroaromatic herbicides

This group includes nitrophenolic and nitrocresol chemicals. These agents are used as herbicides, nematocides, insecticides, and fungicides. Now rarely used in the US, these chemicals are still used internationally and continue to contaminate surface water wells in agricultural areas. They are absorbed efficiently dermally, through the lung (if droplets are inhaled), or orally. A unique yellow discoloration to contaminated skin and fingernails may result from contact with these chemicals. With LD₅₀s in the 25–50 mg/kg range, they are highly toxic. These chemicals uncouple oxidative phosphorylation resulting in hyperthermia, tachycardia, fatigue, and, if sufficiently severe, death. Tissues with

high metabolic needs such as liver, kidneys, nervous and reproductive systems are the most susceptible tissues. These chemicals are detectable in urine and serum by gas chromatographic methods. The fat solubility of these chemicals may assist in the diagnosis, as their elimination half-life is as long as 14 days. Treatment is directed at reducing hyperthermia and providing supportive care. Use of salicylates may paradoxically worsen hyperthermia, as they too uncouple oxidative phosphorylation. Atropine can worsen tachycardia. Decontamination is very important, and as with other highly toxic chemicals, caution should be exercised to avoid healthcare provider bystander exposure.³³

Other herbicides

Dormex is a herbicide that contains hydrogen cyanide. Overexposure has led to skin manifestations that include pruritic, erythematous, macular, or papular rashes. Skin burns have been reported. Other symptoms are related to systemic metabolic effects and include tachycardia, weakness, palpitations, headache, dizziness, vomiting and/or nausea, dyspnea, and hypotension.⁵⁶

FUNGICIDES

Ferbam (4)
Hexachlorobenzene (4)
Mancozeb (4)
Maneb (4)
Methyl mercury
Pentachlorophenol (2)
Thiram (3)
Zineb (4)
Ziram (3)

Fungicides applied to seeds, crops, and gardens encompass a wide variety of chemical classes, including copper, cadmium, organomercury and organotin compounds, substituted benzenes, dithiocarbamates, thiophthalimides, and others. Acute toxicity is related to dose. In general, there is no specific antidotes for poisoning with these compounds. Supportive measures are described in the section on the general approach to the pesticide-exposed patient.

The dimethyldithiocarbamates ziram, ferbam, and thiram inhibit acetaldehyde dehydrogenase and have a disulfiram (Antabuse) effect. There have been reports of illness consistent with disulfiram reactions (nausea, vomiting, headache, diaphoresis, thirst, chest pain, and vertigo) among thiram-exposed workers who subsequently consumed alcohol-containing beverages. Ziram and ferbam are irritants; hemolysis has been reported in one case of ziram poisoning. All dithiocarbamates are metabolized to carbon disulfide, which may explain similarities in the symptoms of poisoning. Following ingestion, poisoning by thiram has been reported to cause nausea, headache, tremor, encephalopathy, hepatic and renal injury, and peripheral neuropathy. Treatment is supportive. Syrup of ipecac is contraindicated in the treatment of dithiocarbamate poisoning as it may contain ethanol.

The ethylene-bis-dithiocarbamates (maneb, mancozeb, and zineb) are metabolized to ethylene thiourea, a potent animal carcinogen. This metabolite may also account for the antithyroid effects that occur in animals exposed to these compounds. Ethylene thiourea may concentrate on cooked food previously treated with ethylene-bis-dithiocarbamates. Maneb is of interest because it contains manganese, which can produce a condition similar to Parkinson's disease. In one study of maneb-exposed workers in Brazil, movement disorders were reported suggestive of preclinical Parkinson's disease. Hemolytic anemia was reported in a worker with glucose-6-phosphate dehydrogenase deficiency exposed to zineb. Treatment includes decontamination and supportive care.

Although little used currently in the United States, alkyl mercury has resulted in occupational poisoning in seed treating facilities, and in epidemics of catastrophic fetotoxicity among peasants who consumed treated seed grain or meat from animals that had consumed this grain. Alkyl mercury compounds are absorbed from the gut and skin. Methyl mercury is volatile, and may be inhaled. Acute poisoning is manifested by headache, metallic taste, paresthesias, tremor, inco-ordination, slurred speech, constricted visual fields, hearing loss, loss of position sense, and spasticity. Among survivors, permanent neurologic effects are common. Decontamination is essential, and treatment of acute poisoning with D-penicillamine (Cuprimine, 0.5 g every 6 hours before meals and at bedtime for 5 days) may reduce the biologic half-life.

Consumption of hexachlorobenzene-treated seed grain in Turkey in the 1950s resulted in an epidemic of thousands of cases of poisoning that resembled porphyria cutanea tarda. Hexachlorobenzene is a potent inhibitor of uroporphyrinogen decarboxylase, resulting in increases in photosensitive porphyrins. Chronic bullous dermatitis, liver damage, hypertrichosis, and arthritis occurred in many exposed individuals. Acutely, hexachlorobenzene levels can be measured in blood, and metabolites can be measured in urine. Significantly elevated 24-hour urine concentrations of uro- and coproporphyrins in the appropriate clinical setting are diagnostic of porphyria cutanea tarda. Cholestyramine (3–8 g before each meal and at bedtime) has been recommended to accelerate elimination by interrupting the enterohepatic circulation of porphyrin metabolites in individuals with high levels in their tissues. Exposure to sunlight should be avoided in individuals with porphyria cutanea tarda.

Pentachlorophenol, used as a wood preservative, is well absorbed through the skin, and numerous occupational deaths have occurred from hyperthermia resulting from uncoupling of oxidative phosphorylation (similar to the nitroaromatics described above). Clinical features include fever, thirst, sweating, weakness, tachycardia and other arrhythmias, and tachypnea. Restlessness, anxiety, and dizziness reflect injury to the central nervous system. Albuminuria, glycosuria, azotemia, hepatomegaly, and elevated transaminase and alkaline phosphatase levels may be seen. Diagnosis is based on consistent clinical findings in the setting of exposure. Symptoms typically do not occur if the pentachlorophenol level in the serum or urine is less

than 1 ppm. Treatment is directed toward reducing the body temperature, e.g., cooling blankets, cooling baths, and cold fluids by mouth. Salicylates are contraindicated, and other antipyretics are ineffective. Benzodiazepines may be used to control agitation. Fluid replacement is an important aspect of therapy given substantial insensible volume loss. Pentachlorophenol is contaminated with TCDD and other PCDDs; the chronic effects of pentachlorophenol exposure may result from PCDDs, especially hexachlorinated dioxin contaminants (see above, and Chapter 45). Aplastic anemia has been reported anecdotally in association with pentachlorophenol exposure. Elevated serum and urinary pentachlorophenol levels have been found in residents of log homes built with logs dipped in the pesticide.

