Chapter 49

Low-Level Environmental Exposures

Mark R Cullen

One of the cardinal rules of toxicology is that the biologic response to a physical or chemical hazard is a definable function of the exposure dose. Although this relationship may take one of several forms, depending on the toxin and the response, the general principle is that health effects from higher levels of exposure will be more frequent and/or more severe than those associated with lower levels. This is one of the guiding principles of occupational and environmental medicine (OEM) diagnosis and management.

Fortunately, extremely high levels of exposure to hazards, although risky, are generally uncommon. For any given substance, only a relatively small number of people, if any, are likely to be exposed to doses in the lethal or highly toxic range (e.g., accidental or uncontrolled exposure), although proportionally more may have moderate exposures (e.g., controlled occupational exposures). Many more people may encounter low-level exposures in the general environment (e.g., from air, water, or food contaminated by industrial wastes). A sizable number may have exposure to small doses of potential hazards such as may occur when ambient air is recycled indoors without dilution by fresh air. Finally, almost everybody is exposed to the extremely low levels of contaminants that are the background of modern society. This generic, inverse relationship between the level of hazardous exposure and the numbers of individuals exposed is depicted schematically in Figure 49.1.

Because so many more people are exposed to low levels than high ones, a substantial number of people with symptoms that are attributed to environmental factors are, in fact, only minimally exposed. Such patients are common in clinical practice, even though the proportion of all comparably exposed people who have complaints may be low.

For obvious reasons, patients with environmental complaints associated with small levels of exposure are much more difficult to evaluate than their more extensively exposed counterparts. Using the principles and approach enunciated in the Introduction and throughout this text, establishing a cause-and-effect relationship is difficult because the a priori likelihood for getting sick from such exposures is low; even rare diseases of other causes may strike as commonly. The exposures themselves, often many orders of magnitude lower than presently accepted threshold limit values (TLVs) or health guidelines, may be difficult or impossible to measure. The natural clinical response is to be skeptical, and many OEM experts have taken the view that such cases are so unlikely

to have environmental origins that they should be quickly dismissed and shunted to the care of other specialists. This approach may be reinforced by the impression that complaints by these patients are being driven or amplified by considerations of financial gain, job alienation, or other non-health-related factors.

However, there are compelling scientific and empiric reasons why such cases cannot be trivially dismissed without careful individual consideration of each one.

1. For all mechanisms of toxicity other than direct action, there is no supportable evidence of a clear threshold dose below which the effects cannot occur. This is especially important for idiosyncratic (e.g., allergic) effects, which may occur at very low levels in sensitized individuals. Even assuming that the likelihood of the effects is a function of the dose, the sheer numbers exposed to low doses would predict that the effects would occasionally occur.

2. For direct-acting toxins, the existence of a threshold does not imply that the threshold is the same in all hosts. Again, theoretically assuming that certain variable host factors determine the threshold level, the large number exposed to low doses would favor occasional very low level reactors.

3. In some situations that have been well studied, such as the non-specific building-related illness (NSBRI, see Chapter 50), the epidemiologic pattern of responses strongly supports a toxic response to some environmental factor or factors, even though the mechanism for this remains obscure.

4. Certain recently described patterns of clinical responses to environmental agents are occurring too pervasively and recognizably to dismiss them out of hand, despite the absence of coherent toxicologic or epidemiologic explanation at this time.

Given these foundations, it is the premise of this chapter that individuals with complaints apparently related to an environmental factor or factors at low level merit OEM evaluation. In the sections that follow, we shall discuss the differential diagnosis of health problems associated with low-dose exposures, describe the approaches to the workup and management of these challenging cases, and delineate what is known about these patterns of illness not discussed elsewhere in this text.

DIFFERENTIAL DIAGNOSIS

Some patients or their physicians may come to believe, for whatever reasons, that a chronic or persistent symptom

Figure 49.1: Exponential curve describing approximate relation between dose of any hazard, as an order of magnitude relative to a threshold limit value (TLV), and the number of persons likely to be exposed regularly at that level. In society as a whole, heavy disaster or occupational exposures affect relatively few persons, whereas millions experience low levels of exposure in contaminated food, air, and water

pattern or an established clinical abnormality or diagnosis is caused by a low-level environmental exposure. An example is the widespread attribution of various clinical syndromes to mercury exposure from amalgam in dental fillings (see Chapter 39.9). Similarly, an abnormality of liver function might be attributed to exposure to chemicals in a toxic waste site near the patient's home or a cancer might be attributed to an agent encountered occasionally or at very low levels at work. In such cases, the task of differential diagnosis is straightforward, if technically challenging. The approach is the one outlined in Chapter 3, i.e., the specific exposure is elucidated, the dose is quantified as best possible, data sets (toxicologic, epidemiologic, and clinical) are explored to determine the possibility and likelihood of relevant health effects, and the probability of the purported versus other possible causes is then calculated. The one caveat is to remember the possibility that the patient may be more susceptible than average, so that any significant possibility, even if not highly probable, must be taken seriously.

There are, however, a different subgroup of patients for whom this approach will not work. These are patients whose primary problem is that they react in some predictable way when exposed to certain environments or agents. Although they may differ greatly in the nature and scope of their symptoms, the circumstances that appear to induce them, and the severity of the complaints, they share certain features that are recognizable to the experienced practitioner as follows.

1. Symptoms, typically dermal, cardiorespiratory, gastrointestinal, neurologic, or musculoskeletal, occur episodically after exposure to some environment(s) or environmental agent(s).

2. Chronic fatigue, diffuse musculoskeletal pains or other non-specific complaints may prevail between episodes.
3. Constitutional signs of health, as measured by physical examination and routine laboratory studies, are preserved.

With such patients it is difficult either to confirm or exclude a toxicologic basis for the symptoms. Often, it is difficult to establish even the physiologic nature of the reactions, which may range from short-lived episodes of apparent autonomic discharge, e.g., tachycardia, tachypnea, and sweating, to protracted episodes of symptoms unassociated with measurable physiologic change. Nonetheless, the perceived temporal association between exposure and effect begs consideration of the following possibilities.

1. *Classic allergy to an environmental agent.* Many substances, especially certain small molecules, like formaldehyde, or certain biologic antigens, like those on mold, are ubiquitous in air, food, and water. For patients who are atopic or others whose complaint pattern could be explained by classic immunoglobulin or cell-mediated and related allergic responses, this possibility should never be overlooked. This otherwise straightforward diagnosis may be especially challenging because severely atopic patients often react to non-specific stimuli, such as irritants, and symptoms may persist between attacks, despite the absence of any stimulus, for unclear reasons.

2. *Chemically induced stimulation of a vascular or secretory disorder.* Migraine syndromes, hereditary diseases (such as porphyria), and endocrine tumors (such as pheochromocytoma) have been described that respond to specific chemical or physical stimuli, although almost always the stimulus has been a high-level exposure, such as a drug, alcohol, or other ingestion. Thus, although this possibility

is remote, it should be considered when highly stereotyped responses are described and other features consistent with such a diagnosis are noted.

3. *Classic anxiety disorder.* Phobias, especially claustrophobia and agoraphobia, may present as multisymptom reactions to specific environments; the environmental factor is presumably misinterpreted by the patient. Similarly, panic disorder, by definition attacks unprovoked by a defined stimulus, may be construed by the patient as being caused by the presence of a chemical or other contaminant. Obsessive-compulsive disorder may also present as reactions to environmental chemicals. Somatization disorder is characterized by a constellation of complaints referable to many organs that defy explanation. Typically the pattern is life-long, and the symptoms do not cycle in any predictable fashion related to environmental exposure. These diagnostic considerations are important because the disorders are common and treatable. However, they are not diagnoses of exclusion (as is often presumed) but are, in fact, well-characterized, affirmatively diagnosable conditions that should be assessed by a specialist (see Chapter 28.3).

4. *Non-specific building-related illness (NSBRI).* As noted previously and described in detail in Chapter 50, an epidemiologically defined disorder caused by poor ventilation has emerged, which is characterized by fatigue, respiratory, dermal, and central nervous system complaints associated with a specific environment. The hallmarks are the concurrence of illness in coworkers and the isolation of difficulties to a single environment with improvement in others.

5. *Multiple chemical sensitivities (MCS).* This syndrome of unknown pathogenesis applies to the subgroup of these patients whose symptoms are referable to multiple systems and occur in multiple, unrelated environments in which low levels of chemicals are perceived. Common stimulants are perfumes and fragrances, petroleum derivatives, and smoke. The syndrome often, but not always, starts after a well-defined environmental event, such as a reaction to a more demonstrably toxic dose of an organic solvent, pesticide, or respiratory irritant, or after an episode of apparent NSBRI. Although manifestations of anxiety and/or depression are evident in many severely affected individuals, not all meet established criteria for primary anxiety. More importantly, neither the peculiar pattern of symptoms nor responses to therapy directed at these associated disorders suggest that MCS – whatever it is – is merely a misdiagnosis for anxiety or depression.

DIAGNOSTIC APPROACH TO PATIENTS WITH EPISODIC SYMPTOMS

Because the management and environmental ramifications differ greatly among these alternatives, it is crucial to differentiate them. However, usually these patients are referred to an OEM physician relatively late, after extensive workup and treatment has already been attempted, frustrating the patient, physicians (often many), and employ-

ers. For this reason, it is important to proceed efficiently and, to the extent possible, avoid extensive use of the laboratory and/or consultants to endlessly explore 'one last possibility' before providing a diagnosis and associated management plan.

Fortunately, although the stakes are high, the problem of differential diagnosis is not insurmountable, or even difficult, on close scrutiny. A detailed illness and exposure history, repeated and reviewed as often as is necessary, is the most important differential tool; the physical examination and laboratory results play an ancillary role. The following five historic features can provide considerable diagnostic insight.

1. *The spectrum of symptoms.* Classic allergies, secretory or vasospastic disorders, and panic disorder are characterized by fairly discrete and specific attacks. Usually, the manifestations of each attack are similar; between the attacks, there is recovery. Anxiety disorders (except pure panic) and MCS, on the other hand, share a more pleomorphic clinical character, often with diverse and changing patterns of symptoms and frequent persistence of symptoms between the exposures that precipitate the acute reactions.

2. *The diversity of environmental circumstances in which reactions are reported to occur.* NSBRI is characterized by reactions to a single, usually work, environment, in which the patient spends a large portion of time. An occurrence after only a brief exposure or in multiple settings rules this diagnosis out or suggests that NSBRI has been complicated by another problem, such as MCS. Similarly, although allergic reactions or stimulation of a secretory or vasospastic event could occur in several different settings, such reactions occurring ubiquitously or to dozens of apparently unrelated precipitants is biologically implausible.

3. *The nature of the environments that are associated with reactions.* Tolerance to an offending agent in one situation, e.g., at work, but not in another, e.g., outdoors, suggests that some characteristic of these environments other than the suspect agent is central; one must consider the possibilities of claustrophobia and agoraphobia. Such circumstantial factors also strongly militate against the classic allergy and secretory and vasospastic stimulation. Likewise, tolerance to tobacco smoke, which contains substantial doses of numerous chemicals at impressive levels, usually excludes MCS, although severe, dysfunctional addiction may rarely persist even after MCS is acquired.

4. *The predictability of environmental response.* The frequent occurrence of reactions in the absence of any environmental factor evident to the patient suggests the likelihood of panic, other anxiety disorder, or an endogenous precipitant of a secretory problem. Although unprovoked attacks occur in classic allergy or MCS, such episodes rule out NSBRI entirely or suggest it has become complicated.

5. *The onset of illness.* The patient's description of the earliest manifestations of illness, coupled with a detailed review of all prior medical conditions, can be helpful. NSBRI typically begins insidiously some time after beginning work in a specific building or after a building is renovated or otherwise physically altered. Classic allergies and MCS may occur after some period or episode of a demonstrably toxic

Syndrome	Spectrum of symptoms	Number of precipitating environments	Types of environments	Symptoms occur in unpredictable environment	Symptom onset
Classic allergy	Limited	Few	Specific	Occasionally	May be discrete
Secretory syndrome	Limited	Few	May appear diverse	Often	May be discrete
Panic disorder	Limited	Many	Diverse	Often	May be discrete
Anxiety disorders	Diverse	Many	May be recognizable	Often	Insidious
NSBRI*	Diverse	One	Single indoor environment	Never	Insidious or discrete
MCS	Diverse	Many	Diverse	Occasionally	Usually discrete

*NSBRI: Non-Specific Building Related Illness; MCS, Multiple Chemical Sensitivities.

Table 49.1 Differential features of disorders attributed to low-level environmental exposures

exposure associated with severe symptoms, whereas the anxiety disorders rarely have a clear beginning. The history in such patients typically reveals prior unexplained illness, often dating back to childhood. Although such a history does not exclude other possibilities, it should flag the need for a thorough investigation of these treatable disorders.

These historic features are summarized in Table 49.1. Collectively, they should allow the clinician to focus on the most likely entity or entities and reduce the need for exhaustive laboratory testing or referrals in all but the most difficult cases. Further evaluation and testing should follow the basic principles of the most likely candidates. Classic allergic disorders resulting from environmental agents are discussed in Chapters 19.2 and 50. NSBRI is discussed, along with specific building-related illnesses, in Chapter 50. The anxiety disorders are discussed in context in Chapter 28.3. The workup of migraine syndromes and secretory disorders, the rarest but possibly most serious consideration here, is beyond the scope of this text.

What remains is a discussion of the single most common diagnostic category for these patients, i.e., multiple chemical sensitivities (MCS). The remainder of the chapter is devoted to this controversial topic.

MULTIPLE CHEMICAL SENSITIVITIES (MCS)

This label was introduced in the mid 1980s to describe a group of patients who have symptoms in response to multiple low-level environmental exposures.¹ Gradually, the term MCS has emerged as the single most commonly used, but not exclusive designation for those who meet the following case definition.

1. The syndrome is acquired, usually after the occurrence of a more clearly evident (although not necessarily serious) health event caused by environmental exposure, such as solvent intoxication, respiratory tract irritation, pesticide poisoning, or NSBRI.
2. The patient experiences multiple symptoms referable to several organ systems, almost always including the central nervous system.
3. Although there may be persistent complaints between exposures, the symptoms are characteristically and predictably precipitated by a perceived environmental exposure.

4. The agents that may precipitate the symptoms are multiple and chemically diverse.
5. The doses of these agents that precipitate symptoms are at least two orders of magnitude lower than the established thresholds for acute health effects.
6. No test of physiologic function can explain the symptoms. Although there may be clinical abnormalities, such as mild bronchospasm or neuropsychologic dysfunction, these are typically non-specific and insufficient to explain the full scope of the illness pattern.
7. No other organic disorder is present that can better explain the pattern of symptoms.

Similar to other clinical case definitions of disorders of unknown cause that have no specific pathologic finding or test, problems exist with the MCS definition. Most obviously, many clinicians have used and continue to use other less well-defined terms to designate the disorders in these patients, causing confusion in the literature. A new designation² – idiopathic environmental intolerance – has some heuristic appeal but its introduction has only made matters worse. Furthermore, many patients whose syndrome fulfills part but not all of this case definition have had their condition diagnosed clinically as MCS anyway; this avoids having to deal with patients meeting the criteria for no known disorder but creates blurry margins for MCS. Finally, because many clinicians and investigators question whether MCS designates a unique disorder or a new presentation of another disease, which is toxic or psychologic (see subsequent discussion), many refuse to apply it under any circumstance.

These caveats notwithstanding, the MCS designation has allowed at least the beginning of some uniformity in the approach to the study and management of these curious cases. As long as the clinician recognizes that labeling a patient with MCS neither explains the basis of the illness – which remains unknown – nor ensures its successful resolution, a narrow use of this term applied to syndromes meeting the criteria above is probably clinically and scientifically reasonable at this time.

Epidemiology

Since the first edition of this book there has been substantial progress in our understanding of the epidemiology of MCS, despite the absence of a uniform definition or clear

disease marker. Although no evidence has appeared to contradict the perception that clinically manifest MCS is uncommon,³ population surveys in North Carolina and California^{4,5} have demonstrated that as much as 6% of the population may have symptoms compatible with the diagnosis, sufficient to alter their lives in some ways to accommodate them. In the most comprehensive study of veterans of the Persian Gulf conflict of 1990–91, conducted among present and former military personnel in Iowa,⁶ over 5% of military who returned from the war complained of symptoms which met the study criteria for MCS. Perhaps more alarmingly, military personnel *not* in the conflict, presumably a young healthy control population, had a rate of over 2.5% using the questionnaire instrument; two out of three in each group carried a physician diagnosis of MCS or equivalent designation. Another important contribution has been recent evidence of a strong overlap in symptom patterns between clinical patients with MCS and those with both chronic fatigue syndrome and fibromyalgia, better characterized syndromes which themselves lack pathogenic mechanisms or biologic disease markers.