FUMIGANTS AND NEMATOCIDES

Acrolein

Chloropicrin (2*, 0.1)

Dichloropropene (3, 1)

Ethylene dibromide (2, A2)

Ethylene oxide

Formaldehyde (0.1†, A2)

Methyl bromide (2,5)

Para-phostoxin (1, 0.3‡)

Sulfuryl fluoride (1,5)

Among the most acutely toxic of the pesticides are the chemicals used for fumigation. This application involves a chemical designed to permeate into otherwise unreachable spaces. Fumigants are generally non-specific toxicants selected to sterilize a space, object, or substance of a wide array of potential pests. The very non-specific nature of the biologic effects contributes to the collective hazard of these chemicals. Many chemicals have been used in the past as fumigants including oxides of sulfur, cyanides, chlorinated and other volatile solvents. The health effects of these chemicals are covered elsewhere in this book. Chemicals used widely as fumigants such as phosphine gas, methylbromide, dibromochloropropene, and 1,3-dichloropropene will be addressed in this section. Exposure is usually through inhalation, though exposure to liquid preparations during mixing and handling also occurs; ingestion of certain fumigant chemicals (particularly aluminum phosphide) is common in suicides in certain developing countries.

Grain may be fumigated by mixing with granulated fumigant compounds such as aluminum phosphide. The chemical reacts with the moisture in the grain, causing release of phosphine gas. A building may be fumigated by releasing or pumping fumigant into interior spaces after

*EPA toxicity category (described in Table 48.1) followed by threshold limit value (in parts per million); A2 indicates suspected human carcinogen.

†Threshold limit value.

‡Threshold limit value for phosphine.

sealing the entire structure in plastic or a tarp. Overexposure may occur during the venting or opening of buildings (e.g., grain storage facilities). Diffusion of residual fumigant from closed wall spaces has resulted in overexposure within fumigated living structures. Fumigants have caused problems by diffusing through previously unrecognized conduits into inhabited spaces distant from the fumigated area. Several halogenated hydrocarbon fumigants are suspected or proven animal carcinogens.

Aluminum phosphide (AlPO_4) is a fumigant that breaks down into phosphine and aluminum salts when combined with water. Phosphine is volatile and represents the fumigant moiety. AlPO_4 is either directly exposed to water by the user, or left in closed spaces to react with ambient moisture, gradually off-gassing phosphine. An example of this is the use of AlPO_4 in stored grain fumigation. AlPO_4 is also used for rodent control in the west, where it is inserted into rodent or mole burrows which are then sealed closed. Exposure to AlPO_4 generally occurs through inhalation. The odor threshold is between 0.02 and 3 ppm, with an odor described as that of rotten fish.

Methyl bromide is a fumigant gas that occurs naturally at very low levels, particularly near salt water, and in high concentrations is an effective soil sterilizant. It is still used widely in California for nematode control in strawberry production. In California alone, some 16 million pounds of the gas were applied to the soil in 1997. The compound is also used for structural fumigation and has resulted in intoxications among people residing in fumigated buildings.

Acrolein is a colorless gas at room temperature. It has a pungent odor and is used as an algicide and aquatic herbicide. It reacts with sulfhydryl groups on enzymes interfering with enzymatic function. It is a prominent respiratory irritant and recognized asthmagens, and has an oral LD_{50} of 29 mg/kg in rodents.

Chloropicrin, developed as a lacrimating 'tear gas' agent in World War I, has found use as an insecticide and nematocide; the potent irritant qualities also act as a warning agent for less irritating, but more toxic, agents. It is thus often mixed with other fumigants to increase warning characteristics. It finds some use in the control of wood fungi.

Dibromochloropropane is a nematocide that is no longer registered in the US. It was formerly widely used in pineapple and banana production where it was applied through direct injection into the soil or through irrigated routes. It is a potent reproductive toxin causing direct damage to testicular tissues and has been associated with male infertility in many developing countries.

Acute effects

Mucous membrane and respiratory tract irritation are common with exposure to many of the fumigants. Chloropicrin and other irritants or odorants may be added to fumigants as warning agents. Several fumigants may be toxic at levels below odor threshold concentrations, resulting in overexposure without recognition of the chemical by those exposed.

The acute symptoms of occupational overexposure to phosphine are generally respiratory, and include acute chest

discomfort with substernal burning, shortness of breath, chest tightness, as well as palpitations. Gastrointestinal symptoms are not uncommon, with diarrhea, nausea, abdominal pain, and vomiting. Central nervous system symptoms include headache, dizziness, and unstable gait. No specific diagnostic tests are available, and aluminum levels are not elevated in phosphine gas exposure. Abnormalities in liver enzymes and renal function parameters are reported. Phosphine is a poorly soluble gas and is thereby able to penetrate deeply into the lung without reacting with moisture in upper respiratory tract mucous membranes. This results in the potential for late-onset pulmonary edema and thus warrants close observation with hospitalization or prompt follow-up visit (including chest radiograph) within 24–48 hours of exposure.

Methyl bromide has a slightly sweet but barely noticeable odor, and is only moderately irritating, which makes it particularly dangerous. Overexposure causes respiratory irritation, pulmonary edema, anorexia, nausea, vomiting, headache, visual disturbances, agitation, dizziness, tremor, inco-ordination, myoclonus, and muscle weakness. Liquid methyl bromide can cause severe skin burns with substantial systemic absorption. Chloropicrin, which is intensely irritating, is added to methyl bromide formulations to warn applicators of overexposure. Due to its use as a structural fumigant in poorly ventilated indoor spaces, and its physical property of being heavier than air, it has been the cause of death and injury to people entering such structures, and from seepage through sewer systems into adjacent structures. In one case, accumulation of methyl bromide resulted in death and illness among infants.^{57,58} Intoxication has also been reported during untarping of fumigated soil, a common activity in areas where soil fumigation is performed with methyl bromide.⁵⁹

Aluminum phosphide (phostoxin), magnesium phosphide, and zinc phosphide slowly release phosphine gas; the release is more rapid in a moist environment. Phosphine is a mucous membrane and respiratory irritant that produces nausea, vomiting, diarrhea, headache, vertigo, fatigue, paresthesias, cough, dyspnea, chest tightness, and pulmonary edema. Renal, hepatic, cardiac, and central nervous system toxicity are common. Patients may smell of rotten fish or garlic. Deaths have occurred among individuals living near recently fumigated granaries or as a result of early re-entry into fumigated structures.

DBCP is irritating to skin and mucous membranes, and if absorbed in sufficient quantities can cause renal and liver damage. Acute high-level exposure may present with headache, nausea and vomiting, ataxia and slurred speech.

The nematocide dichloropropene (DCP) has an odor threshold between 1 and 4 ppm and an LC_{50} of between 855 and 1035 ppm in animal studies. Acute high-level overexposure results in liver, kidney, and lung injury in rats. A human fatality with DCP has been reported. DCP is both irritating and sensitizing to the skin and mucous membranes. Respiratory and mucous membrane irritation, headache, malaise, abdominal pain, and elevated hepatic transaminase levels were reported among persons who inhaled dichloropropene spilled in a highway accident.

Follow-up of exposed individuals documented altered personality, persistent headache and chest pain 2 years after the incident. Studies of dichloropropene have been inadequate to evaluate its carcinogenic effects, and it appears not to have the spermatotoxic effects of DBCP.

Chronic effects

Survivors of acute poisoning with methyl bromide may be left with residual organic brain damage, seizures, and personality changes. Ethylene dibromide is a potent animal carcinogen and a human spermatotoxin, and is no longer used in the United States. As early as 1961, published studies of rodents showed that DBCP caused diminished sperm counts and testicular atrophy. In 1977, almost half of a group of poorly protected production workers exposed to DBCP were demonstrated to be azospermic or oligospermic. Recovery was better among initially oligo- than among azospermic workers. DBCP is an animal carcinogen, and it has been removed from the continental United States market. However, biopersistence in ground water has been a problem, and in some parts of southern California, wells were found to be contaminated with residues as high as 39 parts per billion in 1979, years after the use of DBCP was banned.

Evaluation and treatment

Diagnosis of acute fumigant poisoning is made by consistent history and clinical findings in the setting of exposure to the responsible fumigant. Bromide ion may be elevated in blood and urine in poisonings with methyl bromide. With sulfuryl fluoride poisoning, fluoride may be measurable in blood. In general, treatment of poisoning includes decontamination of the eyes, skin, and gastrointestinal tract; respiratory support, including appropriate treatment of pulmonary edema with severe respiratory injury; and supportive care. Intravenous glucose may help reduce risk for hepatic injury. Dimercaprol (3–5 mg/kg every 6 hours in vegetable oil intramuscularly for four to six doses) has been used to treat poisoning with methyl bromide, although there is little evidence of efficacy.

OTHER REPELLANTS AND PESTICIDES

In the United States, *N,N*-diethyltoluamide (DEET) is the most commonly used insect repellent. Unlike other pesticides, repellents are purposely applied topically or to clothing by the general public. Severe irritation of the eyes and mucous membranes, and exacerbation of pre-existing skin disease have been reported. Application of formulations with high concentrations (more than 75% active ingredient) in tropical climates has resulted in severe dermatitis in antecubital and popliteal fossae (consistent with atopic reactions). It is rapidly absorbed dermally and by ingestion. Behavioral effects have been demonstrated in chronic feeding studies in rats, and several idiosyncratic cases of encephalopathy and death have been reported among

children heavily treated with DEET. In one study of exposed workers, there was an increased prevalence of symptoms associated with impaired cognitive function and sleep disturbances, and a trend toward poorer objectively measured neurobehavioral performance among highly exposed workers. Low-concentration active ingredient formulations of DEET are recommended and should be applied primarily to clothing and boots. Skin application should be kept to a minimum, especially in individuals with pre-existing skin conditions and in children. Quantitative measurements of DEET are only available in specialized laboratories, where absorbed DEET or its metabolites may be measured in the blood or urine. Treatment of acute poisoning includes decontamination and supportive care.

Boric acid has been promoted as an alternative to synthetic organic insecticides (organophosphates, carbamates, and pyrethroids) for cockroach and other insect control. Although the acute toxicity is low with some irritant effects, there have been numerous instances of poisoning from ingestion of boric acid and borates, especially in children. Though poorly absorbed across normal skin, boric acid and borates are well absorbed across damaged or abraded skin. Injury to the gastrointestinal tract, vascular system, and brain has been observed. Nausea, vomiting, diarrhea, tremors, stiff neck, seizures, metabolic acidosis, elevated blood urea nitrogen level, and jaundice have been reported. A beefy red rash with a boiled lobster appearance is characteristic of poisoning. Treatment includes decontamination. Activated charcoal is not helpful in the management of ingestion. Occupational poisoning has not been reported, and no chronic effects have been reported among exposed workers or survivors of acute poisoning.

New pesticides

There has been a new expansion of pesticidal chemicals, that present new challenges to clinicians responsible for caring for exposed subjects. Chemicals affecting biologic systems specific to the pest, such as chitin production in insects, are less likely to produce acute effects in humans. Others, such as the neonicotinoids (e.g., imidacloprid), have direct toxicologic mechanisms relevant to humans. Spinosins, spinosoids, and indoxacarb may activate nicotinic receptors and interact with GABA receptors, but to a lesser degree in mammalian tissues. Chlorfenapyr appears to uncouple oxidative phosphorylation, though human toxicity has not been reported. Fipronil, an insecticide, appears to act through blocking of GABA receptors, similar to but more specifically than lindane and endosulfan. No human intoxications have yet been published. Amitraz is a central α -(2)-agonist, and some human toxicity has been reported with overdoses, with the initial signs and symptoms being altered consciousness, disorientation, vomiting, variable miosis or mydriasis, hypotension, bradycardia, tachypnea, hypothermia, and generalized seizures. Hyperglycemia, glycosuria, and minimal increase in transaminase levels have been observed. CNS depression resolved spontaneously within 4–28 hours in all, with generally a good clinical outcome.⁶⁰

Given that many new chemicals are aimed at physiologic targets with homology in humans, it is likely that reports of human toxicity will emerge, as experience with these agents increases.