The newly available data have lent further support to the idea that women are more frequently affected than men, by perhaps 2–4-fold,^{3–6} but the disease is not unheard of in men, who constitute the majority of those with symptoms acquired after the war. Middle age is still the most commonly affected age group, but cases have been described from school age through retirement. Contrary to earlier speculation, risk for the disorder appears relatively evenly distributed by social class and race.^{5,6}

Pathogenesis

As noted, the cause of MCS remains obscure. Broadly speaking, there are two schools of thought, i.e., the biologic and the psychologic. The former likens MCS to other allergic disorders and has postulated immune, epithelial, or central nervous system dysfunction as the basis for MCS. There were early data to support abnormal chemosensory responses in affected subjects, such as altered olfaction or trigeminal function, which could be related to such a proposed mechanism, but there are more comprehensive recent data which suggest the alteration is in conscious perception, not sensory function *per se*.^{7,8} Data on immunologic defects and abnormal regional central nervous system metabolism have been reported but not confirmed by blinded and well-controlled studies.^{9,10} Whether any such lesions, even if confirmed, are predisposing or represent the manifestation of disease also remains to be determined.

The psychologic view of the illness is based on the well-documented high rate of anxiety and affective symptoms evident in patients compared with other populations.^{11–13} A model using classic constructs from behavioral theory has elegantly explained some cases, and therapy based on behavioral approaches has been anecdotally successful.¹⁴ One investigator has reported a high rate of childhood abuse among patients with MCS, along with anecdotal

data on effective therapy focused on this issue.¹⁵ Others have attempted to demonstrate that patient responses to environmental agents that purportedly cause symptoms do not do so predictably when blinded placebo challenges are interspersed among the offending agents, implying that suggestion or other psychologic factors are important. Acute reactions to chemicals in these patients bear some clinical resemblance to panic attacks, another feature suggesting a possible psychologic mechanism.¹⁶

Unfortunately, neither view has been subjected to adequate scrutiny. One randomized, double-blind controlled therapeutic trial of a selective serotonin uptake inhibitor with excellent activity against known anxiety disorders and depression found, surprisingly, that patients with MCS had no reactions to the placebo yet a marked increase in their apparent reactivity while receiving the active medication; none improved, as had been anticipated by the investigators.¹⁷ All other existing studies have been cross-sectional and suffer from either inadequate control or unsatisfactory classification of patients using a standard set of criteria.

Given these inconsistencies, many suggest that both organic and psychologic factors may be operating. Meanwhile, it is probably prudent to avoid any dogmatic view that is likely to be incorrect when a fuller appreciation of MCS becomes available.

Clinical course

Uncertainties about its pathogenesis notwithstanding, much experience has been gained with MCS and its natural history. Two distinctive illness patterns are discernible among these patients. Some have striking attacks after exposure, followed by recovery to normal or near normal; they remain well as long as the offending agents are avoided. Others have persistent and often disabling symptoms, which are made worse by exposure but never entirely relieved. Contrary to the perception of many patients that the illness runs an inexorable downhill course, current experience suggests that MCS tends to run a naturally cyclic pattern after initial onset. Irrespective of the therapies the patient or clinician may try, the illness is punctuated by periods of greater and lesser discomfort associated with exposure to environmental agents and constitutional complaints. While it may be tempting to ascribe these changes to environmental or therapeutic factors, observations over longer periods suggest an unrelated rhythmicity.

The observation of the cyclic nature of the illness has two important clinical corollaries. First, no established, measurable physiologic consequences or complications over long-term follow-up have been documented. Limited data on psychotherapy to the contrary, there is no convincing evidence that patients with MCS ever revert to their premorbid state. This is not to say that major functional and symptomatic improvements are not achievable but that the goal of cure, i.e., return to prior health, does not occur spontaneously and is not generally achievable with present therapeutic modalities.

Treatment

As these considerations would suggest, there remain no established specific therapies for MCS. Almost every patient needs the following four things.

1. *Education.* A careful explanation of MCS, including what is and is not known about its cause and natural history, is required for the patient, their family, and often the employer. It is crucial that the patient understand that the disorder is neither lethal nor curable.

2. *Support.* This may include self-help groups, counselors, social workers, or more formal clinical care to manage the inevitable psychologic and social issues that the patient with MCS will have to confront. The goal should be return to the highest level of social, personal and occupational function of which the patient is capable. Problematically, patients who believe fervently that their disorder is purely physical in nature often resist such efforts, or view them as merely 'tactical'. Evidence suggests it is worthwhile trying to convince them otherwise.

3. *Environmental modification.* Although removing the patient from all contact with modern life is both highly counterproductive and unlikely to succeed, some changes are important, especially removal or reduction in the heaviest exposures that were associated with the onset of illness. Often, this entails a work modification and changes in the home environment to make it comfortable and safe. Unfortunately, clinicians inclined to the view that MCS is purely psychological often resist this aspect, wishing to avoid 'reinforcing' the patient's sometimes intractable view that the problem is purely physical. However, with or without the clinician's support, most patients make the changes anyway; withholding approval breeds distrust and undermines the possibility for a therapeutic relationship.

4. *Economic support.* If MCS results in profound levels of disability or a marked reduction in income because of job modification, it is necessary to use available entitlement and benefit programs to guarantee that severe hardship does not undermine treatment and rehabilitation. Rehabilitation to promote new occupational possibilities within limitations is highly desirable. The same comments as above with regard to the views of the clinician are also germane in this regard.

Beyond these measures, little else has been helpful for more than an occasional patient. Radical therapies, including isolation from all chemicals (e.g., moving to the desert or mountains), megavitamins, antioxidants, desensitization regimens, and fat purification are expensive and of unproved value. Behavioral therapy has been successful in a few widely reported cases¹⁸ but has not been studied in a larger population, so efficacy currently remains unproven. Similarly, although psychiatric treatment, including either pharmacologic and/or psychotherapeutic modalities, is always indicated to manage depressive features or trou-

bling anxiety when present, current evidence does not suggest that such therapy is particularly successful for modifying the manifestations of MCS, nor is it clinically indicated for that purpose.

Chapter 50

Exposures in Indoor Environments

Michael J Hodgson, Michelle R Addorisio

In industrialized societies individuals may spend up to 90% of their time indoors. Therefore, it is essential for the clinical practitioner to have an understanding of the indoor environment and its contribution to health. Providing adequate air quality, or ambient conditions, serves two separate and distinct, although overlapping, purposes – to provide comfort and protect health. Depending on the definition used, these two may not result from similar conditions. For example, benzene or asbestos concentrations may be imperceptible and yet pose at least a measurable risk. Yet, discomfort from offensive odors may not pose a health risk in the traditional sense. Nevertheless, such discomfort may lead to decreased productivity, increased concern, and social and organizational dysfunction. Since this discomfort may have a substantially greater influence on the overall performance of a workforce than more clearly measurable or estimable health risks, both health and comfort must be considered.

Indoor air quality presents a challenge to occupational and environmental health professionals that differs from traditional industrial worksites. First, it involves exposures that cross the divide between occupational and non-occupational settings. Second, little formal regulation exists. Although recommended exposure levels have been established by several organizations these may not be enforceable and serve as professional guidelines with an inadequately defined scientific basis.¹ Third, exposures usually are better characterized by assessment of processes and exposure determinants, rather than quantitative measurements of specific pollutants. Buildings and indoor environments in general must be examined as to whether they function as they are supposed to, i.e., whether they provide acceptable working or living conditions.^{2,3}

This chapter addresses several approaches to indoor air quality in occupational settings. It presents an overview of the three standard approaches to buildings: occupant complaints, building systems, and pollutants. It summarizes current thinking about indoor exposures in the home. Finally, it makes recommendations on the prevention of building problems.

APPROACHES TO BUILDING PROBLEMS IN THE OCCUPATIONAL ENVIRONMENT

Three basic approaches are available to the investigation of building complaints or problems. The first focuses on health problems among building occupants and helps

classify syndromes and identify diseases. Yet, it may not identify specific sources within buildings because the same pollutant may result from different building components. A typical example is the association of legionnaire's disease with both cooling towers and potable water systems. Therefore, although this approach may narrow the potential scope of the problem, it generally does not implicate a specific source.

The second approach focuses on environmental control, identifying deviations from good design, operations, and maintenance procedures. Deficiencies may be present and recognizable and still not be associated with the complaint or illness. This approach is therefore independent of medical evaluations and may not predict actual exposures or disease at any given time.⁴

The third approach focuses on specific pollutants and exposures. Frequently, the likely pollutants can be identified during a careful walk-through. Focusing on specific pollutants in problem-solving situations may utilize valuable resources on extensive quantitative air sampling measurements and actually delay identification and resolution of problems. This can lead to unnecessary turmoil, lost productivity, and progressive adverse health effects. A pollutant-oriented quantitative approach may be necessary from a research and regulatory standpoint, but frequently is not useful for solving practical indoor air clinical problems.

In the following sections, these three approaches are summarized separately and focus on disease identification, analysis of design deficiencies, and recognition and measurement of pollutant sources.

PARADIGM 1: DISORDERS ASSOCIATED WITH INDOOR POLLUTANTS

Health effects attributable to indoor pollutants have been recognized for centuries and began with the identification of adverse health effects from wood smoke in closed rooms in the 18th century. Max von Pettenkofer, in the mid 19th century, measured indoor CO₂ levels in an attempt to define health requirements. In the late 19th century, decreased ventilation was recognized as a contributing factor to the transmission of tuberculosis.

Building-related illness

During the last 20 years, complaints attributed to buildings have generally been classified as one of two broad groups:

Selected diseases	Selected agents
Rhinitis, sinusitis	Allergens, molds, spores
Asthma	Irritants – chemicals, cleaning agents, VOCs
Hypersensitivity pneumonitis	Irritant exposures, including cleaning agents, VOCs
Organic dust toxic syndrome (inhalation fevers)	Allergens, molds, chemicals
Infectious diseases	Wood dust, MDI, chemicals, thermotolerant bacteria related to moisture
Legionnaire's disease	Gram-negative bacteria, molds
Tuberculosis	<i>Legionella pneumophila</i>
Upper respiratory tract infection	<i>Mycobacterium tuberculosis</i>
Allergic contact dermatitis	Viral infections
Irritant contact dermatitis	Molds, chemicals, photoactive copy paper, formaldehyde; molds; laser toners
Lung cancer	Fiberglass, VOCs, low humidity, office products
	Radon, environmental tobacco smoke, asbestos

Table 50.1 Specific building-related illness agents

Mucus membrane irritation	Eye irritation, throat irritation, cough
Neurotoxic effects	Headaches, fatigue, lack of concentration, memory loss
Respiratory symptoms	Shortness of breath, cough, wheeze
Skin symptoms	Rash, pruritus, dryness
Chemosensory changes	Enhanced or abnormal odor perception; visual disturbances

Table 50.2 Typical symptoms in SBS

specific building-related illnesses and sick building syndrome (SBS). Building-related illnesses (BRI), which are listed in Table 50.1, are diseases that have multiple etiologies, one of which is a specific factor in an indoor environment.⁵ They are summarized here but readers are referred to the appropriate chapters for a more detailed discussion. Some, such as eosinophilic fungal sinusitis, remain controversial. BRI are generally distinguished from the non-specific symptoms that make up sick building syndrome (SBS) (Table 50.2).⁶ Although the distinction between specific building-related illnesses and SBS is widely used, outbreaks of specific diseases have often been associated with excess rates of non-specific symptoms in individuals that do not meet formal case definitions. This has been used as one argument to suggest that SBS may be an early stage of a BRI, which if left unchecked may progress to a recognizable pathophysiologic entity.^{7,8}

Respiratory tract disease

Respiratory tract diseases such as rhinitis and asthma are the most common building-related illnesses. Diseases have been described at all levels of the respiratory system and are attributed to a variety of mechanisms but most often to

bioaerosols and irritants.^{9,10} Diagnostic workups usually do not implicate any specific organism or single irritant. Disorders associated with bioaerosols are seen in settings with inadequate moisture control and poor housekeeping leading to bioaerosols growth. This growth is usually evident on visual inspection and through the sense of smell.¹¹

Rhinitis and sinusitis

Complaints consistent with allergic and irritant rhinitis and sinusitis are commonly encountered in buildings and overlap with SBS (see also Chapter 20.3). The diagnosis is often based on the clinical history but may be embellished by tests, including nasal swabs, immunologic testing (skin and blood testing), rhinometry, and rhinomanometry. Recently, nasal lavage has documented abnormalities related to bioaerosols exposures.^{12–14} Cases have been attributed to inadequate maintenance of ventilation units (see subsequent discussion). Even when preventive maintenance on central units is done, frequently no similar attempts are made to remove housings from window units for routine cleaning, perhaps because of cost or because of inadequate foresight. Accumulation of biologic materials supporting microbial growth is common as a consequence and may lead to odor complaints and allergic disease.

Asthma

Reversible airway dysfunction may be related to indoor air in buildings. Difficulties exist with defining whether cases are exacerbated by working in the building or whether some specific etiologic agent is present (i.e., occupational asthma).¹³ Exposures may be present either at work/school or home, or in both settings concurrently. This makes the etiology of disease difficult to establish. Since substance-specific challenges are not practical and generally unavailable, alternative approaches are usually used. These include: spirometry before and after work and on a control day, peak flow tracings during the day, and sequential methacholine challenges¹⁵ (see Chapter 19.2). It has been suggested that asthma exacerbations may be attributed to general growth of microbial agents on carpets or bedding, microbial contamination of ventilation systems, humidifiers, and to office products.

Management strategies for all three of these disorders may be frustrating, since the work environment may continue to exacerbate symptoms. Reassignment of a patient to other sites within the building may be attempted and is frequently met with success. Reduced exposures through improved ventilation and reduction of indoor sources can be effective with some patients. Removal from the environment may be necessary.¹² Following the patient's status with peak flow measurements or forced expiratory volumes will provide a reasonable indication of whether or not the patient's disease is reasonably controlled.

Humidifier fever

Humidifier fever, an acute inhalation syndrome similar to organic dust toxic syndrome related to malfunctioning air conditioning units, was one of the first diseases attributed to

indoor spaces, initially in a carpentry shop. The symptoms include both systemic (headaches, feverishness, myalgias, and chills) and chest (chest tightness, cough, and wheezing) complaints, although the former are generally more prominent. The etiology is believed to be related to endotoxin and micro-organisms. The diagnosis is based largely on the clinical presentation and ruling out asthma and hypersensitivity pneumonitis.

Hypersensitivity pneumonitis

The syndrome of hypersensitivity pneumonitis may occur acutely, chronically, or in an intermediate form, with both chest and constitutional complaints (see Chapter 19.6). Symptoms include cough, chest tightness, fever, chills, and myalgias. In several outbreaks, wheezing was also reported.¹² The diagnosis is based on the clinical picture and confirmed by several or all of the following: lung function tests, chest x-ray studies, high resolution CAT scan, bronchoalveolar lavage, and biopsy. Serum antibodies can document exposure and an immune response. As awareness has increased, outbreaks have been documented with few clinical signs or physiologic abnormalities. Documentation of changes in lung function related to a specific site is generally possible and indicates the need for remedial action.

Outbreaks have usually been attributed to the contamination of ventilation systems. The primary sites have included: mold at the air intake, water pump contamination, sources for water incursion, contamination of duct liners and filters, and, rarely, sources such as those contaminated by residual sawdust, plumbing leaks, and standing water sources. The occurrence of this serious disease requires that the specific source be identified so that further cases may be prevented and the identified cases do not progress.¹⁶

Other non-infectious interstitial lung diseases

Several forms of non-allergic disease of the respiratory tract have been described. Asbestosis has been demonstrated in occupational groups with exposure to asbestos in indoor environments.¹ For example, maintenance plumbers and custodians in buildings and building tradespersons in general have been shown to be at increased risk for asbestos-related pleural disease. This occurs not because of work in buildings with exposure to ambient concentrations of asbestos fibers but because their job activities generate asbestos dust similar to that generated in industrial or construction environments.