INERT INGREDIENTS

Pesticidal active ingredients are only a proportion of most pesticide formulations. In most countries, the rest of the formulation is listed on the label as inert ingredients, i.e., solvents, emulsifiers, spreaders, stickers, penetrants, anticaking agents, and other chemicals used in formulating the pesticide product. Volatile mixtures of aliphatic and aromatic hydrocarbons are the most common inert ingredients. Solvents and anticaking agents added to granulated formulations to prevent clumping, including some methyl naphthalenes, may be skin irritants and photosensitizers. Some hydrocarbon agents used to facilitate the penetration of active ingredients to the interior of plants (penetrants) may be skin and eye irritants. The identity of these ingredients, some of which have acute and chronic (carcinogenic, neurotoxic, or reproductive) systemic toxicities of their own, or may enhance absorption and bioavailability of the active pesticide, is frequently not provided. Many consumer groups have argued that inert ingredients should be identified to the public. Pesticide manufacturers maintain that such information is proprietary. A treating physician can request such information if it is necessary for the care of an exposed patient. The California Department of Food and Agriculture, unlike EPA, registers approximately 100 adjuvant chemicals as pesticides. In the treatment of acute pesticide poisoning, the potential effects of these components should be considered. In particular, tachypnea, cyanosis, tachycardia, hypoxia, and fever may indicate a lipoid pneumonitis from aspiration of petroleum distillates.

DERMATOLOGIC EFFECTS OF PESTICIDES

Dermatitis accounts for approximately one-third of reported pesticide-related illness, although for many more cases (for example, dermatitis in a golfer on a thiram-sprayed green), the cause may go unrecognized. One-half of all skin disease caused by pesticides in California is associated with the following six compounds: propargite, sulfur, glyphosate, methyl bromide, benomyl, and captan (Table 48.6). Many fungicides are skin irritants or sensitizers, especially chlorothalonil, thiram, maneb, zineb, captan, copper compounds, tributyl, and triphenyl tin compounds, and benomyl. Irritant and allergic dermatoses are common among fungicide-exposed individuals. Although allergic dermatitis is more likely to have a delayed onset following exposure, the clinical features are similar to irritant dermatitis and include erythema, blistering, fissuring, cracking, and lichenification. Patch testing is often necessary to identify allergic dermatitis and to distinguish it from the many other causes of dermatitis in agricultural workers. Because

contaminants or inert ingredients may be responsible for dermatitis, it is sometimes useful to test the commercial product in addition to the specific analytic-grade active ingredients. Treatment of contact dermatitis involves protection from exposure, including removal in cases of allergic or recalcitrant contact dermatitis (see Chapter 29.1), and may require moisturizing creams and topical steroids.

Phototoxic dermatitis has been caused by phenothiazine insecticides and by glyphosate. Chloracne and porphyria cutanea tarda associated with PCDDs and hexachlorobenzene are described above.

CARCINOGENIC EFFECTS OF PESTICIDES

Cohort studies of commercial pesticide applicators, who were exposed previously primarily to organochlorines, have

Table 48.7 Selected studies in which an association has been reported between cancer or congenital malformation and pesticide exposure

demonstrated a small increased risk of lung, bladder, brain, lymphatic, and hematopoietic cancers. In a few case-control studies, exposure to organochlorine insecticides (especially DDT, chlordane, and lindane) has been associated with soft tissue sarcoma, leukemia, and non-Hodgkin's lymphoma, although some workers may have had concomitant exposure to dioxin-contaminated herbicides. Among farm workers there are significant increases in risk for leukemia, stomach cancer, cervical cancer, and uterine cancer.⁶¹ A proportional mortality study of farm workers also observed increases in buccal cavity, larynx, esophagus, stomach, skin, and cervical cancers.^{62,63} Because most groups studied are exposed to multiple pesticides, it is difficult to identify specific carcinogenic agents, such as arsenic, which is a known cause of lung cancer, basal cell carcinoma of the skin, and hemangiosarcoma of the liver. In several case-control studies of childhood leukemia, parental use of pesticides in the home or garden was associated with a several-fold increase in risk. A few other selected pesticide exposures that are expected to cause human cancer are shown in Table 48.7. The relationships between chlorophenoxy acid herbicide exposures (including dioxin contaminants) and soft tissue sarcoma and non-Hodgkin's lymphoma have been discussed above. A list of pesticide agents associated with cancer is provided in Table 48.8. Toxicologic (usually rodent) studies are necessary to assess the risk of cancer from pesticides for which adequate epidemiologic data are not available.

In the United States, EPA generally sets legally established maximum limits (known as tolerances) for food residues, based on risk estimates from animal studies, which would allow no more than one additional cancer in 100,000 to 1 million persons exposed. Using EPA's risk estimates, one study estimating cumulative excess risk of cancer from food-borne residues to tolerances for 28 pesticides over a 70-year lifetime was 6 in 1000. Because children consume larger quantities of fruits and juices per kilogram of body weight than do adults, they may have a greater exposure to carcinogenic pesticide residues than is estimated by EPA for adults. This exposure occurs at a time when there exists the greatest potential latency for the subsequent development of cancer. Workers are another high-risk group because allow-

able exposures often are orders of magnitude greater than for consumers. The animal carcinogen alachlor, the most widely used herbicide in the United States, has been found to contaminate ground water, and has been banned for use in Massachusetts and Canada. Although most organophosphates have not been found to be carcinogenic in animals, dichlorvos is a probable human carcinogen. It has been estimated that there is a substantially increased risk of cancer from lifetime exposure to common household dichlorvos-impregnated insecticide strips. Many pesticides may be converted to carcinogenic nitroso compounds in the gastrointestinal tract; these include carbaryl, propoxur, fenuron, benzthiazuron, morpholine, atrazine, simazine, ziram, thiram, and ferbam.

REPRODUCTIVE EFFECTS OF PESTICIDES

Nasal hypoplasia is a well-recognized result of coumarin exposure among children of medically treated pregnant women. There are few other specific associations between a pesticide and congenital malformations, in part, because it is difficult to characterize exposure to a specific pesticide among pregnant women to allow assessment of teratogenicity. Unfortunately, exposure to mixtures of different pesticides is more frequent. The effects of exposure to herbicides, including those potentially contaminated with TCDD, have been most thoroughly investigated. More than 30 epidemiologic studies have looked at the relationship between birth defects, stillbirth, spontaneous abortion, and infertility, with chlorophenoxy acid herbicide exposure, yielding inconclusive results. Nevertheless, avoidance of exposure yielding to certain pesticides is important for pregnant women, especially during the first trimester, in view of the demonstrable animal teratogenicity of certain pesticides and some suggestive associations observed in epidemiologic studies, listed in Table 48.9.

The highest risk of adverse reproductive effect has been seen among male production workers heavily exposed to the nematocide DBCP. Production workers exposed to chlordecone also are reported to have developed oligospermia. An

MONITORING POPULATIONS EXPOSED TO PESTICIDES

Well-established parameters for monitoring workers for overexposure to most pesticides do not exist. In contrast, pesticide parent compounds or metabolites can be measured for a large number of pesticides to confirm exposure. Among the best characterized metabolite profiles are those of the organophosphates. Metabolites of many organophosphate pesticides in urine can be identified, and increasingly the specificity of the metabolite profiles is allowing for the identification of specific pesticides from urine samples. Table 48.10 presents the metabolite tests presently available through the Centers for Disease Control Division of Laboratory Sciences.

Monitoring of workers for pesticide overexposure requires more than the ability to measure a parent compound or metabolite. An effective monitoring program should include a well thought out and efficient plan for obtaining samples, interpreting data, and acting upon the results. Although true cholinesterase activity in the nervous tissue is not accessible, cholinesterase activity may be measured effectively in the plasma and in erythrocytes. Cholinesterase depression is often a preclinical indicator of overexposure to these compounds. At least one pre-exposure baseline measurement should be obtained but an average of two or three measurements is preferable due to the variability in many laboratories. The need for a

Table 48.10 Pesticides and the 'specific' metabolites that are measured at CDC

pre-exposure baseline is due to the fact that interindividual variability is large (observed 23% in one study).⁶⁴ The present standards in California recommend that if a worker's level falls below 80% of baseline, a workplace investigation should take place to ascertain the source of overexposure. Removal from exposure is required in California if erythrocyte cholinesterase activity falls to 70% or less of baseline or plasma cholinesterase falls to 60% of baseline value.

Workers removed from exposure should not return to work with pesticides until the cholinesterase activity returns to greater than 80% of baseline, and the reasons for the initial overexposure have been identified and corrected. Inter- and intra-laboratory variability over time may be considerable. Therefore, baseline and follow-up measurements of cholinesterase activity should be made by the same laboratory. Where feasible, in the setting of clinical screening or in epidemiologic studies, blood from the same unexposed individual (or individuals) may be included with samples of monitored workers to identify any major artifactual drift in laboratory results over time. The average range of variability of the activity of erythrocyte cholinesterase in unexposed individuals has been reported to be 8–12% (24–25% for plasma) over a 1-year period.

Where available, both erythrocyte and plasma cholinesterase measurements may be of value in the diagnosis and monitoring of exposed populations. There is some evidence that the plasma cholinesterase level may be a more sensitive indicator of low-level organophosphate exposure than is the erythrocyte cholinesterase concentration. The resolution of symptoms of acute poisoning also corresponds more closely to the early return of the plasma cholinesterase level to baseline. However, there are a few organophosphates (e.g., temephos and methyl parathion) that are reported preferentially to depress erythrocyte cholinesterase activity (Table 48.11). In addition, a variety

Adapted from: Hayes WJ, Laws ER. Handbook of pesticide toxicology. San Diego: Academic Press, 1991.

Table 48.11 Selected pesticides preferentially inhibiting erythrocyte or plasma cholinesterase

of other conditions (including hepatic disease; many chronic diseases; acute infections; myxedema; pregnancy; and treatment with estrogens, β -blockers, steroids, and isoniazid) may depress plasma cholinesterase activity. Plasma cholinesterase levels also may be genetically low in a small proportion (3%) of the general population (of clinical importance because of the prolonged paralysis that follows administration of succinylcholine [Anectine]).

With the exception of anemia, there are few clinical conditions that will artifactually depress erythrocyte cholinesterase. Erythrocyte cholinesterase once inhibited by an organophosphate often remains depressed for the life of the erythrocyte (and thus better reflects accumulated effects of exposure over weeks or months). Some guidelines for the interpretation of cholinesterase activity are presented in Table 48.12. Cholinesterase measurements may be of limited utility for screening *n*-methyl carbamate insecticide exposed workers, because carbamate-induced inhibition of cholinesterase is rapidly reversible, particularly with the dilution used in many cholinesterase testing methods. Specialized isotope-based techniques can be applied, but these are not routinely available for most laboratories.⁶⁵

Other monitoring tests for organophosphate exposure include urinary alkyl phosphates, which may be a more sensitive indicator of exposure to organophosphates than cholinesterase; however, these are not specific to individual agents. Measurement of urinary para-nitrophenol concentration has been used to monitor workers exposed to parathion. Although techniques are available for monitoring workers exposed to pesticides other than organophosphates (e.g., pentachlorophenol, DDT, synthetic anticoagulant rodenticides, and paraquat), these tests are not reliably predictive of clinical toxicity on an individual basis, and most are available only from specialized laboratories.