Another form of interstitial lung disease may be associated with exposure to mycotoxin-producing fungi. Animal models document that mature rats develop pulmonary disease after exposure to spores of either *Aspergillus versicolor* or *Stachybotrys chartarum*. This effect is related to the methanol extractable fraction of the spores.¹⁷ Case control studies suggest an association with industries, occupations, or exposures to bioaerosols. Case reports and clusters of interstitial disease suggest that moisture, dirt, and bioaerosols indoors are not as harmless as previously assumed.¹⁸

Infections

More important are the viral and bacterial infections attributed to building sources. Evidence exists that mechanical ventilation is associated with up to a 50% increase in respiratory tract infections and an estimated 500,000 lost work days.¹⁹ Whether this is related to the recirculation of air, inadequate filtration, increased concentrations of air-borne droplet nuclei, relative humidity changes, or to increased infection susceptibility is a matter of dispute and scientific uncertainty. Several outbreaks of other viral illnesses, including measles and varicella, have been attributed to the dissemination of infectious particles after entrainment into the airstream. Tuberculosis and Q fever transmission can occur in a similar fashion. A single outbreak of pneumococcal pneumonia remains controversial, as it may have occurred from crowding alone rather than through airstream dissemination.²⁰

The most frequently discussed bacterial infectious disease attributed to indoor spaces is caused by *Legionella* sp., including both legionnaire's disease and Pontiac fever.¹⁷ The case fatality rate of 15% has not changed markedly, despite introduction of appropriate antibiotics. Two modes of transmission are recognized: (1) inhalation of droplet nuclei and (2) aspiration of Legionellaceae that colonizes the oropharynx in susceptible hosts (smokers, asthmatic patients, individuals with chronic obstructive pulmonary disease and immune suppression). Although most outbreaks in the first 15 years were attributed to cooling towers and to the drift of infected plumes, more recently an alternative hypothesis has been proposed. Most outbreaks reported since 1982 have been attributed to potable water systems. Although there are outbreaks clearly attributable to cooling towers and plume drift, potable water sources, including showers and home water heaters, are now a major concern.²¹

Since *Legionella* strains appear to be in more than one-half of water bodies in the United States, it is unclear why the disease is not more prevalent. The risk factors for transmission likely depend on the concentration of Legionellaceae in the water and host risk factors. In addition, electric water heaters, blind pipe ends, sluggish water flow, kinking in pipes, and leaks in water cooling systems may also contribute to disease transmission. Controversy exists as to whether cultures should be performed to keep Legionellaceae counts below a specific threshold or whether maintenance per se affects the rate of legionnaire's disease. In some settings, such as healthcare, this is standard practice.^{22,23}

Work-related outbreaks have been documented in a broad range of settings, including cooling tower operations, steam turbine cleaners, plastic press cooling water leaks, and oil mists. Criteria for work-relatedness include growth of the agent from a specific source, serologic evidence for the presence of the same strain in victim and source, and adequate evidence of legionnaire's disease. Home sources should also be cultured since transmission from potable residential water is equally likely.

Dermatitis

Skin complaints have been described frequently in buildings and are also an integral component of the SBS. Although irritant, allergic, and photodermatitis have been documented, there is a question about the frequency and importance of each in indoor environments.

Irritant dermatitis

Irritant dermatitis has been attributed to chemical, physical, or a combination of both causes (see Chapter 29.1). The most easily recognized is induced by fiberglass fibers, classically described as itching without an obvious cause that is relieved by showering. The glass fibers may also be demonstrated in horizontal surface wipe samples. Itching occurring more frequently during the winter months may be associated with the lower relative humidity in indoor spaces, frequently below 20%. Such complaints have been attributed to the combination of low relative humidity and volatile organic compounds (VOC). Finally, some compounds, such as formaldehyde and phthalates in carbonless paper, are irritating on their own.

Allergic dermatitis

Cases of allergic skin disease have been described in buildings and are usually attributed to a specific source.¹⁵

Photodermatitis

Several reports have described erythema associated with video display terminal use, which has been localized to both the face and hands. The mechanism postulated was the relatively high intensity of the monochromatic light in such terminals compared with the broader range of frequencies from other sources. However, it is still difficult to prove an association since one of the cases listed was convincing but subsequently proved to be factitious.²⁴

Lung cancer

Lung cancer is widely discussed as a chronic disease resulting from exposure to multiple risk factors. These include agents present in indoor environments, such as asbestos, radon, and environmental tobacco smoke (ETS).²⁵ Risk assessment for each of these does not suggest that work in the modern office is a significant risk factor. Individuals with traditional occupational exposures, such as plumbers and other building tradespersons, may be at risk for asbestos-related disease.

Sick building syndrome (SBS)

The term 'sick building syndrome' refers to problems related to indoor air quality in non-industrial buildings. Three very different approaches to its understanding have evolved and no operational criteria exist for its documentation. These three paradigms are: (1) building occupants and their symptoms, disease, or discomfort, (2) the environmental design and control of the building, and (3) specific pollutants and exposure assessment. It is clear that

symptom prevalence varies from building to building, often without a recognized problem or an identified cause. Similarly, a substantial number of building systems do not meet professional design criteria or are operated in substandard ways. Finally, specific pollutants have been identified with reasonable measurement methods, physiologic markers of exposure, and predictable dose-response relationships.^{19,26} Therefore, it is possible that many of the 'non-specific' symptoms of SBS may have a clear etiology.⁷ The etiologic factors that are believed to contribute to SBS are defined in Table 50.3.

Building occupants

In the 1980s and 1990s numerous cross-sectional questionnaire investigations were published from several countries which suggested that complaint frequencies are associated with a series of environmental risk factors (Table 50.4). The most prominent risk factor was mechanical ventilation, which was consistently associated with a 50% increase in symptoms. Panel evaluations of office buildings in Denmark suggested that approximately 40% of the complaints could

Air contaminants	Building materials
Indoor sources	Moisture
	Office cleaning products
Outdoor sources	Automobile exhaust
	Industrial plants
HVAC system	Moisture
	Ventilation
	Heating/air conditioning
Work organization	Humidification
	Job satisfaction
	Stress
Host factors	Social structures
	Sex
	Atopy
	Airway hyper-reactivity
	Pre-existing disease

Table 50.3 Determinants of indoor air quality and symptoms

Volatile organic compounds	Formaldehyde; paints and resins; solvents; printed materials; printer and photocopier emissions
Dust/fibers	Asbestos; man-made mineral fibers (fiberglass); dirt, construction, and paper dust
Bioaerosols	Bacteria; fungi; molds; dust mites; viruses; pollen; animal danders and excreta
Entrapped outdoor sources	Vehicle exhaust; industrial exhaust
Physical factors	Temperature; humidity; noise; lighting
Contaminants generated by human activity	Carbon dioxide; perfume
Other	Fuel combustion products; radon; pesticides; cleaning agents; environmental tobacco smoke (ETS); building materials

Table 50.4 Common contaminants in indoor air

be attributed to ventilation systems, although it could not be determined if the pollutants were generated elsewhere and recirculated or if they were generated directly within the system. ETS, office machines, and human off-gassing contributed 25%, 20%, and 15% respectively to the remaining 60%.²⁷

Over the last 15 years our understanding of the indoor environment and related health issues has increased significantly. While some symptoms, such as headaches, fatigue, and difficulty concentrating, are considered 'non-specific', others have better defined pathophysiologic mechanisms and markers.²⁸ In addition, it appears that personal characteristics modify the likelihood of symptoms. Atopic individuals describe higher symptom frequencies, have been shown to respond to irritants at lower levels, and have lower irritant thresholds than non-atopics.^{29,30} Individuals with decreased tear-film break-up time and less protection for the ocular mucosa have higher rates of symptoms. Therefore, some of the symptom variability may result from defined, recognizable differences.

One of the better studied symptoms is mucosal irritation. Itching, irritation, tearing, and redness of the eyes, nasal mucosa, and throat mimic symptoms attributed to stimulating the irritant receptor, or the common chemical sense.³¹ Physiologic techniques to measure these are well defined. Although headaches are widely recognized as a symptom of a poor indoor environment, there are no studies that examine them using standard diagnostic classifications. Data on headache treatment effectiveness in the office exist.³² Dermal complaints have been reported to be associated with personality traits, dermal sensitivity to irritants, a history of eczema, and specific hormonal profiles.¹⁵ Work stress is also associated with symptoms. Of some interest is the recent recognition that some mucosal symptoms appear related to specific fungal exposures in office buildings.

It is more difficult to address fatigue, headaches, lethargy, and other 'non-specific' symptoms.³² Some data suggest they may in fact be related to endotoxin exposure and associated with moisture or humidity. Even though there appears to be a relationship between ventilation rates, moisture, infections, and symptoms, much still needs to be done to establish these associations. Stress and certain organizational factors at work may be risk factors.

PARADIGM 2: ENVIRONMENTAL DESIGN AND CONTROL

The first use of mechanical ventilation indoors occurred in 18th-century England when the new House of Parliament was fitted with blowers to distribute warmth from the furnaces. In 1860, Max von Pettenkofer calculated that indoor air was likely to be acceptable as long as the levels of carbon dioxide did not exceed 1000 ppm. Since 1892, the recommended indoor ventilation rates have ranged between 4 and 60 cubic feet of outdoor air per occupant per minute. The latter was recommended for tuberculosis prevention in the 1890s and to decrease tobacco irritation

in the 1970s; the former to keep miners alive in the early 19th century and during the energy crisis. The current standard recommends approximately 20.

At present, buildings in the US must be ventilated according to the local building code. Required outdoor air rates differ substantially between the building code and professional design recommendations. The most widely recognized standard, 'Ventilation for Acceptable Indoor Air Quality', promulgated by the American Society of Heating, Refrigerating, and Air-conditioning Engineers (ASHRAE), recommends approximately 20 cubic feet of outside air per occupant per minute for most commercial applications. Additional specific standards recommend boundaries and guidelines for thermal, acoustic, and lighting comfort. None were developed explicitly to protect completely against health effects.¹ Careful scrutiny of the scientific basis for each of these standards, therefore, suggests major gaps and assumptions. Health scientists must therefore remain aware that even when buildings 'meet all professional standards', a substantial proportion of occupants may be dissatisfied or even become ill from exposures.¹¹

An ASHRAE commissioning guide provides detailed procedures to ensure that buildings 'work' at the beginning of their occupancy, but such guidelines are often not followed. Reviews of building systems suggest that the majority of buildings in the US simply do not meet professional design standards and therefore contribute to health concerns and occupant discomfort.

A review of structural and functional issues in problem buildings serves to identify specific sources. This may be done without necessarily linking the problem sources to concomitant medical problems or complaints, or even implicating specific pollutants. Nevertheless, the identification of engineering or architectural deficiencies by themselves should lead to remediation strategies.^{4,29} Even if specific deficiencies have not caused the problem under investigation, they could do so in the future.

Newer building designs focus more on control of the microenvironment, such as: control of lighting, thermal parameters, and acoustics in the specific work zone.² In the long run, such systems may serve the occupants better, support higher productivity, and lead to greater occupant satisfaction.

Heating, ventilating, and air-conditioning systems

The first system usually examined closely in a problem building is the heating, ventilating, and air-conditioning (HVAC) system. HVAC systems were initially designed for pollutant removal and filter, but during the last 50 years they have served primarily to provide comfort. Ideally, ventilation systems distribute outside fresh air, condition (heat or cool) the air, control the humidity, and remove pollutants. Figure 50.1 provides a schematic of the design of a generic HVAC system.

Return and outside air are mixed in a plenum. The first basic assumption is that the outside air is clean. However, ambient air may not meet air quality guidelines

Figure 50.1: Schema of a basic ventilation system (HVAC). Arrows represent airflow; slashes represent dampers. (1) Outdoor air supply air intake, (2) mixing plenum, (3) prefilter, (4) filter, (5) heating coil, (6) cooling coil, (7) condensate/drip pan, (8) drain, (9) steam humidification, (10) supply fan, (11) supply duct, (12) reheat coil, (13) variable air volume box, (14) supply diffuser, (15) occupied space, (16) return air louver, (17) return air duct, (18) booster fan.

(Environmental Protection Agency guidelines and Clean Air Act) and therefore, the outdoor environment must be considered in evaluating systems. For example, placement of air intakes may lead to circadian changes in pollutant loads (intake at freeway level leading to carbon monoxide intake).

Air then passes through a filter bank to filter out the dust. All filters are rated for two specific factors. Arrestance refers to the ability to remove coarse dust. Dust spot efficiency refers to the ability to remove fine particulates of specific sizes, defined by mass median aerodynamic diameters. Various kinds of filters are frequently used to decrease cost, and most commercially available filters will not remove the particulate phase of ETS. Specific filters may remove gases and volatile organic compounds, but large banks are needed with frequent replacement for any useful filtration.

Next, air passes through a heat exchanger and is either heated with electricity or hot water or cooled by cold water, halocarbons, ammonia, or glycol ethers. As the air is cooled, water will condense on the cooling coils when the cooling coil surface is below the dew point temperature of the air (based on the water content). Although the temperature of the air leaving the coil is no different from air in which less latent cooling has occurred, the water content is substantially lower. The condensed water collects in drain pans. Adequate drainage is of paramount importance to prevent the growth of microbial agents and their dissemination in the airstream. Supply fans then carry the air to ducts. Air is distributed to occupied spaces through supply air louvers, whose design ensures that air is brought to the breathing zone of occupants, and thus, the microenvironment.

Air is returned to the central system through collecting ducts, open plenums, or open spaces. Some availability of relief pressurization must be provided otherwise the outside air may not be able to be distributed against the local pressure.²⁷

A major concern in all systems is the integrity of the lining of ducts and plenums. If unsealed fiberglass, spray

insulation, or other porous material becomes wet after attracting dust, ideal conditions are present for the growth of micro-organisms. Inadequate latent cooling may leave more water in the distributed air and lead to microbial overgrowth.

Two basic forms of air conditioning are currently in use: variable air volume (VAV) and constant flow (CF) systems. VAV systems mix air of different temperatures to achieve a desired temperature in occupied spaces. That is, when the temperature in the occupied space has reached a pre-set level, no further air flow may occur until the temperature has exceeded the thermostat trigger. CV systems, on the other hand, regulate temperature by varying the amount of initial conditioning and mixing, ensuring air flow at all times. Some VAV systems do have provisions for minimal air flow even when temperatures are in a desired range. Nevertheless, the balancing and maintenance of VAV systems require substantially more expertise than that of CV systems.³³

Space design

Placement of distribution louvers, furniture, and partitions may influence the distribution of air flow and the adequacy of microenvironmental circulation. Retrofitting of walls in spaces without regard for the placement of louvers may lead to air quality complaints.

Office materials

A growing recognition that mucosal irritation is associated not only with inadequate ventilation but also with the accumulation of specific pollutant groups, i.e., VOC, has led architects, designers, and building owners to scrutinize the emissions from newer office products. A four-step process has been suggested to evaluate materials properly. Identification of target products allows the user or designer to identify potential sources of concern.^{6,21} Screening for such products occurs based on information from existing

databases and manufacturers' data. If no prior information is available on a product of interest, data may be collected on emissions rates, duration, and health effects. Finally, these three factors are reviewed, and manufacturers may be contacted for help in the modification of products before or after installation.

Products may be a primary or secondary problem source, e.g., materials with high surface areas, such as carpets, drapes, and upholstery, may actually serve as secondary sinks. These sinks absorb emitted agents at one point in time and contribute to the delayed decrease in concentrations of those agents by re-releasing the agent later on and therefore potentially contributing to adverse health effects.

PARADIGM 3: SPECIFIC POLLUTANTS – EXPOSURE ASSESSMENT

A discussion of specific pollutants ideally encompasses standard measurement techniques, exposure–effect relationships, and the pertinent standards. Providing this information for all the pollutants found in indoor environments is not possible here. Therefore, only a short discussion on seven of the more prominent pollutants will be given. These are also listed in Table 50.4, which compiles some of the common contaminants in indoor air. In an environmental evaluation, any consideration of pollutants must first address the representative pollutant and the multiple contaminant problems.

First, indoor environments involve multiple exposures. Sources of these contaminants include the outdoor environment, materials and products within the building, and the building occupants. Outdoor contaminants such as vehicle exhaust fumes can become trapped indoors. Individual agents are often present in concentration ranges of 1 to 100 parts per billion, which may be orders of magnitude below the recognized occupational criteria. Nevertheless, the best way of estimating their collective effects is currently uncertain. Most have both an odor and an irritant component to be considered.³⁴ Specific pollutant effects may be modified through additional exposures, such as noise and vibration, lighting factors, and thermal parameters.²¹ It is therefore generally agreed that the use of environmental criteria alone, such as is commonly done in applied industrial hygiene, is unsuitable for evaluation of the non-industrial workplace.

Second, pollutants rarely are generated alone. Many sources emit multiple agents, leading to the search for a representative pollutant. For example, ETS consists of thousands of different compounds. Nicotine, or its metabolite cotinine, may be a reasonable indicator of recent exposure. Measurement difficulties and decay in the smoke question whether these are the ideal sentinel compounds.

Third, the shape of dose–response curves, effects thresholds, and susceptibility variability suggest that focusing on single levels for specific pollutants will not lead to effects on indoor environmental regulation.³⁵ Although a pollutant-oriented paradigm is useful for scientific discussions, measurement, and analysis, it is less useful for problem

solving in regard to indoor air or for regulatory approaches to indoor environments.

Microbial agents

Evidence exists that microbial agents lead to allergic respiratory tract disease in public access buildings and residential environments. Symptoms appear more frequently in buildings with higher endotoxin levels or moisture problems, and in atopic individuals. Microbial agents proliferate wherever dirt, water, air, and heat coincide. To break the cycle of replication, the reservoir must be eradicated. This is best done through moisture prevention and cleaning.^{28,36} Measurement of air-borne levels is of great scientific interest but typically of little practical use in individual cases. Speciation of the organisms demonstrates the presence of agents with the potential to form mycotoxins, and may provide useful scientific information. Also, immunologic testing, i.e., substance-specific challenge or documentation of antibodies, may be part of the evaluation.³⁷ Usually, in practice, sources can be identified by visual inspection or smell, and remediated without such testing.

Although a guideline was suggested of 1000 colony-forming units per m³ of micro-organisms for indoor environments, many practitioners have interpreted this as a standard distinguishing safety from hazard, which was not the intent of the initial guideline. Currently, levels in the range of 1000 to 10,000 colony-forming units with clear gradients from outdoor concentrations are viewed with concern, although there are no specific standard guidelines.

Volatile organic compounds

Chamber studies of volatile organic compounds (VOCs) have suggested that many of the complaints induced by indoor environments may result from exposure to low levels of VOCs. Systematic assessment has, over the last 10 years, identified irritant and odor thresholds for several homologous series of agents (aliphatic aldehydes, ketones, alcohols). There are many sources of VOCs in the indoor environment; these include, but are not limited to, paints, adhesives, cleaners, plastics, and fabric protectors.³⁸

VOCs can be skin and mucous membrane irritants. These health symptoms appear to be related to the difference in VOC concentrations on entering and leaving a room, to screening measures of VOC quantities, and to pollutants grouped by exposure sources (carpets, paints, etc.). It has been postulated that VOCs may trigger migraines; however, this is not established and most indoor headaches are not labeled as such. Central nervous system toxicity of solvents has only been described after substantially high exposures. Usually, specific total VOC levels can be measured in indoor environments but are typically very low and not felt to pose a permanent health risk.³⁹

Environmental tobacco smoke

Recently, research has been establishing a link between environmental tobacco smoke (ETS) and adverse health

effects. Some component of non-specific complaints can result from this exposure. The primary cause of the irritation and health effects is believed to reside in the gaseous rather than the particulate phase.¹⁰

A broader issue is raised by epidemiologic literature that suggests a variety of chronic diseases are attributable to ETS. Although the literature is somewhat limited, the chronic conditions linked to ETS include: lung cancer, heart disease, asthma, and chronic obstructive pulmonary disease.^{25,40} This evidence is based on ETS as a risk factor for intense household contacts (spouses or parents) and the proportion of chronic disease attributable to levels typically found in the office or other workplaces appears exceedingly small.

A third issue is that of irritation and odor discomfort and required ventilation. The gas phase of ETS carries potent irritants, including sulfur dioxide, ammonia, and formaldehyde.⁴⁰ Ventilation rates required to ventilate ETS adequately in rooms and buildings may need to be three-fold higher than those recommended by ASHRAE in the 62 standard. The ventilation rate required to address typical smoking in smoking environments leads to conditions described by some as 'a tornado on your desk'.

Asbestos

Asbestos products were used in a broad range of applications in buildings. With inadequate maintenance these materials decay, leading to some degree of exposure. The intensity of this exposure varies considerably, depending on the activities of the individuals under scrutiny. Office workers, in general, are considered at very low risk for asbestos-related disease. Air sampling has generally not indicated fiber exposures above background levels. The risk from asbestos exposure in public access buildings can reasonably be considered negligible in most environments.

Radon

Radon in indoor environments as a cause of lung cancer has come under considerable scrutiny. Although it is clearly important in certain parts of the world, in the United States the risk is primarily in residences and not the workplace. The Environmental Protection Agency has recommended remediation when levels in living space exceed 4 pcu/l, as measured over a 3-month period. The risk of lung cancer at these low doses remains a focus of study. A substantial portion of its risk arises from the potentiation of smoking risk, so that smoking cessation efforts may have substantially greater beneficial effects.⁴¹

Biomass and fossil fuels

In public access buildings, the entrainment of vehicle exhaust sometimes leads to carbon monoxide and irritant (NO_x/SO₂) exposures. Usually exposure is because of poorly designed and located air intakes.²³ It is important to monitor the source of these exposures because these reactive agents can form reaction products with unsaturated hydrocarbons

indoors, therefore generating two additional moles of products generally more reactive than the original agents.

Carbon dioxide

CO₂ has been the subject of great interest in indoor air and is frequently (mis)named a pollutant. It is widely used as an indicator of adequate ventilation based on considerations in the ASHRAE 62-89 standard. Because humans are the primary source of CO₂, many consider it a reasonable indicator of ventilation adequacy.⁴² In fact, data generally support its use not just as an indicator of ventilation but also as a reasonable predictor of symptoms. However, CO₂ levels may not accurately reflect the ventilation. In relatively low occupant/density rooms (less than seven persons per 1000 ft²) and in spaces that have not reached steady state due to unstable numbers of occupants or too short a time to equilibrate, measured CO₂ levels may be a poor indicator of overall ventilation and ventilation efficiency. Second, if there are unexpected, strong sources that far exceed the usually expected pollutant load, specific exposures may remain uncontrolled. Nevertheless, reviewing CO₂ levels is appropriate in many situations. Levels above 1000 ppm (0.1%) indicate that a specific environment does not meet basic ventilation requirements.²³ However, this is not an absolute level. In the presence of definable building system problems a level in the range of 500 ppm can be present.⁴³

RESIDENTIAL EXPOSURES

Homes remain a major source of exposures, with no organized lobby to support problem prevention. As in commercial space, construction is regulated through the building code, which does not address ventilation rates, moisture control, or physical safety hazards.

Moisture and disease

Since the late 1980s, data have suggested an association between childhood airways disease and moisture in the home. Moisture is associated with dust mite and cockroach exposures, and careful intervention has been shown to reduce dust mite antigen levels.⁴⁴ More controversial is the relationship between fungi, moisture, and asthma in adults and children. Although rare, case reports identify fungi as a possible cause of asthma. Recent studies suggest an association of fungi and also endotoxin, which may serve as a reasonable marker of biomass or direct pulmonary effects.

A controversial issue regarding mold in the home is that of 'idiopathic pulmonary hemorrhage' associated with *Stachybotrys chartarum*. After an initial case-control study of 10 such cases in Cleveland, additional cases have been reported. An animal model was developed in rat pups, identifying capillary fragility as a consequence of controlled exposure to *Stachybotrys chartarum* toxins likely to cause protein synthesis inhibition. This can be measured with assays standardized to other well-known carcinogenic toxins such as fumonisin.^{45,46} As for adult interstitial pneumonitis,

the combination of an animal model with suggested mechanism, an exposure trail, a formal case-control study, and case reports suggest the possibility of a causal association. However, it should be noted that the data from these studies are inconclusive and are reviewed in detail in *Clinical Microbiology Reviews*.⁴⁷

The question of moisture sources in the home remains of great interest and concern. This refers to any moisture incursion, leaks through roofs and wall penetrations, windows and doors, most of which represent straightforward construction defects. Additional moisture sources differ by geographic area. In the northern US, below-grade moisture seepage remains a very common problem. In humid areas, inadequate enthalpy control (high indoor moisture content, often exacerbated by improper air conditioning sizing) represent a more common problem. Often it is a combination of below-grade moisture incursion, enthalpy design problems, and bulk moisture incursion that leads to negative health effects.

Fossil fuel combustion

Also of concern is domestic exposure to indoor combustion of wood, grass, dung (biomass fuels), coal, or petroleum derivatives, such as kerosene (fossil fuels) for cooking and heating. Combustion products include gaseous irritants (NO_x/SO_2), asphyxiants (CO), and complex hydrocarbons in particulate (e.g., polycyclic aromatic hydrocarbons).¹⁰ Levels of these pollutants in unvented houses may reach industrial doses, especially in the Third World; the levels may be lower in developed countries but are still worrisome.²⁵

Given overall health patterns, the biggest concerns in developing countries have focused on epidemic childhood acute respiratory illness. Evidence suggests stove exposures enhance the risk of this multifactorial killer, and may increase the risk of low birth weight, lung cancer, and possibly obstructive airways disease.²⁵

In developed countries, stove and heater exposures are considered a possible contributor to childhood respiratory infection and diminished lung function. Exposures may be a risk factor for the development of asthma or for more severe asthma in established cases. Long-term sequelae remain inadequately investigated. In addition, an association between indoor CO exposures and adverse cardiovascular and central nervous system effects has been suggested. Unusual point sources, entrainment of exhaust from portable grills, entrainment of exhaust from garages, and furnace air supply interruption are associated with mortality and morbidity.¹⁰

DIAGNOSTIC STRATEGIES AND PREVENTION

Separate diagnostic strategies should be pursued for individual patients and the workplace. If the patient's complaints fit a specific pattern (i.e., a specific building-related illness), the likely source should be identified and remediated. Where no prior reports of an exposure-effect relationship

exist, a diagnostic trial may be necessary. Identification of the likely pathophysiologic outcome allows the investigator to focus on a specific target organ under conditions that are measurable and reproducible. If an effect is identified, this may provide adequate evidence for intervention. If no change is identified, at least no disease severe enough to lead to pathophysiologic changes is present.

At the same time, the building should be evaluated, preferably by someone with ventilation expertise. Walk-throughs generally involve a review of the building's plans, inspection of various components of the HVAC system, and a review of other building systems and sources, such as may be present in mixed-use buildings. Occupant interviews or a questionnaire survey may be useful to characterize complaints, although they may not be helpful unless some specific disease is under investigation.³⁹ Likely causes may be identified during the initial review, and a hypothesis should be formulated. Additional evidence may then be collected and some intervention undertaken. Buildings must frequently be examined under different environmental conditions (e.g., temperatures and seasons) because many problems become evident when the conditions change.⁴⁸ If necessary, targeted sampling to document the presence of specific exposures may be useful to persuade the responsible parties of the appropriateness of or need for intervention. In general, extensive sampling is not helpful early in building investigations.

There is growing recognition of the importance of preventive maintenance and careful planning in renovation work. The former includes regular servicing of induction units, cleaning systems, and the like.⁴⁹ None of these have been subjected to scientific scrutiny as the new industry has arisen. The latter requires considerations of timing and design in renovation. Renovation during continued occupancy without isolation of the renovated space or isolation of the HVAC system serving the construction sites leads to avoidable mistakes and occupant exposure.⁵⁰

A widely discussed approach to indoor air is to focus on prevention of sick buildings, called the healthy building movement. This has led to several changes in design and construction practices including: closer co-ordination between architects and engineers, the use of outside peer reviewers for overall project evaluation, the rigorous evaluation and commissioning of newly constructed buildings, the selection of low-emitting materials, and the contracting of designers and builders for a period after the completion to oversee the maintenance.⁶

Finally, careful scrutiny of the workplace organizational function may prevent the development of problems. Several studies have suggested that, in addition to specific environmental contaminants, various work stress parameters may influence building-related complaints. The development of crisis buildings is generally caused by poor labor-management communication. The failure to act appropriately early in the course of building complaints and to take occupant concerns seriously may contribute to many of the health complaints that are clearly preventable.

As the Occupational Safety and Health Administration has withdrawn its proposed standard, no regulatory

approach appears imminent. Other occupational environments, such as healthcare with the Joint Commission on Accreditation of HealthCare Organizations, have developed effective self-regulation. Office buildings are a large enough class of buildings, with enough hazards, to warrant some similar approach.

Chapter 51

Exposures in Outdoor Air

Mark W Frampton, Jonathan M Samet, Mark J Utell

Outdoor air pollution has numerous man-made and natural sources. In the US, approximately one-half of the population is exposed to pollutants at levels exceeding the current federal air quality standards. Concern for adverse health effects may be raised by persistent pollution with sustained exposure, as occurs in regions with photochemical pollution or smog; by dramatic releases of toxic chemicals, such as in the tragic release of methylisocyanate in the Bhopal incident and the subsequent release of aldcarboxime in Institute, West Virginia; by the presence of visible sources of community pollution such as smelters, power plants, or refineries; and by outbreaks of symptoms or illnesses possibly caused by air pollution. But even without visible or dramatic emissions, air pollution may harm public health.^{1,2}

Assessment of the adverse effects of outdoor air pollution typically requires toxicologic and epidemiologic investigations.³ Addressing these adverse effects may require reduction of emissions through engineering controls or changes in source operations, or even elimination of some sources. Legislation or prolonged litigation may be involved. While control of air pollution is a societal matter, physicians and other healthcare practitioners need to understand the effects of outdoor air pollution as they relate to the care of individual patients, and to potential community concerns. Patients often turn to their physicians for advice concerning possible harmful consequences of air pollution. For example, high levels of photochemical oxidants (i.e., smog) may prompt persons with asthma or chronic obstructive pulmonary disease (COPD) to ask about the safety of being outside; healthy persons may ask about the consequences of exercising.

Physicians also may be viewed as the community's experts on the consequences of air pollution or other forms of environmental contamination.⁴ They may serve as sources of information and expertise for environmental groups, voluntary health agencies, municipal boards or other governmental bodies. Thus, the range of physician involvement with outdoor air pollution is potentially broad, spanning from the care of individual patients to issues of local, regional, or even national scope.

This chapter provides a broad perspective for clinicians on the adverse effects of outdoor air pollution. It reviews the principal forms of outdoor air pollution and associated health effects and considers approaches at the levels of the community and the individual patient for reducing morbidity and mortality resulting from exposure. Emphasis is placed on the problems likely to be found in

the developed world; the situation in many developing countries is, regrettably, far worse.

SOURCES AND TYPES OF OUTDOOR AIR POLLUTION

Pollutant types	Sources
Particulate matter, sulfur oxides	Fossil fuel combustion, motor vehicles, power plants, combustion of coal for heating
Photochemical oxidant	Fossil fuel combustion, motor vehicles, oil refineries, power plants, other hydrocarbon sources
Carbon monoxide	Fossil fuel combustion, motor vehicles, industry
Toxic air pollutants	Fossil fuel combustion, industry, other

Table 51.1 Principal types and sources of pollutants

Outdoor air pollution has myriad natural and man-made sources. From the perspective of concern about adverse health effects, outdoor air pollutants can be classified into four broad groups (Table 51.1). Combustion of sulfur-containing fossil fuels, primarily coal and crude petroleum products, produces sulfur oxide and particulate pollution. The combustion gases, sulfur oxides and nitrogen oxides, are precursors of acid pollution and contribute to the formation of small particles. The use of tall stacks promotes the formation of acidic sulfate and nitrate species by spewing precursor pollutants high into the atmosphere, where the prolonged residence time facilitates the occurrence of chemical reactions that form acid particles.

Photochemical pollution or smog results from the action of sunlight on a precursor mixture of hydrocarbons, nitrogen oxides, and carbon monoxide (CO). This type of pollution tends to occur in areas with a high density of motor vehicles and warm, sunny climates. Although smog was first found in the Los Angeles air basin, it is now a regional problem in many parts of the US, including the East Coast. Smog is a complex mixture containing diverse oxidant pollutants; acidic species may also be present. The concentration of ozone is used to index the severity of photochemical pollution.