Clinical setting	Cholinesterase activity	
	Erythrocyte	Plasma
Acute, severe, organophosphate poisoning	Decreased	Decreased
Early recovery from poisoning (days to weeks)	Usually decreased	Decreased or normal
Late recovery from poisoning (weeks to 3 months)	Decreased or normal	Normal
Falsely normal activity:		
Mild poisoning (no baseline)	Often normal	Often normal
Carbamate poisoning	Often normal	Often normal
Early recovery of activity	Sometimes decreased	Often normal
Falsely decreased activity:		
Anemia	Often decreased	Normal
Liver disease	Normal	Decreased
Genetic plasma cholinesterase deficiency	Normal	Decreased
Pregnancy	Usually normal	Decreased

Table 48.12 Common clinical settings and relationship to cholinesterase activity

OTHER CONSIDERATIONS

Food and water contamination

The general public is routinely exposed to several pesticides. The National Health Assessment studies and other population studies have demonstrated that the vast majority of the US population have detectable levels of pesticide metabolites in urine. In a recent sampling of the US population (NHANES study) 2,5-dichlorophenol and n-naphthalene (constituents of moth repellents), TCP (the unique metabolite of chlorpyrifos), and pentachlorophenol (a wood preservative) were found in 94%, 86%, 82%, and 64%, respectively, of individuals sampled.⁶⁶ A study of a small sample of non-occupationally exposed individuals in Germany yielded similar findings.⁶⁷ In the United States, monitoring of pesticide residues in food by the Food and Drug Administration (FDA) routinely identifies 2–3% of samples with residues exceeding the EPA's tolerances, including 6% of samples of imported food. The FDA's testing methods can routinely test for only 163 of 316 pesticides for which legal maximum residue levels have been set. In addition, agricultural chemicals frequently impact on water quality. Although residues are generally low level, the EPA has found 74 pesticides in drinking water in 38 states. Forty-six of these pesticides are believed to have contaminated drinking water due to normal agricultural use. Although there are few epidemiologic studies, one investigation demonstrated subclinical abnormalities of immune function, including increased numbers of T8 lymphocytes and a decreased ratio of T4:T8 lymphocytes, among a cohort of women in Wisconsin drinking ground water contaminated with low levels of aldicarb (< 61 parts per billion). The impact of ground water contamination may be substantial, as over 75% of US cities and over 95% of rural populations in the US rely on ground water for drinking.

Domestic exposure to pesticides

Although for many workers pesticide use is associated with agriculture, the most intensive applications per acre occur

in cities, where insecticides are applied for cockroach and termite control, and insecticides, fungicides, and herbicides are applied to gardens and lawns. In one study, the estimated infant exposure to chlorpyrifos after a routine treatment for fleas was 1.2–5.2 times the No Observable Adverse Effect Level (NOAEL).^{66a} Although no systematic surveys have been conducted, in one study of chlordane-treated homes, more than 5% had persistent air-borne residues at levels above the National Academy of Sciences interim recommended limit of 5 micrograms/m³. Chlordane, which was until recently the treatment of choice for termite control, has been withdrawn by the manufacturer from the United States market; however, it continues to be marketed overseas. In Australia, increased breast milk organochlorine concentrations have correlated with applications for termite control.

A study of farm worker families from Washington State demonstrated a significant correlation between organophosphate pesticides in dust from homes and vehicles, with urinary metabolites in members of the household. This suggests an important contribution of indirect exposure to organophosphates among household contacts of farm workers.⁶⁸ A study of urban children demonstrated detectable levels of OP metabolites in nearly all participants studied, correlating with garden pesticide use.⁶⁹ A single study has pointed to food as the main source of organophosphate exposure in children; urban children eating an organic diet showed dramatically lower levels of organophosphate urinary metabolites than children eating a conventional diet.⁷⁰

ISSUES IN DEVELOPING COUNTRIES

Central America: A case study of pesticides in the developing world

Pesticide use

Pesticide use in Central America continues to increase, with annual consumption as high as 2 kg per inhabitant

and 20 kg per agricultural worker. Many of the most heavily used pesticides have high acute and chronic toxicity, including paraquat, mancozeb, terbufos, methamidophos, methyl bromide, carbofuran, methyl parathion, endosulfan, atrazine, copper arsenate, and aldicarb.²⁴ Additionally, the environmentally persistent organochlorine agents DDT, heptachlor, lindane, mirex, and pentachlorophenol are still registered in one or more Central American countries.⁷¹

Occupational exposures

Many toxic substances are frequently used in unsafe conditions, without adequate personal protective equipment, defective application equipment, and inappropriately high application rates. This results not only in risk to the applicator, but in contamination of the environment through runoff into waterways, and indirect exposure to living quarters. While there is evidence of increasing awareness of the dangers of pesticides, exposure assessment studies among small producers and plantation workers in Nicaragua and Costa Rica have observed significant ongoing problems in the handling of pesticides, despite training.^{21,23} Production factors (manual applications, open mixing and loading systems) and application technologies (knapsack and aerial spraying) result in risk for high exposure levels, with frequent accidents. Personal protective devices, even when used properly, may not provide sufficient protection under tropical conditions. In hot and humid conditions, clothing saturated by perspiration or by contact with wet plants allows pesticides to penetrate the skin. Paradoxically, occlusion of pesticides under improperly fitting protective clothing may result in increased dermal uptake.⁷²

Even when programs for safe pesticide use are fully implemented, protection of workers from pesticide-related illness remains limited as can be seen among pesticide poisonings on banana plantations in the Atlantic region of Costa Rica. Improvements in working conditions for applicators of toxic nematocides, including elimination of the extremely toxic aldicarb, resulted in a substantial decline in pesticide poisonings from 50 per 1000 in 1987 to 8 per 1000 banana workers in 1992. However, no further decrease could be achieved under the existing production techniques, with the incidence remaining about 7 per 1000 total banana workers between 1993 and 1996.¹⁴

Environmental exposure

Pesticide exposures extend to all sectors of the population. While less attention has been given to environmental than occupational health issues, non-occupational pesticide exposures in agricultural areas with intensive pesticide use may be considerable and complex. In Nicaragua, a population living in proximity to cotton fields with aerial spraying had significantly lower cholinesterase levels than a referent population in a non-adjacent field. These lowered levels were also associated with more acute and chronic health symptoms.⁹ Organophosphate residues were detected in the urine of about 30% of children in El Salvador whose fathers sprayed methyl parathion.⁷³ In Costa Rica, a number of studies have analyzed pesticides in

environmental samples in banana production areas. Surface waters, including rivers and creeks in national parks located downstream from banana plantations, have evidence of contamination by multiple pesticides.⁷⁴ Environmental samples taken near and inside houses and schools next to banana plantations demonstrated residues of the fungicide propiconazole in surface water and soil, and the insecticide chlorpyrifos in air samples.⁷⁵ Residues of multiple pesticides have been found in wells used for drinking water, in soil around the houses, in house and school dust, and in dust from mattresses of children (e.g., the fungicide chlorothalonil, the insecticide chlorpyrifos, and the nematocide ethoprophos).⁷⁶

Health effects of pesticides in Central America

Investigating health effects of pesticide exposures is often a difficult task in developing countries, due to financial and technical constraint, limited infrastructure, and insufficient expertise in occupational and environmental hygiene and epidemiology. Research on acute poisonings has been carried out in all seven Central American countries, but research on chronic and delayed health effects has occurred primarily in Nicaragua and Costa Rica.