CO is also produced by combustion sources, both stationary and non-stationary. The toxic pollutants have

diverse sources, including both small and large industries, and vehicles.

PERSONAL EXPOSURE TO AIR POLLUTION

Patterns of time-use and activity place children and adults in diverse indoor and outdoor environments throughout the day, each environment having its own unique set of air contaminants. Perhaps because of the distinct sources contaminating outdoor air and indoor air and the separate regulatory mechanisms for outdoor air, the workplace, and the home, the health effects of air pollution have often been addressed separately for outdoor and indoor air.

However, the concept of total personal exposure is more relevant for health; personal exposure to air pollution represents the time-weighted average of pollutant concentrations in microenvironments, which are environments having relatively homogeneous air quality (Fig. 51.1). Thus, for an office worker, relevant microenvironments might include home, office, car, outdoors at home, outdoors at work, and a movie theater. For some pollutants, such as ozone or acid aerosols, outdoor environments make the predominant contribution to total personal exposure; for others, such as

radon and formaldehyde, indoor locations are most important. In considering the health consequences of air pollution, the physician should recognize that outdoor air is only one potential vector for pollution exposure.

PRINCIPLES OF INHALATION INJURY (see Chapters 19.5 and 47)

Atmospheric pollutants exist in both gaseous and particulate forms. In relating clinical diseases to specific exposures, the clinician should recognize that penetration and retention of toxic gases in the respiratory tract can vary widely, depending on the physical properties of the gas (e.g., solubility), the concentration of the gas in the inspired air, the rate and depth of ventilation, and the extent to which the material is reactive. Gases that are highly water soluble, such as sulfur dioxide (SO_2), are almost completely extracted by the nose and pharynx of resting healthy subjects during brief exposures. In contrast, the removal of less water-soluble gases, such as nitrogen dioxide (NO_2) or ozone, is much less complete, and thus, these gases penetrate deeper into the respiratory tract. CO is poorly soluble in water and is not removed in the upper airways. On reaching the lung, CO diffuses across the alveolar-capillary membrane and binds avidly to hemoglobin in the blood.

Penetration of gases into the deep lung, and thus the total dose to the lung, can be greatly enhanced by exercise. Not only does exercise increase the dose directly by increasing minute ventilation but also, because many people switch from nasal to oral breathing during moderate to heavy exercise, the more efficient removal by the nasal passages is bypassed.

Pollutants in particulate form are usually found in nature as aerosols. These small liquid droplets or solid particles are dispersed in the atmosphere with sufficient stability to remain in suspension. Examples of common aerosols are sulfuric acid mists, sulfate salts, and nitrate salts. Although deposition of inhaled particles depends on multiple factors, including the aerodynamic properties of the particle (primarily its size), airway anatomy, and breathing pattern, several generalizations can be made. Inhaled particles larger than $10\ \mu\text{m}$ are effectively filtered out of the respiratory tract by the nose and nasopharynx. These relatively large particles tend to deposit rapidly because of impaction against surfaces and gravitational forces. Particles trapped in the nose and nasopharynx are cleared in nasal secretions, coughed out, or swallowed. Particles less than $10\ \mu\text{m}$ in aerodynamic diameter may be deposited in the tracheobronchial tree; deposition in the lung's alveoli is maximal for particles of 1 to $2\ \mu\text{m}$ diameter. Particles smaller than $0.5\ \mu\text{m}$ are carried by diffusion to the alveolar level, where they collide with gas molecules by brownian movement and come into contact with alveolar surfaces. Removal of particles from the upper airways is efficient and occurs within hours; this rapid clearance contrasts with clearance from the deep lung by alveolar macrophages, which may require days to months.

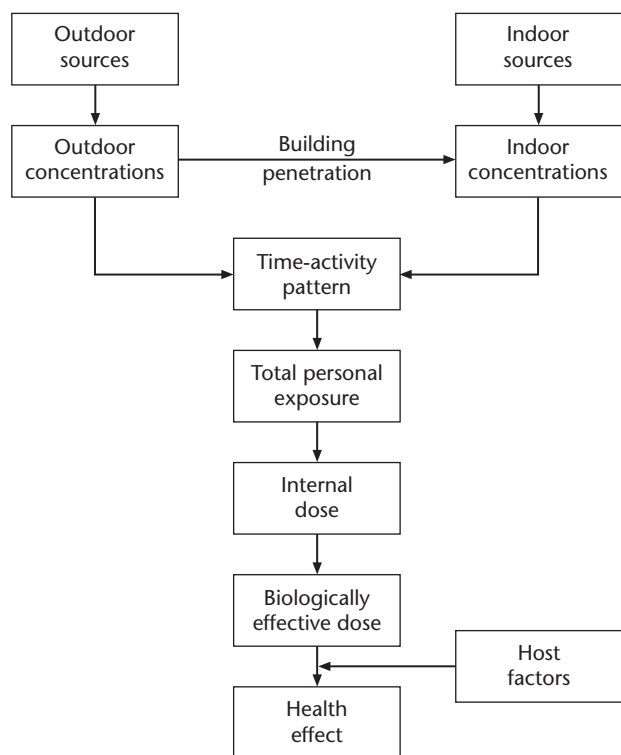

Figure 51.1: Framework for considering exposure, dose, and development of health effects. (Modified from Committee on the Epidemiology of Air Pollutants, Board on Toxicology and Environmental Health Hazards, Commission on Life Sciences, National Research Council. *Epidemiology and air pollution*. Washington, DC: National Academy Press; 1985.)

Population	Potential mechanism	Consequences
Infants	Immature defense mechanisms of the lung	Increased risk for respiratory infection
Elderly	Impaired respiratory defenses; reduced functional reserve	Increased risk for respiratory infection; increased risk for clinically significant effects on function
Asthmatics	Increased airways responsiveness	Increased risk for exacerbation and respiratory symptoms
Persons with COPD	Reduced level of lung function	Increased risk for clinically significant effects on function
Persons with CHD	Impaired myocardial oxygenation	Increased risk for myocardial ischemia
Cigarette smokers	Impaired defense and clearance; lung injury	Increased damage through synergism

CHD, coronary heart disease; COPD, chronic obstructive pulmonary disease.

Table 51.2 Populations considered most susceptible to air pollution

The mechanisms by which inhaled gases and particles injure the lung are diverse and not yet fully understood. The respiratory epithelium is the first point of contact with inhaled pollutants. Oxidant gases and reactive components of inhaled particles may injure respiratory epithelium via generation of reactive oxygen species. Airway epithelial cells and alveolar macrophages may respond with release of pro-inflammatory cytokines and chemokines, initiating a cascade of events, leading to airway inflammation, edema, and increased airways responsiveness. Inhalation of particulate matter is also associated with adverse cardiovascular events. The mechanisms remain unclear, but hypotheses include neurogenic reflexes influencing cardiac function, or translocation of particles to the heart. Organic materials on particles may also act as initiators or promoters of cancer.

DETERMINANTS OF RESPONSE

The likelihood of an adverse response to an inhaled pollutant depends on the degree of exposure to the pollutant and individual characteristics that determine the susceptibility of the exposed person. The relation between exposure and response may have different forms, depending on the mechanism by which the pollutant causes disease. If some minimum degree of exposure is required to produce disease, then a threshold is present. Alternatively, the risk of effect may increase with any exposure; the relationship may be linear or take a curvilinear or other form. For most inhaled pollutants, the evidence indicates increasing risk with increasing exposure. Most often, a linear relationship without a threshold is assumed, although the relevant data may be compatible with alternative exposure-response relationships. The assumption that a threshold does not exist implies that any exposure carries some risk. The shape of the dose-response relationship is relevant to the setting of regulations to protect public health.

The concept of susceptibility is highly relevant to the care of individual patients.⁵ Physicians inherently consider susceptibility in the diagnosis and management of disease. Does family history increase the probability of disease? Does age increase the chance of an adverse drug reaction? Susceptibility refers to an altered degree of responsiveness, whether increased or decreased. Epidemiologists use mathematical approaches to describe the degree of altered susceptibility associated with having a particular characteristic. In considering the combined effects of two factors, synergism is considered present if the combined effect

exceeds that predicted by the sum of the risks produced by the two factors acting independently. For some risk factors and diseases, the synergism is multiplicative; the combined risk equals the product of the two independent risks, such as lung cancer, asbestos, and smoking. For others, the interaction may be less than or greater than multiplicative, depending on the mechanism of interaction.

Factors determining susceptibility may include inherent individual characteristics (e.g., sex, age, degree of airways responsiveness, or presence of α_1 -antitrypsin deficiency) and exposure to other agents that also have adverse effects on the same target organ (e.g., cigarette smoke or asbestos). Thus, many segments of the population have been considered at increased risk from air pollution (Table 51.2). An array of epidemiologic and laboratory evidence as well as clinical judgment support the determination that these and other groups are susceptible. For example, during the dramatic London Fog of 1952, infants, the elderly, and persons with cardiorespiratory diseases experienced a particularly high rate of mortality. Laboratory exposure studies suggest that persons with asthma or with coronary artery disease may experience adverse effects from exposure to SO_2 and CO, at lower concentrations than healthy persons, and these exposure levels often occur in the US. Patients with chronic respiratory conditions are frequently aware of their own susceptibility and report being affected adversely by exposures that might seem trivial to healthy persons.

Aspects of lifestyle may also increase the risk of an adverse effect from inhaled pollutants. Cigarette smoking impairs defense mechanisms and induces chronic inflammation and permanent structural damage in the lung. The combined effects of smoking and air pollutants may be additive or synergistic. Exercise may increase the likelihood of an adverse effect by increasing the dose of pollutants delivered to target sites in the lung as ventilation increases to meet metabolic demands. The choice of microenvironments may also influence exposure; the decision to spend time outside during a period of higher pollution concentrations may markedly increase personal exposure.

SOURCES OF INFORMATION ON AMBIENT AIR QUALITY

Achieving full understanding of the health effects of any air pollutant is a daunting task. The relevant literature includes information on sources and concentrations, and comple-

mentary data from toxicologic investigations, human exposures, and epidemiologic studies. Each approach has specific strengths and weaknesses in evaluating the impact of pollutants on human health.⁶

Epidemiologic studies involve examining the relation between exposure and health effects in the community setting and typically in large populations. Respiratory effects are usually assessed by questionnaire and by tests of pulmonary function that can be used in the field setting, most often spirometry. Inherent methodologic problems may limit the results of epidemiologic studies. Accurate estimation of exposure to a pollutant is typically difficult, and many outdoor pollutants of concern are components of complex mixtures. Confounding factors including environmental agents other than the pollutant of concern and factors determining the susceptibility of subjects may further limit interpretation of epidemiologic studies.

Controlled human exposures, involving short-term inhalation of pollutants by small groups of subjects, allow strict control of the experimental subject and the environment. They often include more invasive measurements of effects than is possible in the population setting; some protocols even include bronchoscopy and lung biopsy, for example. The limitations of using environmental exposure chambers rest on ethical and practical considerations. The safety of volunteer subjects is a primary concern, so that chronic exposures cannot be performed and the investigator is limited to examining mild, acute, and reversible effects. Exposures to pollutants are usually for short durations, such as a few hours, and at low concentrations. The results of controlled human exposures cannot be extrapolated to chronic effects. Clinical studies have proved quite effective, however, in determining threshold concentrations of individual pollutants that may cause specific health effects; susceptible populations, particularly persons with asthma, have often been the focus of clinical studies.

Animal studies provide the opportunity to evaluate pathogenic mechanisms of injury by pollutants. Carefully performed exposure-response data can be collected using a wide array of biologic parameters in multiple species. The difficulty in interpreting data from animal exposures lies in extrapolation from an animal model to human health effects. Differences in respiratory tract morphology, regional deposition of pollutants within the lung, and interspecies differences in biologic and physiologic sensitivity to given concentrations of pollutants contribute to the uncertainty of this extrapolation. Additionally, we lack animal models that are closely comparable to the chronic human diseases associated with susceptibility to air pollution.

Information on air pollution from these investigative approaches is published in a broad array of journals and technical reports. Criteria documents prepared by the Environmental Protection Agency (EPA) for its regulatory process offer lengthy reviews that are periodically updated and available at the EPA website, but these summary reports are potentially overwhelming in size and scope. The American Thoracic Society periodically has prepared summary statements for health professionals on the health effects of ambient air pollution.

HEALTH EFFECTS OF SPECIFIC OUTDOOR POLLUTANTS

About 121 million people in the US lived in counties that exceeded at least one air quality standard during 2000.⁷ By pollutant, the number of people affected include 81.5 million by ozone, 9.7 million by CO, and 75.0 million by particulate matter. Although the pollutants are considered on an individual basis in the following section, it should be re-emphasized that exposure is often difficult to characterize because a mixture of pollutants is usually involved, and risk attributed to any particular pollutant may reflect the toxicity of the air pollution mixture more generally. The following discussion refers to health effects at levels of exposure encountered in outdoor environments in the US at present. A fuller discussion of health effects of exposure to agents at high concentrations is provided in Chapters 19.5 and 47. This chapter does not address the health effects of the 'hazardous pollutants', because of the large number of agents of concern.

Particulate matter, acid aerosols, and sulfur oxides

Sulfur oxides are produced by combustion of fuels containing sulfur, such as coal from the Eastern United States and crude petroleum.⁸ In the past, scientific research and regulatory concern in relation to the sulfur oxides were directed primarily at the health effects of SO₂, an oxidant gas. Particulate matter was considered separately. Particles in the air have numerous natural and human-made sources, including the same combustion processes that also produce SO₂ and another group of oxidant gases, the nitrogen oxides. These gases, through transformations, may make a substantial contribution to the mass of small particles in many parts of the US. The chemical composition of particles is complex and highly variable, but along with the size of the particle, the composition is a major determinant of toxicity in the respiratory tract.

Individuals with asthma are particularly susceptible to SO₂, responding to exposures in controlled experiments with increased airways resistance and reduced lung function. With hyperventilation, which increases the dose delivered to the respiratory tract, some asthmatics are adversely affected at levels common in ambient air and well below those that might occur transiently with direct exposure to the plume from a power plant or factory. From a clinical perspective, SO₂ might worsen asthma for persons living in communities with point sources, such as smelters.

The adverse effects of particles are thought to depend on their chemical composition, such as the presence of trace metals and hydrocarbons, and on size, which determines the site of deposition within the respiratory tract. Inflammation with symptoms and reduction of lung function in healthy persons, those with asthma, and persons with COPD are of concern, as is carcinogenesis. Diesel exhaust, for example, is mutagenic and causes lung cancer in toxicologic studies involving exposure of rodents to high concentrations. Epidemiologic data provide supporting

evidence that diesel exhaust is a human carcinogen. In experimental animal models, diesel particles enhance allergic sensitization.

A now substantial body of epidemiologic evidence has raised concern that even current concentrations of particulate matter in cities of the US (and other developed countries) may be adversely affecting the public's health. Studies in many cities show small increments in numbers of deaths, particularly from cardiopulmonary causes, on days with higher particulate matter levels compared to days with lower levels. The National Morbidity, Mortality, and Air Pollution Study (NMMAPS), conducted in 90 US cities, found that for each 10 $\mu\text{g}/\text{m}^3$ increase in PM10 (particles smaller than 10 microns) daily deaths increased 0.5%.⁹ There also appear to be adverse effects over the longer term. Mortality among persons with underlying cardiopulmonary disease is increased in more polluted cities compared with less polluted cities. There are supporting findings on particulate matter and measures of morbidity: particulate air pollution shows associations with rates of hospitalization and emergency room visits among children and adults with asthma, and among adults with heart disease. Analyses suggest particular risk associated with the most highly respirable fraction, those less than 2.5 microns in diameter (PM2.5).

The evidence was considered sufficiently compelling by the US EPA in 1997 to warrant a new standard for fine particulate matter (see Table 51.3). Many questions remain and are under active investigation; research is in progress on mechanisms and also on the toxicity-determining characteristics of particles.¹⁰ From a clinical perspective, the new findings on particulate matter reinforce the need for clinicians to consider air pollution as a factor that may adversely affect the status of their patients with heart and lung disease.

Ozone

Photochemical pollution is a complex oxidant mixture produced by the action of sunlight on vehicle exhaust. Through a series of photochemical reactions involving hydrocarbons and nitrogen oxides, various oxidant pollutants are produced, including ozone, which serves as an index for this type of pollution. Photochemical pollution was first recognized about 40 years ago in southern California, where the combination of sunlight and heavy vehicle travel promotes its formation. Ozone has now

become a problem in many other locations including other western cities in the US with similar sprawling growth, in the eastern US during the summertime, and in many other densely urban locations throughout the world, such as Mexico City.

The toxicology of ozone has been extensively investigated.^{11,12} Low-level exposures cause damage to the small airways of experimental animals; the demonstration of subtle fibrosis in one animal model raises concern for permanent structural alteration. Volunteers exposed to ozone at concentrations in the range of the present standard, often present during pollution episodes, have transient reductions of lung function; healthy subjects have a range of responsiveness that is broad but repeatable for individuals. More recently, evidence of an inflammatory response and biochemical changes in bronchoalveolar lavage fluid has been detected 18 hours after an exposure to ozone at a level below the current standard. Taken together, the progressive decrements in pulmonary mechanics during exposure coupled with the persistent biochemical changes many hours after cessation of exposure indicate the potential for chronic effects from repeated inhalation. Increased susceptibility to ozone in asthmatics has recently been demonstrated for the first time.¹³ The evidence for short-term effects of ozone exposure on the lung function of healthy volunteers has raised concern about possible long-term effects of living in southern California and other locations with sustained photochemical pollution. Relevant epidemiologic data are suggestive of chronic effects of ozone, but these data are not definitive.

Nitrogen oxides

Nitrogen oxides, like sulfur oxides, are produced by combustion processes, and contribute to the formation of ozone and secondary particles.¹⁴ NO₂ is regulated by the EPA as a criteria pollutant. Exposure also occurs indoors from unvented combustion sources such as kerosene heaters and gas stoves. NO₂ is an oxidant gas that can penetrate to the small airways and alveoli of the lung. The toxicologic evidence suggests that NO₂ exposure can impair lung defenses against respiratory pathogens and cause airways inflammation, with associated effects on lung function and respiratory symptoms. The epidemiologic evidence remains inconclusive, largely because of methodologic problems arising in attempting to separate the effects of NO₂ from those of other pollutants, especially fine particles. Similarly, controlled clinical studies provide inconsistent findings on the effects of low-level NO₂ exposure on the lung function of asthmatics. The conflicting results are probably related to differences in subject selection and exposure protocols. Individuals with COPD may represent a group with increased susceptibility to short-term NO₂ exposure, but further study of this issue is needed.

Carbon monoxide

CO, another criteria pollutant, binds to hemoglobin to form carboxyhemoglobin (COHb) and reduces the

Pollutant	Standard	Averaging time
SO ₂	0.03 ppm	Annual mean
	0.14 ppm	24-hour average
PM10	50 $\mu\text{g}/\text{m}^3$	Annual mean
	150 $\mu\text{g}/\text{m}^3$	24-hour average
PM2.5	15 $\mu\text{g}/\text{m}^3$	Annual mean
	65 $\mu\text{g}/\text{m}^3$	24-hour average
Ozone	0.08 ppm	8-hour average
NO ₂	0.053 ppm	Annual mean
CO	9 ppm	8-hour average
	35 ppm	1-hour average

Table 51.3 National ambient air quality standards: criteria pollutants.

capacity of the blood to deliver oxygen to the tissues. At high levels, CO can cause severe neurologic damage and even death in otherwise healthy persons. At low levels, individuals may have reduced oxygen uptake during exercise. Evidence indicates that controlled CO exposure of patients with stable coronary artery disease can induce earlier subjective and objective evidence of myocardial ischemia at venous COHb levels as low as 2% to 4%.¹⁵ Such data are relevant to the urban environment, where individuals may be exposed to sufficient air pollution to have blood COHb levels elevated to this range. Furthermore, moderate exercise results in even greater CO loading. Thus, for patients with coronary disease, exposure to CO can exacerbate myocardial ischemia. In addition, at a COHb level of 6%, patients with coronary artery disease have an increased frequency of arrhythmias. On a practical level, physicians should advise patients with exertional myocardial ischemia that personal exposure to CO is potentially modifiable. The unborn fetus as well as patients with COPD may be particularly susceptible to effects of CO.

Lead (see Chapter 39.8)

The population may be exposed to lead through multiple environmental media, including ambient air. Fortunately in the US, the importance of ambient air as a source of population exposure to lead has diminished with the removal of lead from gasoline, although point sources (e.g., smelters) may still be important in some communities. Children are particularly vulnerable to lead exposure, and for US children, lead paint in older, urban housing remains a significant source of exposure. Even levels previously considered safe have been associated with adverse effects on neural cognitive development. As the scientific evidence on lead and child health has developed, the Center for Disease Control has progressively reduced the blood level of lead considered acceptable, to the present value of 10 µg/dl. In some countries, leaded gasoline continues to be a significant source of environmental pollution.

CLINICALLY RELEVANT HEALTH EFFECTS OF OUTDOOR AIR POLLUTION

Our knowledge of the adverse consequences of outdoor air pollution, reviewed earlier, is largely based on investigative efforts directed at characterizing adverse effects in populations. Epidemiologic studies provide estimates of the average effect and the range of effects on groups. Studies involving controlled human exposures offer more relevant information for clinicians; however, the most susceptible subjects typically are not included in these studies.

Nevertheless, the available evidence suggests that even the relatively low outdoor levels of pollution found in the US and in other developed countries cause adverse effects of consequence in clinical practice (Table 51.4). Persons made susceptible by underlying heart or lung disease are most likely to present to clinicians with adverse effects

Pollutant types	Health effects
Particulate pollution, sulfur oxides	Increased mortality/morbidity from respiratory and cardiac disease; exacerbations of asthma and COPD; respiratory symptoms, particularly in children
Photochemical pollution	Acute respiratory symptoms; reduced lung function in exercising persons
Carbon monoxide	Ischemic symptoms in persons with coronary heart disease and possibly with peripheral vascular disease
COPD, chronic obstructive pulmonary disease.	

Table 51.4 Some clinically relevant health effects of outdoor air pollution

related to exposure to outdoor air pollution. In the evaluation of persons with difficult-to-control asthma or COPD, personal exposures to inhaled agents both indoors and outdoors should be considered as potential factors. Similarly, CO exposures should be considered in patients with ischemic heart disease having persistent angina or arrhythmias.

Even healthy persons may have acute respiratory symptoms or eye irritation from exposure to photochemical oxidant pollution. With exercise during smog episodes, lung function may also be substantially, although transiently, reduced.

Outdoor air pollution may also contribute to the development of chronic diseases and respiratory cancer. However, in an individual patient, there are currently no markers that distinguish the causative role of air pollution separate from other factors, such as smoking. Short-term excursions to places with higher levels of both oxidant pollution as well as sulfur oxide and particulate pollution may also increase the occurrence of respiratory infections, particularly those involving the lower respiratory tract.

CONTROL STRATEGIES

Regulation of outdoor air quality

The principal US federal statute addressing outdoor air quality is the Clean Air Act, which was last amended in 1990. The Act's structure and authorities are complex; it addresses mobile (automobiles and trucks) and stationary sources of pollution (power plants and industry), and requires that air quality standards be established for two sets of pollutants, so-called criteria pollutants (Table 51.3) and hazardous pollutants. These two groups of pollutants are regulated through different mechanisms. For the criteria pollutants, National Primary Ambient Air Quality Standards are set after extensive review of all relevant evidence; the standards must afford protection to the entire population, including those with heightened susceptibility, and offer an adequate margin of safety. The hazardous pollutants are predominantly carcinogens, such as asbestos and radionuclides, and standards for maximum concentrations are also intended to provide a

margin of safety. The most recent amendments listed 189 toxic agents for regulation at a prescribed and rapid pace. The Act includes mechanisms for achieving compliance with the standards and for enforcement. In spite of having federal standards in place for ambient air quality, excess levels of exposure are common in many areas of the country, particularly for ozone.

The goal of achieving a minimum level of air quality should afford protection to most persons. However, in some persons, particular combinations of susceptibility and exposure might still produce clinically relevant effects of individual pollutants at concentrations below the regulatory limits.

Patient-oriented control

Approaches for limiting the health risks of breathing polluted ambient air have received little investigation. Present understanding of the determinants of exposure suggests that modifying time-activity patterns to limit time outside during episodes of outdoor pollution represents the most effective strategy. The potentially limited efficacy of this approach in settings of high indoor air pollution needs to be recognized (see Chapter 50). The levels of some reactive pollutants tend to be lower indoors than outdoors. Ozone levels in buildings are lower than outdoor levels but can be driven upward by increasing the rate of exchange of indoor with outdoor air. Fine particles can also penetrate indoors. Nevertheless, healthcare providers can reasonably advise patients to stay indoors during pollution episodes. Vigorous exercise outdoors, which increases the dose of pollution delivered to the respiratory tract, also should be avoided at such times.

Susceptible patients should be counseled concerning the nature and degree of their susceptibility. The use of

medication should follow the usual clinical indications, and therapeutic regimens should not be adjusted because of the occurrence of a pollution episode without evidence of worsening of symptoms or function. In the laboratory, inhalation of cromolyn sodium and bronchodilating agents may block the response to some pollutants, but use of these drugs solely because of exposure to air pollution cannot be advised.

Respiratory protective equipment has been developed for use in the workplace in order to minimize exposure to toxic gases and particles. Many of these devices, particularly those likely to be most effective, add to the work of breathing and cannot be tolerated by persons with respiratory disease. Under most circumstances, healthcare providers should not suggest respiratory protection as a method for reducing the risks of ambient air pollution. Similarly, air cleaners have not been proved to have health benefits, whether directed at pollutants generated by indoor sources or at indoor pollutants brought in with outside air.

Community-oriented control

Frequently, communities become concerned about the impact of particular local sources, perhaps a power plant, manufacturing facility, or a truck or bus depot. Disadvantaged communities and populations are aware that they may have greater exposure to air pollutants and other environmental contaminants than more well-to-do communities. The term 'environmental justice' is used for efforts to address these inequities. Concern about the health risks may quickly lead to controversy and litigation. Thus, understanding the health risks posed by local sources may be difficult and requires skills in community health as well as in epidemiology and toxicology. Local physicians may become involved through concerns

AQI value	Descriptor	Pollutant level breakpoints		Cautionary statements	
		PM _{2.5} , 24 hr ($\mu\text{g}/\text{m}^3$)	PM ₁₀ , 24 hr ($\mu\text{g}/\text{m}^3$)	PM _{2.5}	PM ₁₀
0-50	Good	15	50	None	None
51-100	Moderate	40	150	None	None
101-150	Unhealthy for sensitive groups	65	250	People with respiratory or heart disease, the elderly, and children should limit prolonged exertion	People with respiratory disease, such as asthma, should limit outdoor exertion
151-200	Unhealthy	150	350	People with respiratory or heart disease, the elderly, and children should avoid prolonged exertion; everyone else should limit prolonged exertion	People with respiratory disease, such as asthma, should avoid outdoor exertion; everyone else, especially the elderly and children, should limit prolonged outdoor exertion
201-300	Very unhealthy	250	420	People with respiratory or heart disease, the elderly, and children should avoid any outdoor activity; everyone else should avoid prolonged exertion	People with respiratory disease, such as asthma, should avoid any outdoor activity; everyone else, especially the elderly and children, should limit outdoor exertion
301-400	Hazardous	350	500	Everyone should avoid any outdoor exertion; people with respiratory or heart disease, the elderly, and children should remain indoors	Everyone should avoid any outdoor exertion; people with respiratory disease, such as asthma, should remain indoors
401-500	Hazardous	500	600	Same as above	Same as above

Table 51.5 The Air Quality Index (AQI) for particulate matter

about the health of their patients or as advocates for the community's environment or for the polluting facility. Most often, the dimensions of such complex problems exceed the skills of local physicians. Nevertheless, involvement may be appropriate but guidance should be obtained from appropriate public health and environmental agencies.

The interplay of factors that must be manipulated to prevent environmentally induced disease is complex, but standards are considered to be objective indicators of successful preventive measures or strategies. In 1976, the EPA proposed cautionary statements for public reporting of outdoor air quality, the Pollutant Standards Index (PSI) for criteria pollutants. In the 1999 revision,¹⁶ the name was changed to the Air Quality Index (AQI). The actions taken when 'Alert Levels' are reached or are expected to be reached include the issuance of health advisories or cautionary statements to the public. As an example, Table 51.5 shows the AQI, pollutant levels, and cautionary statements for particulate matter. The EPA's advice is intended to be applied by local air pollution agencies in preparing daily air quality summaries, which are disseminated to the media. The AQI provides useful guidelines for physicians and public health officials.

Chapter 52

Hazardous Waste

52.1 Hazardous Waste Workers

Michael Gochfeld

A hazardous waste includes any hazardous substance that is or has been treated, stored or discarded, as well as any uncontrolled release of such a material.¹ Knowledge regarding health risks of hazardous waste has increased substantially in the years since the Phillips and Silbergeld,² and Andelman and Underhill³ reviews. Many new environmental epidemiologic studies have appeared which warrant treating community exposure in a separate chapter (52.2). While substantial progress has been made at many sites in the previous decade, Barry Johnson, former head of the Agency for Toxic Substances and Disease Registry, emphasized, 'the high percentage of sites with completed exposure pathways and the toxicity potential of substances in these pathways show that uncontrolled hazardous-waste sites are a major environmental threat to human health'.⁴

During the 1990s many US Department of Energy and Department of Defense hazardous waste programs were recognized as inadequate, with many hazardous waste sites and facilities in close proximity to populated areas. This has prompted a significant investment in environmental remediation. Also during the 1990s, whole new toxicologic problems such as endocrine disruptors were recognized, focusing attention on sublethal and non-cancer effects. Risk assessment procedures continued to evolve in terms of both mathematical and social complexity, and the field of risk communication to workers and communities has expanded.

Hazardous waste is a universal problem and the 1990s saw the recognition of hazardous waste as well as trade in hazardous materials and industries as a major problem particularly in Eastern Europe and in developing nations. The disproportionate exposure of poor people, both at home and abroad, to hazardous waste has made 'environmental justice' an important policy area. Partly for this reason, the international trade in hazardous waste poses serious ethical as well as environmental and economic problems. Altered processes to improve efficiency and reduce waste generation, coupled with recycling, offer the promise of minimizing many adverse impacts of solid and liquid forms of chemical, biologic, and radioactive wastes on people and the environment.

BACKGROUND

Well-publicized descriptions of events such as Love Canal (New York 1978), the Chemical Control fire (New Jersey 1980), and Samuel Epstein's 1982 book on *Hazardous Waste in America*⁵ brought hazardous waste to public attention. As

the number of recognized hazardous waste sites has grown, communities have come to realize that they live in close proximity to such sites, with increasing public concern. Until the 1960s, toxic and radioactive waste was considered a challenge for solid waste systems.⁶ It was then recognized that disposal of toxic substances in landfills posed hazards, and attention focused on incinerator technologies. In the 1970s major laws governing toxic substances were implemented including the Toxic Substances Control Act 1976⁷ and the Resource Conservation and Recovery Act 1976.⁸ In the 1980s governmental agencies focused attention on the magnitude of hazardous waste generation and disposal^{9,10} and on the hazards facing workers.¹¹

Initially it was proposed that hazardous waste management be assigned to governmental agencies, e.g. the Army Corps of Engineers, rather than the private sector.¹² In the 1970s, New Jersey developed a state initiative to clean up contaminated sites and taxed chemical and petrochemical industries to support a 'Spill Fund' allowing immediate cleanup. This successful program became a model for the nationwide 'Superfund' program. In the ensuing decades it became apparent that hazardous waste is a social as well as a technologic problem. Recycling and pollution prevention joined cleanup and incineration on the waste management agenda. Now many different federal agencies play a role in some aspect of hazardous materials management.¹²

Hazardous waste poses a threat to workers with occupational exposures (this chapter) and to the public potentially exposed in their homes, schools, or communities (Chapter 52.2). Exposure may occur at or near the sites of generation, along transportation routes, and near sites of ultimate disposal (i.e. hazardous waste sites). Indeed, in many communities, hazardous waste has emerged as a major public health concern. Hazardous waste management is often divided into two areas: the management of abandoned hazardous waste sites and the control of hazardous waste that continues to be produced, each governed by different federal laws.¹³ Source reduction of waste ('pollution prevention') is an important component of the latter. The modern emphasis on brown-fields redevelopment offers the opportunity to utilize partially remediated sites, with economic and social benefits, and low risk to future site occupants.