Acute poisonings

As early as in the 1980s, a well-organized pesticide poisoning surveillance system was established in a cotton-growing area in Nicaragua. Its existence facilitated a series of studies on pesticide health effects in the region. These included a study describing trends of poisonings in the area and an outbreak with carbofuran,⁷⁷ and several studies of depression of cholinesterase levels among mechanics of fumigation airplanes,¹⁰ workers using closed pesticide mixing and loading systems, and among children living close to a fumigation airport.⁷⁸ A study assessing the degree of under-reporting concluded that despite education of physicians in the reporting area, only one-third of acute medically treated pesticide poisoning cases were reported to the registry. During the last half of the 1990s, surveillance systems of acute health effects from pesticides were established in all Central American countries, with 6934 acute pesticide poisonings reported during 2000. However, under-reporting and under-registration are estimated to be in excess of 95% in most countries.⁷⁹ Based on the degree of under-reporting in six of the seven countries, there are an estimated 400,000 symptomatic poisoning episodes annually.¹⁷

Skin injuries

Today, skin injuries are probably more widespread than systemic poisonings. Increasing rates of dermal lesions have been observed, particularly among female agricultural workers, with annual rates as high as 7.5 per 100 women employed in the banana and ornamental plant industries in Costa Rica.⁸⁰ Among men, the herbicide paraquat is the most frequently reported pesticide associated with skin and eye injuries in Costa Rica.⁴⁸ In 1993 and 1996, 40 and 25 per 100 herbicide sprayers on banana plantations, respectively, filed a claim for an occupational pesticide-related

accident requiring medical attention – the majority due to paraquat.⁴⁸ The fungicide chlorothalonil has been identified as a risk factor for dermatitis among banana plantation workers in Panama.⁸¹ On Panamanian banana plantations, pesticide applicators are at risk for allergic and contact dermatitis.⁸² At least 16% of the workers were sensitized to one or more pesticides in use, including carbaryl, benomyl, ethoprophos, chlorothalonil, imazalil, glyphosate, thiabendazole, chlorpyrifos, oxyfluorfen, propiconazole, and tridemorph.

Chronic and delayed health effects

Cancer risk in populations of rural counties of Costa Rica with high pesticide use tends to be higher than in rural counties with low pesticide use. This ecologic association was evident for both the overall cancer risk, and the risk for a number of specific cancer sites, in particular female reproductive cancers in women, and lung cancer; in men and women.⁸³ Male banana workers in Costa Rica had excess risk for penile cancer, melanoma, and lung cancer; and female banana workers had increased risk for cervical cancer and leukemia.⁸⁴ The lung cancer excess was evident also among a subset of DBCP-exposed workers.⁸⁵

The most striking reproductive effects have been related to sterility occurring in thousands of male banana workers exposed to DBCP during the 1970s throughout Central America and other countries.⁸⁶ In Costa Rica, wives of congenitally DBCP-exposed men have also claimed reproductive effects, such as sterility and congenital malformations, but no formal studies have been carried out. Genotoxic effects were observed among banana workers who had been exposed to the nematocide dibromochloropropane (DBCP) in the 1970s, more evident in those with specific polymorphisms.⁸⁷ Among female packing plant workers employed at banana plantations, with exposure to the fungicides thiabendazole and imazalil, an increased prevalence of genotoxic changes was observed.⁸⁸

Persistent damage to the central and peripheral nervous systems has also been observed in workers previously poisoned with cholinesterase-inhibiting pesticides in both Nicaragua and Costa Rica.^{39,77,85,89–91} Neurobehavioral deficits were found among male vector control sprayers in Costa Rica who had been previously exposed to DDT.⁹² An association between long-term paraquat exposure and respiratory symptoms was observed in Nicaragua, but no alterations were found in tests of pulmonary function.⁹³

Pesticide policies

For decades, 'safe use' approaches have been espoused by the pesticide industry to reduce risks in Central America and developing countries in general, presuming that pesticides are indispensable and, if properly handled, will not cause unreasonable harm.⁹⁴ Environmental contamination related to pesticide use has been attributed to insufficient regulation and unawareness among pesticide users, and it has been assumed that strengthening of regulations and education of users would lead to an acceptable level of pesticide safety. However, the major international 'safe use' initiatives have been limited in scope. Adherence to Food and Agriculture

Organization International Code of Conduct (the most important initiative to prevent undesirable effects of pesticides in developing countries by strengthening pesticide regulation) is voluntary. The Prior Informed Consent (PIC) list of the Rotterdam Convention contains only a few dozen pesticides, and does not include some pesticides causing unique problems in developing countries.

The 'Safe Use Initiative' of the Global Crop Protection Federation (today, Croplife International), aimed at widespread training in collaboration with governments, has not produced evidence of substantial improvements. In fact, many industry-based training materials promote pesticide use in developing countries, and a number of industrialized countries continue to manufacture domestically prohibited pesticides for export to developing countries. The WHO International Program for Chemical Safety (IPCS), with guidelines for pesticide registration and control in developing countries, emphasizes the prevention of acute health effects. Pesticides classified as 'non-hazardous' but with acknowledged chronic and delayed effects are ubiquitous, such as mancozeb, maneb, and chlorothalonil in Central America. Thus, 'safe use' programs have yet to achieve pesticide safety in agriculture in developing countries.

A major limitation experienced by many developing countries is lack of human and technical resources. Often the risk assessment performed by regulatory authorities in registering pesticides in these countries is no more than the copying of international guidelines or decisions by major regulatory agencies. There is often incomplete comprehension of this information. No resources exist to carry out systematic, continuous monitoring of hazards, exposure, or adverse health or ecologic effects. Preventive approaches, based on available technology, training and regulation, is generally absent in developing countries. Additionally, 'safe use' efforts often promote the use of pesticides, and may subtly encourage countries to desist from investing in sustainable agriculture, with alternative pest control approaches.

A reduction in pesticide use has been achieved in some developing countries. Many select examples do exist of successful Integrated Pest Management (IPM) programs, with drastically reduced pesticide use, in Southeast Asia and Central America, for important crops such as sugar cane, coffee, corn, citrus, and potato. Beyond IPM, organic agriculture integrates other principles of sustainable land use. Studies are increasingly showing that organic agriculture can produce compatible yields with traditional pesticide-dependent production systems, and may be more profitable in the longer term. However, profound changes in international and national agricultural policies, steering towards sustainable agriculture based on non-chemical pest management, are needed to effectively address pesticide-related health risks in developing countries.

PREVENTION AND REGULATION

Until recently, the most important legislation concerning pesticides in the United States has been the Food,

Insecticide, Fungicide, and Rodenticide Act (FIFRA) of 1947. First enforced by the FDA, EPA became the lead agency in its implementation in 1970. For a new pesticide to be registered for sale, the registrant must submit acute and subchronic toxicity studies, as well as chronic studies of neurotoxic, reproductive, mutagenic, and carcinogenic effects. Based on these data, food tolerances are set. Labeling requirements specifying permitted uses are designated, including general use (for sale to the general public) or restricted use (only for use under the supervision of trained licensed operators). Unfortunately, there was a large backlog of old pesticides that were registered without appropriate toxicologic studies under a “grandfather” clause in FIFRA. Many of these pesticides still have not been adequately evaluated.

In addition, the credibility of the registration process was undermined in the early 1980s, when it became known that the largest private contract testing laboratory in the United States had conducted 200 scientifically invalid or fraudulent studies that were relied on to support registration of 140 pesticides. A recent Federal survey found that the data required by EPA for chronic toxicity were incomplete for all 50 widely used agricultural pesticides reviewed. In the United States, regulations may vary from state to state, with some states having more stringent registration standards and re-entry intervals (Table 48.13). Because the EPA was primarily concerned with environmental and food contamination, there existed no standard requirement for data to be collected on worker exposure or worker health effects. As a result, relatively little was

known or available about the health effects of pesticides among workers exposed to levels occurring in the agricultural workplace.

A new act, the Food Quality Protection Act (FQPA; FFDCA P.L. 104-170), amended the FIFRA and Federal Food, Drug, and Cosmetic Act in 1996. Under the amended Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA) the EPA registers pesticides for use in the United States and prescribes labeling and other regulatory requirements to prevent unreasonable adverse effects on health or the environment. EPA also establishes food tolerances (maximum legally permissible levels) for individual pesticides in food. The FQPA facilitates a more consistent, scientifically-based, and protective approach to regulating pesticide use. The FQPA requires that EPA control, through registration, the amount of pesticides to which one is exposed through all possible routes of exposure. Pesticides are grouped according to mechanisms of action. For example, all cholinesterase inhibitors are considered and regulated as a whole. Reasonable certainty of no harm is a criterion for regulation, and accounts for vulnerable populations such as infants and children. Safer pesticides receive expedited handling and are thus encouraged.

Among pesticide laws, only the 1992 Worker Protection Standard (WPS) is designed to safeguard the health of agricultural workers and pesticide handlers. Other US pesticide regulations address primarily the risks posed by pesticides to the purchaser of the product, the environment, and the consumer. The WPS covers several important groups (e.g., handlers and field workers), regulating certain

Pesticide	California						EPA

Table 48.13 Field re-entry intervals in days or hours for selected pesticides (California and Environmental Protection Agency [EPA] Regulations)

application activities and stipulating several safety practices. Components of the regulation include training, re-entry, decontamination, personal protective equipment, and referral to medical providers. Workers are excluded from entering a pesticide-treated area during the restricted entry interval, which must be stated on the pesticide label. Personal protective equipment (PPE) must be provided to the handlers, and anyone entering the area before the restricted entry interval expires. PPE must be maintained by the employer. Notification must be posted clearly in areas of application to prevent early entry; water, soap, and towels for routine washing and emergency decontamination must be available to handlers.

The employer is responsible for assuring emergency transportation and information on the pesticide to a medical care facility, in the event that a worker or handler is made ill by exposure. Training is required for all workers and handlers, and a pesticide safety poster must be displayed. Handlers and workers must be informed of pesticide label requirements. Unlike standards developed by OSHA, no exposure measurements or biologic monitoring are required under WPS, despite the high toxicity of many of the chemicals involved. The effectiveness of the rule rests on the assumption that personal protective equipment will be effective for handlers, and that field workers will be adequately protected by restrictions from entering treated fields.

Exposure control

Engineering controls (for example, enclosed cabs with filtered air on tractor-pulled sprayers) have been demonstrated to reduce exposure markedly. Closed-system mixing and loading units, which are required for EPA category 1 pesticides in California, are reported to decrease exposure to these high-risk workers by as much as 10-fold. Correctly engineered mixing equipment will prevent the backflow of pesticides into water sources, and pastes may reduce exposure compared with liquids. Some inert solvent ingredients may reduce or increase toxicity. For example, parathion formulated with xylene is less toxic than an equivalent dose of parathion alone. Granules result in less respiratory exposure and perhaps less dermal exposure than powders, and powders in water-soluble bags may eliminate the need for human contact with the product during mixing and loading. Unfortunately, despite the fact that engineering controls are most effective in preventing overexposure, the WPS puts little emphasis on them. In California, engineering controls are required for all Category 1 pesticide loading operations.

Workers should be trained in the use of engineering controls, in appropriate personal hygiene (washing before eating, bathing on finishing work, and no smoking on the job), in the appropriate use of personal protective equipment, and in first aid measures in case of an accident. Gloves and coveralls are important measures of protection, although few data exist on the penetration of rubber or neoprene materials by the liquid formulations of many pesticides. Work clothes should be laundered separately

from regular clothing. In a study of clothing contaminated with dilute methyl parathion (1.25% active ingredient), a significant reduction in residues was seen with each of the first three washings, whereas clothing contaminated with methyl parathion concentrate continued to have significant residues after 10 washings. In general, clothing contaminated with pesticide concentrate should be discarded, and disposable coveralls should be considered for workers who are exposed to concentrates of hazardous pesticides.