This and the next chapter cover individual workers and community exposures, respectively, and how such exposures can be evaluated and prevented. For most purposes, the clinician need not distinguish between a worker who manages currently generated hazardous waste on a factory site and one who manages formerly generated waste on an

abandoned site. Although the two settings are subject to different regulations governing waste management, worker protection on both is covered by the same OSHA regulation.¹⁴ Worker and community exposure are intertwined, because much of the hazardous waste remediation work is undertaken for the purpose of averting community exposure. Recent studies have attempted to balance the risk to workers from remediation against the community risks averted.

DEFINITION OF HAZARDOUS WASTE

Under RCRA⁸ solid waste is determined to be hazardous if its 'quantity, concentration, or physical, chemical or infectious characteristic' leads to mortality or serious illness or otherwise poses a 'substantial present or potential hazard to human health or the environment, when improperly treated, stored, transported, or disposed of, or otherwise mismanaged'. The definition is very broad, and under the Toxic Substances Control Act of 1976⁷ more than 55,000 chemicals are listed as falling under this definition. In reality most hazardous waste involves mixtures of several or many of these chemicals.

Procedures to identify hazardous waste

The Environmental Protection Agency developed tests to determine whether materials and soils qualified as hazardous. The Extraction Procedure (EP) designed to measure the extractability of inorganic materials from municipal solid waste has been supplanted by the Toxicity Characterization Leaching Procedure (TCLP). This uses a variety of solvents, including organic acids, to quantify how much organic and inorganic hazardous substances can be leached out of a waste or soil under controlled conditions. Both tests determine the mobility of toxic constituents of wastes. In tests, a physical process is used to reduce the particle size, followed by the application of extraction solvents. The resulting leachate fluid is then analyzed for the presence of 39 designated contaminants to determine if they are present at levels of regulatory concern.

REGULATORY FRAMEWORK

The US Environmental Protection Agency (EPA) and many of the states regulate hazardous waste generation, transportation, and disposal. The Occupational Safety and Health Administration (OSHA) regulates worker exposure. The Agency for Toxic Substances and Disease Registry (ATSDR), a component of the Centers for Disease Control and Prevention (CDC), and the EPA are the federal agencies most likely to become involved in evaluating the community health impact of, and actual or potential exposure to hazardous waste. The Nuclear Regulatory Commission with the EPA are involved in regulations related to radioactive waste.

Two pieces of legislation are of primary importance in regulating hazardous waste. The Resource Conservation and

Recovery Act of 1976⁸ set requirements for the management of hazardous wastes that are currently being generated. The Comprehensive Environmental Response, Compensation and Liability Act of 1980 (CERCLA; often referred to as the 'Superfund Act') focused on abandoned hazardous waste sites, and developed a trust fund, through a tax on the chemical and petroleum industries, to provide for hazardous waste cleanups or remediation at these uncontrolled or abandoned sites. This came to be known as Superfund, which is administered by EPA and modeled after the New Jersey Spill Response Act established to clean up chemical and oil spills. Both RCRA and CERCLA have been reauthorized with additional amendments, particularly the Superfund Amendment and Reauthorization Act (SARA 1988) which established a community infrastructure for managing toxic wastes and responding to hazardous chemical emergencies. Other relevant laws include the Water Pollution Control Act (1952), Clean Air Act (1963), Solid Waste Disposal Act (1965), Safe Drinking Water Act (1974), and Toxic Substances Control Act (1976).

EPA is authorized to perform short-term removal actions or longer-term remedial actions, and to force parties responsible for producing waste to conduct cleanups or reimburse EPA cleanups. Mitigation ranges from total cleanup to on-site containment, destruction or treatment, as well as cleaning up contaminated soil and ground water. Responsible parties can enter into administrative consent agreements with either EPA or a state, and undertake the site survey and mitigation under government supervision. If a responsible party refuses to participate, the government can undertake mitigation and assess triple damages. While regulations offer a framework for protecting workers, good planning and appropriate expertise in safety engineering, industrial hygiene, worker training, and occupational nursing and medicine are essential for implementation.¹²

EXPOSURE TO HAZARDOUS WASTES

Exposure to hazardous waste can be divided into occupational exposures (this chapter) and community exposures (Chapter 52.2).

Exposed workers

Employees who handle waste material directly are termed 'generator' workers. These employees may be exposed during storage procedures (e.g., loading into drums), pumping, inspection, maintenance of equipment, treating waste water, or preparing waste for shipment. Waste site employees may operate bulldozers, or crush waste drums for distribution. Transporter employees include truck, train, and barge loaders and operators. Environmental consultants, scientists, technicians, hydrologists, ecologists, geologists may inspect, sample, and analyze waste sites or perform ecologic risk assessments. Other specialized workers include well drillers who drill sampling wells on sites, remediation workers including laborers, building trades, and equipment

operators, laboratory analysts who process wastes, public safety officials (e.g., security and firefighters) and workers from governmental agencies (e.g., inspectors and contract auditors).

Subcontract workers

Although responsible parties or public agencies will usually identify one or more prime contractors to conduct various phases of hazardous waste site investigation and remediation, much of the actual day-to-day work on site is likely to be done by subcontractors. Examples of subcontractors include those involved with infrastructure (road building and paving, fencing, electricians), site security, well drilling, construction/demolition, environmental monitoring and industrial hygiene, and medical monitoring. Much of the construction/demolition work on a site will be done by construction trades (e.g., laborers, equipment operators, painters, metal workers, masons) usually hired as subcontractors. Even if the prime contractor specializes in hazardous waste work, they will frequently use local contractors for many hazardous waste operations. These subcontractors rarely have safety and industrial hygiene resources, and provision for these services may be inadequate. Moreover, since subcontractor workers may not identify themselves as hazardous waste workers, they may not recognize the need for training, protection, or monitoring. Throughout this chapter, particular hazards facing subcontract workers will be identified.

Infrastructure

Many trades may become involved in building infrastructure on hazardous waste sites. Their exposure to hazardous substances will depend on their contact with contaminated media (e.g., soil or water), or concurrent remediation activities, or unanticipated exposure from explosions, fires, or spills. Hazardous waste work is usually a small part of their overall employment, and training and experience with hazardous waste are often scant.

Well drillers

Well drilling has become an important part of both site investigation and monitoring, with an estimated 37,000 new wells drilled annually for assessment of ground water quality and contamination. Well drillers experience mechanical safety hazards and noise, and their risk may be augmented by the protective equipment they are required to wear. Heat stress and exposure to toxic materials in soil and ground water are potential problems. Inadequately protected workers may be exposed to air-borne contaminants from the site, particularly if there is concurrent remediation or other sources of disturbance.¹⁵ Vapor extraction systems and appropriate fans may be needed to reduce exposure.

Field workers

Many outdoor workers may be called on to assess resources or damages at hazardous waste sites (e.g., during ecologic assessments). Since they may not consider themselves or

be recognized as hazardous waste workers, there is a high likelihood that they will not have the training or protection or monitoring provided to other hazardous waste site workers.¹⁶

Worker injuries and exposures

Although potential exposure-related health risks facing hazardous waste workers have been reported frequently, documentation of exposure events is often minimized. In a study of an Ohio-based remediation company, 1607 illness/injury incident reports over a six-year period revealed that 75% involved mechanical trauma, 10% chemical exposure, 5% poisonous plants or insect bites, 2% temperature extremes, 1% cumulative trauma, with 7% unidentified.¹⁷

Community residents

Community residents may be exposed if their homes or workplace are in proximity to hazardous waste or contaminated industrial sites, resulting in soil contamination, because they walk or play on or near the site, or because their drinking water or air is contaminated by chemicals from the site (see Chapter 52.2).

Community vs worker risks

There are interactions between community and worker exposures. For example, strong environmental regulations regarding lead pollution of wetlands require bridge maintenance workers to work in enclosed 'tents' to contain lead dust. This, however, greatly increases the potential for worker exposure, and elevated blood lead levels are regularly encountered, even with aggressive use of personal protection.

Recently controversy has arisen over whether the risks to workers from hazardous waste remediation are warranted when weighed against the slight risk reduction to the public that remediation achieves,^{18,19} which has encouraged focusing attention on cleanups where there are well characterized exposure pathways to the public.

With the practice of 'hazardous waste days', community exposure is reduced by the opportunity to bring household hazardous waste to centralized collection centers (usually on a county-wide basis). There the chemicals are classified, bulked, and shipped to permanent secure disposal sites. Workers (usually public works employees) involved in bulk-ing activities are potentially exposed to hazardous materials, particularly in winter when such activities are likely to be conducted indoors in inadequately ventilated spaces.²⁰

HAZARDOUS MATERIAL RELEASES: SPILLS, FIRES, EXPLOSIONS

Although the concept of 'hazardous waste' connotes landfills and drum dumps, the most serious health hazards are frequently posed by the sudden and accidental releases of chemicals during spills (tanks, pipelines, vehicles), fires, and

explosions. This was highlighted by the tragic release of methyl isocyanate at Bhopal, India, which encouraged other countries to develop systems for preventing and responding to such emergencies. The train spills at Mississauga, Canada (chlorine, butane, toluene), and the metamsodium spill near Sacramento, California, highlighted transportation risks. The SARA Title III legislation emphasizes the need for local emergency planning groups, and the need to obtain information from chemical facilities located in each community, so that emergency responses can be anticipated. Such programs should involve community physicians, including emergency room and public health physicians, in the emergency planning; local hospitals need to have information on potential releases.

HAZARDOUS WASTE SITES AND NATIONAL PRIORITIES LIST

There is no single definition for a hazardous waste site, nor is the number of existing sites known with certainty. Estimates have ranged from 40,000²¹ to 50,000 for the United States alone.⁴ Only about 1500 sites have been listed on the National Priorities List (NPL), termed 'Superfund' sites. The NPL is EPA's list of uncontrolled or abandoned sites identified for possible long-term remedial action under Superfund. The list is dynamic; once a site is successfully remediated according to EPA state agency criteria, it is removed from the list. The Department of Defense has developed an analogous Priority Model to rank the potential threat of contaminated sites to health and the environment, addressing the hazard, exposure pathway, and populations at risk.²² The Department of Energy has developed an Environmental Restoration Priority System, which it uses to document its budget requirements.²²

Although NPL sites are generally considered the most hazardous, many highly hazardous sites are not on the NPL. States have the option of seeking NPL listing for a site, or may choose not to do so if a responsible party is willing to undertake the investigation. Remediation of Superfund sites has been slowed by insurance and regulatory issues, which made it attractive to undertake cleanups under state auspices. EPA provides a website (<http://www.epa.gov/superfund/sites/npl/npl.htm>), which is the entry point for information on all NPL sites (Superfund sites).

At more than half of NPL sites, exposure pathways to human populations have been identified, indicating that they pose a health hazard. The sites are compared based on a hazard ranking system (HRS). Community involvement is included in the designation of a Superfund site, and a public comment period follows entry in the Federal Register that proposes listing a site on the NPL.

The first stage in the Superfund process is identification of the hazardous waste site. Once a site is identified, the state agency or EPA conducts a preliminary site assessment, including an inventory of known wastes on the site, to determine if there is a potential hazard. If a hazard exists, this may require emergency remediation or, more often, a

remedial investigation/feasibility study (RI/FS) is conducted, usually by private contractors.²³ The RI/FS serves as the mechanism for collecting data to:

1. characterize site conditions;
2. determine the nature of the waste;
3. assess risk to human health and the environment; and
4. conduct treatability testing to evaluate the potential performance and cost of treatment technologies.

The latter provides the mechanism for the potential development, screening, and detailed evaluation of alternative remedial actions.

Remediation may range from simple enclosure and warning signs to complete removal of waste, treatment of soil and ground water, and capping. The Superfund Trust monies can only be used for sites that meet the HRS criteria for inclusion on the National Priority List. Details on the HRS criteria and process are provided at: http://www.epa.gov/superfund/programs/npl_hrs/hrsint.htm

Hazard ranking system

The Hazard Ranking System (HRS) is the principal mechanism EPA uses to place uncontrolled waste sites on the NPL. It is a numerically based screening system that uses initial site inspections and preliminary investigations to assess the potential of the site to pose a hazard to human health. The HRS yields three scores. The first evaluates the possibility that hazardous chemicals can migrate offsite. This depends on their likelihood of becoming air-borne (a function of soil dustiness and chemical volatility) or of moving through ground or surface water. These depend on geologic hydrologic features (slope, streams, aquifers), soil characteristics (organic content, colloidal nature, percolation), as well as on the chemicals' solubility characteristics. The second evaluates the likelihood that humans (often referred to as human 'receptors') or 'sensitive environments' will come in contact with the contaminated air, water, soil, or organisms. This depends on proximity, population density, prevailing winds, recreational activities, sources of drinking water and food, and the local topography. Some hazardous waste sites adjacent to residential areas are favored for recreational purposes, increasing the likelihood of human exposure. The third score is determined by the quantity and toxicity of the waste and its explosive or fire hazard properties.

The public is often confused by the designation Superfund site. This does not necessarily mean that a site will be cleaned up or even that it poses a real hazard. The listing designates the need for investigation of the site, and determination of how the site will be handled. Many Superfund sites remain today, unchanged from when they were listed nearly two decades ago. Posted public warnings at sites are variable. Occasionally Superfund sites, such as the Frontera Creek site in Puerto Rico, are found to pose little public health or ecologic threat.²⁴

Under the law, responsibility for cleaning up or otherwise 'mitigating' a site lies with the responsible parties that generated the waste. Often the responsible parties cannot be identified, or may no longer represent a financially viable entity. Even when the original generator still exists,

or when a legally responsible corporate heir is identified, years of legal action may ensue. In the interim, Superfund monies can be employed for mitigation, and the government will subsequently attempt to assess damages and seek reimbursement of the Fund.

CHEMICALS IN HAZARDOUS WASTE SITES

Discussion of chemical agents can be organized along structural (organic vs inorganic) or functional parameters (e.g., pesticides, solvents, etc). In order to characterize complex chemical mixtures it is essential to organize agents into groups that can be described generically. Fortunately, many chemicals are used only in research or in small quantities by very few industries, so that approximately 2000 are of widescale concern, and only about 300 are commonly used in large quantities. Indeed, since analytical laboratories normally provide information on only a few hundred chemicals, we are effectively limited to discussing those on which we have data. The US EPA has narrowed attention to about 150 chemicals, the so-called Hazardous Substance List or HSLs, which include the most toxic, widely encountered, or most useful surrogates (chemicals that may indicate that certain other chemicals or pollutants in general are present). This list includes 129 chemicals termed 'priority pollutants', plus some additional compounds. The priority pollutants are further broken down into groups based on analytical protocols: volatiles, semivolatiles, base neutrals, acid extractables, and heavy metals. Evaluations of hazardous waste sites or other contaminated sites often begin by measuring the priority pollutants in soil or water samples. Table 52.1.1 indicates the ten chemicals most commonly identified on Superfund sites. Thirty substances (18 of which are carcinogens) are present in 6% or more of the NPL sites.

The common solvents found in large amounts at hazardous waste sites are the aromatics (benzene, toluene, ethylbenzene, and xylene, abbreviated BTEX) and chlorinated alkanes and alkenes, particularly 1,1,1-trichloroethane, trichloroethylene (TCE), and tetrachloroethylene (perchloroethylene). These highly volatile compounds, vaporizing both into the atmosphere and into

soil pores, are highly mobile, readily forming underground plumes, which can travel great distances, contaminating both ground and surface water. Heavy metals such as arsenic, lead, cadmium, mercury, and chromium are frequently present, although many compounds have low mobility and bioavailability. Polyaromatic hydrocarbons are also present at many waste sites and are the main contaminants of concern at gas plants and refineries.

Worker exposure occurs mainly at the source site during production, or during the onsite storage or shipping of the wastes. Occupational exposures also occur during transportation and at the final repository. However, most occupational health concerns focus on the hazardous waste remediation workers, who must be trained and protected to minimize exposure. Many hazardous organic chemicals break down quickly in the environment, but some are stable for years. In contrast, metal compounds persist indefinitely.

Chemical compatibility

Although many hazardous waste sites are drum dumps, tanks, or pits, there are also hazardous laboratory and industrial wastes that require sorting for proper disposal. Such sorting is conducted indoors and can be quite hazardous. These operations are conducted at generator sites to assure that waste streams are properly handled and that incompatible chemicals are not mixed. Incompatibilities can result in fires, explosions, splashes, or release of toxic gases. Oxidizers and reducers mixed together can cause serious reactions. The mixing of acids and bases can accomplish neutralization, but certain acid-base reactions can generate deadly hydrogen sulfide or cyanide compounds.²⁵ Such determinations often require working with open containers, and must be done under optimal ventilation with appropriate protective equipment.

RADIOACTIVE AND MIXED WASTES

Radioactive wastes have been generated in research laboratories, medical facilities, nuclear power plants, and in the development, manufacture, and testing of nuclear weapons. Although the latter activity was curtailed in 1989, the legacy of long-lived radionuclide wastes still exists on sites managed by the Department of Energy (DOE) and related contractors. The waste exists in tanks, drums, or containers of liquids and solids, both indoors and outdoors and above or below ground. Contamination occurs in soil, water, sediment, debris, and buildings. Radioactive sources, both sealed and unsealed, occur on DOE sites. Decommissioning, 'cocooning', and safe storage of cores of numerous reactors pose a particular challenge. In addition, numerous radiation targets and warheads await dismantling and disposal.

Radioactive waste exposure occurs at source sites, during transportation, and at repositories. Some short-lived isotopes decay very rapidly, releasing high energy over a short period of time, but many isotopes – particularly those generated

Chemical	Number of sites
Trichloroethylene	129
Toluene	95
Benzene	94
Lead	93
Chloroform	68
PCBs	58
Tetrachloroethylene	57
Phenol	55
1,1,1-Trichloroethane	54
Chromium	53

*Data from Mitre Corp. 1983, after McDiarmid & Strickland 1990⁶⁴

Table 52.1.1 Top ten chemicals reported in first 546 Superfund sites*

during the nuclear fuel cycle – have half-lives exceeding 100,000 years. Storage repositories must be secure to prevent leakage, theft, or disruption by geologic processes. The workers at greatest risk are those remediating the large scale Department of Energy sites, contaminated by nuclear waste from fuel and weapons production. Remediation activities are regulated by the DOE and contractors performing the work are responsible for meeting training, monitoring, and radiation protection requirements. Imposing and overseeing the regulations for lower-level subcontractors is a challenge for the DOE, which must have teams of industrial hygienists and radiation technicians to oversee subcontractors' performance.

High-level waste from nuclear reactors and nuclear weapons production is now in short-term storage at many nuclear facilities. Waste results in part from reprocessing spent fuel and fuel targets. Much is in liquid form and is potentially explosive. Although the federal government has sought to provide a permanent repository for such waste, and levied a tax on nuclear utilities to develop such a site, this has not been accomplished to date. In February 2002, President Bush approved the development of the Yucca Mountain facility as a permanent repository. This site in arid, sparsely populated country, with seismic stability, has faced opposition from state government and whether it will actually begin receiving such wastes by 2010 is uncertain. The safe and secure disposal of radioactive waste from nuclear power plants represents a severe challenge in the future development of nuclear energy.

Transuranic waste containing elements with higher atomic mass than uranium were formed during production of enriched uranium and plutonium for nuclear weapons. This contains more than 100 nanocuries per gram of α -emitters with half-lives greater than 20 years. This waste has been stored on Department of Energy facilities in several states. Volume reduction is the first step toward remediation followed by encapsulation and transportation to the Waste Isolation Pilot Plant (WIPP) in New Mexico. WIPP began development in the 1980s, but was only opened to receive wastes in 2001.

Low-level waste – a special case of hazardous waste is represented by low-level radioactive waste. In 1980 Congress shifted responsibility for the disposal of low-level radioactive wastes (LLRW) to the states. LLRW is defined as 'any radioactive material that is not high-level waste, transuranic waste (containing more than 100 nanocuries of alpha emitting isotopes with half life greater than 20 years), spent nuclear fuel, or by-product nuclear material', and is thus classified by the US Nuclear Regulatory Commission (NRC) by what it is not. LLRW is considered by many regulators to be relatively benign, including, for example, equipment and gloves used in manufacturing smoke detectors. However, it is difficult for the public to differentiate the hazards of HLRW from those of LLRW, and this hampers efforts to develop an effective disposal strategy. Moreover, some materials classified as LLRW may actually have high radioactivity.

About half the LLRW is generated from commercial nuclear reactors. The other half is from industrial and

medical byproducts (including diagnostic and therapeutic materials). Examples include watch dials, radiographic equipment, and radiopharmaceuticals.²⁶ By definition, LLRW does not pose a substantial or lasting environmental threat to the biosphere or to humans. Compounds in this category require only marginal shielding and will decay rapidly. NRC²⁷ concluded that the threat to public health would be low and only shallow burial at closely monitored sites is required for safe disposal of LLRW.

Mixed wastes contain both toxic chemicals and radionuclides. These range from radiolabeled chemicals used in laboratory research and medical practice, to reactor cooling water containing chromium as a slimicide. They may vary from a few milliliters of a radiolabeled solvent to drums of inadequately characterized material. The safe handling, cleanup, and disposal of these wastes are largely under the jurisdiction of the NRC; however, some may be under mixed jurisdiction, complicating disposal.

BIOLOGIC WASTES

In the past decade, medical waste emerged as a significant public health hazard requiring its own regulations and management systems. Mismanagement of such waste, resulting in syringes, containers of blood, and contaminated medical waste washing up on New Jersey and New York beaches, captured extensive media attention and caused great economic losses to beachfront communities. The public outcry focused attention on this pervasive problem.

Waste from medical facilities is classified as infectious or non-infectious (mainly office and food wastes, or clinical supplies that have not come in contact with blood or other biologic materials). Infectious medical waste is generally defined as any solid waste that is generated in the diagnosis, treatment, or immunization of human beings or animals, in research, or in the production or testing of biologic agents, including but not limited to: soiled or blood-soaked bandages, culture dishes and other glassware, discarded surgical gloves or instruments, syringes and needles used to give shots or draw blood, lancets, cultures and swabs to inoculate cultures, and biologic material, and specimens. Sharps (needles, lancets, etc) are disposed of directly into specially designed and labeled rigid plastic containers. Other infectious waste is disposed of as 'red bag' waste in heavy gauge, red plastic bags.

Medical waste generators include private practitioners, clinics, hospitals and other healthcare facilities. Transporters, handlers and disposal facilities are also covered by regulation. Individual patients who generate medical wastes such as bandages and syringes at home are not covered. Most exposure takes place at the source site to clinical staff, housekeepers, and janitorial workers involved in the generation, collection and disposal of waste. Prior to the 1990s, many hospitals operated their own incinerators and disposed of infectious waste on site. Air quality and odor complaints coupled with stricter federal regulations governing emissions encouraged many hospitals to close down these local incinerators, and ship their wastes

offsite to commercial medical waste treatment and disposal facilities.

The opportunity for exposure is greatest in those directly exposed to an infected patient (nurses, doctors, and other healthcare providers) and in those who collect the waste (housekeeping), particularly when sharps or broken glassware are disposed of improperly. Blood-borne pathogens such as the viral agents of AIDS and hepatitis are the main concerns, and the OSHA Blood-borne Pathogen Standard describes procedures for minimizing exposure. The risks vary with the frequency of the infections in the patient population, the infectiousness of the source blood, the nature of the object involved in the injury, and the characteristics of the injury itself. Needlestick events raise prominent health concerns due to risk of HIV, HBV, and HCV infection. Immunization against hepatitis B is required for personnel who may contact biologic waste, and a needlestick protocol including access to prophylaxis is necessary to prevent transmission of HIV.

The management of medical wastes includes grinding and chlorination, autoclaving, and incineration, which allow the material to enter the solid waste stream. In most cases medical wastes are collected in rigid red containers for sharps, and in red bags for other infectious medical wastes; these are shipped to companies that specialize in their destruction. Regulated medical waste haulers are used to transport the material to their destination. Medical waste disposal is regulated at the state level, but the emissions from medical waste incinerators are regulated by the US EPA. Other federal agencies regulate the transport of wastes (US Department of Transportation and US Postal Service), workplace exposures and blood-borne pathogens (US Department of Labor's Occupational Safety and Health Administration), and radioactive constituents in medical waste (Nuclear Regulatory Commission).

BIOLOGIC TARGETS OF HAZARDOUS CHEMICALS

Toxic chemicals damage living organisms in many ways; toxicologic research has revealed molecular mechanisms underlying genotoxicity, biochemical reactions, affecting organelles, and cells, organs and tissues. In some cases specific physiologic functions are inhibited. These may include diverse effects involving hematopoiesis, renal function, immune function, neurobehavioral performance, and reproduction. Exposure may occur to adults in general or to especially sensitive groups such as small children, pregnant women, or the elderly. Despite the great expansion of toxicologic knowledge, it is usually difficult to predict the effects of a particular exposure to hazardous waste, often involving complex mixtures, on an individual; assessing risk of adverse reproductive outcome or of developing cancer are particular challenges, which are the two greatest concerns voiced by exposed populations.

HAZARDS ASSOCIATED WITH SOLID WASTE MANAGEMENT

Workers who collect, sort, compact, or incinerate waste can be exposed to hazardous materials. Sanitation workers have died from noxious materials thrown out in trash. The more common hazards are organic dusts containing micro-organisms and endotoxins, as well as various chemicals. Landfill workers in New York reported more respiratory, dermatologic, and neurologic symptoms than other sanitation workers.²⁸ Garbage incinerators may emit toxic substances. Knox²⁹ found high rates of childhood cancer within 5 km of garbage incinerators, although the confounding effect of other industrial exposures could not be separated. Men living close to a Montreal landfill had elevated rates of several cancers.³⁰

EXPOSURE PATHWAYS FOR WORKERS

Workers regularly exposed to hazardous waste are required to have training and protection to minimize exposure. Nonetheless exposure can occur when containers are breached, when there are leaks, spills, fires, explosions, or transportation accidents, or where safety measures are not followed.

Occupational exposure is often through inhalation of air-borne vapors or aerosols, but may also be through dermal contact. Inadvertent ingestion may occur if workers eat near the source of exposure or if their food and water are contaminated by aerial deposition. The importance of dermal absorption is probably underestimated in most exposure scenarios.

THE TIME COURSE OF EXPOSURE AND EFFECTS

The temporal features of exposure and effect are critical aspects of hazardous waste (or indeed any toxic) exposure. People may be exposed once to very high amounts (e.g., fire or explosion), or intermittently or continually to low levels. Similarly, effects may be manifest as acute, subacute, or chronic illness. Most troublesome is the long latent period between exposure and many effects. The consequences of some exposures are manifest immediately, while we have learned that the outcome of other exposures, particularly to carcinogens, may not appear for decades. For example, the latent period for mesothelioma from asbestos exposure may exceed 40 years. The long latency for cancer associated with environmental exposures poses challenges in establishing and attributing causality.

The practice of averaging exposure over time may be convenient for managing exposures in industry or for performing risk assessment, but is not biologically sound. Peak exposures may cause much greater damage than the same total amount distributed over time.

HAZARDOUS WASTE REMEDIATION

Remediation options vary greatly in scope and cost from fencing off a contaminated area to excavation and removal of contaminated soil, and pumping and treating the ground water. Research into methods for reducing the volume or toxicity of waste is extremely active. Chemical, physical, and biologic treatments, as well as administrative controls, can be utilized.^{13,23}

There are a number of specialized treatments that can be used to diminish toxicity of hazardous wastes, including bio- and phytoremediation. Bioremediation employing bacteria to metabolically alter organic materials is widely used. An industry has developed around the 'invention' and patenting of new organisms designed to destroy particular substances, and includes the introduction and maintenance of the organisms on contaminated sites. Phytoremediation can be effective since roots and their accompanying microbial fauna can reduce the quantity of PAHs present.³¹ Various plants have the propensity to extract particular substances (especially cations) from soil, and the plant material can be harvested and disposed of as solid hazardous waste.

Immobilization of radioactive wastes involves a variety of new technologies, including vitrification, which entails mixing the waste with borosilicate and heating it until it flows and then hardens as a glass that is then encased in steel canisters.

Remediation of waste often generates secondary waste. Excavation of dirt is the crudest method, and results in no volume reduction. Such dirt is hazardous waste, although it is sometimes mixed with much larger amounts of clean dirt (dilution) until the concentration of contaminants is 'acceptably low', and the soil can then be re-used, e.g., in road construction.

Pump and treat activities produce a water stream that must be processed in some way (for example, with charcoal columns) to remove the main contaminant(s) of concern. The resulting waste water is by no means pure and must be disposed of. Recharging into the ground or even an aquifer may be feasible if the removal efficiency has been high; different classes of compounds are removed with different efficiencies.³²

High temperature treatments and incineration

Incineration remains a standby for destroying organics, although very high temperatures are required for polyhalogenated aromatic compounds such as PCBs and dioxins. It leaves behind an ash, mainly carbon and heavy metals. It requires either the construction of an onsite incinerator or the transport of wastes to a certified incinerator. Incinerator emissions can contain unwanted toxic chemicals as well. Recent studies exploiting advanced gas-phase thermal chemistry have identified how dioxins, furans, and other polycyclic compounds are formed in incinerators, confirming earlier concerns about the gener-

ation of highly toxic air emissions during incineration. A variety of catalysts, including copper ions, play key roles in this transformation.³³ Workers at incinerators are responsible for receiving wastes, completing manifests, sorting wastes, feeding wastes into the incinerator, and maintaining operating conditions. They may be exposed to airborne emissions from the stacks, or during maintenance and cleaning operations. Fires and explosions occur occasionally, such as the Rollins fire in 1977 and the Chemical Control fire in 1980. Improved control methods and the training and monitoring of subcontractors who enter these sites have reduced the frequency of these events.

High temperature can also be applied in the field. In-situ thermal destruction applies a vacuum to subsurface or surface soil to pull air heated to 800°C through the soil. This can be highly efficient at destroying organics such as PCBs and PAHs with a high boiling point, and can greatly reduce the worker exposure involved in dig and carry operations. However, reducing PCB levels to the cleanup standard of 1 ppm may still require soil excavation.

CONCENTRATION, EXPOSURE, BIOAVAILABILITY, AND DOSE

Once an exposure pathway for workers or community has been established, it becomes necessary to estimate the degree of exposure. Usually the concentration in the environmental medium can be measured, and often exposure can be inferred. Bioavailability may be measured with laboratory simulations³⁴ or inferred from biomarkers.

Concentration

Concentration determines how much of a toxic material is present in environmental media, including the air (mg/m³), water (mg/l), and soil or food (mg/kg). Laboratories that analyze these media provide information on the concentrations of dozens of toxic substances in the medium, which is the first step toward estimating hazard. In practice, the laboratories analyze for approximately 129 different substances that EPA has designated as Priority Pollutants.

Exposure

Exposure refers to how and how much of a substance enters the body. The movement of hazardous chemicals is very complex, and has challenged attempts to estimate exposure through modeling. Analytic procedures do allow some measurement of soil concentrations, air levels, and ground water plumes (an underground 'river' of hazardous material that moves slowly from its origin). This must be linked with behavioral data – how much time does an individual spend in proximity to the site, how might they be exposed to soil or dust or water, what level of protection do they use and how consistently? Such exposure data are frequently limited in environmental and occupational epidemiologic studies.

Exposure	Air	Soil/dust/fomites	Water	Food
Dermal	Generally not applicable	Some compounds absorbed from muds or slurries	Some substances absorbed from water or slurries	Not applicable
Inhalation	Primary route	Fine dusts, construction, road traffic	Aerosols during showering and cooking	Not applicable
Ingestion	Airborne deposition on food, crops	Toddlers ingest soil	Primary route	Primary route
Injection	Not applicable	'Sharps' for healthcare facilities	Not applicable	Not applicable

After Gochfeld 1991.⁶⁵

Table 52.1.2 Exposure matrix for human exposure to environmental pollutants

Combining the four environmental media (air, water, soil/dust, and food) and the routes of exposure (dermal absorption, inhalation, ingestion, and occasionally injection) into an exposure matrix (Table 52.1.2) focuses attention on specific pathways.

Bioavailability

A critical factor in exposure analysis is bioavailability. The presence of a toxic material in soil does not establish that it can be taken up by plants or by people. For example, a soil with a high organic content may bind certain pollutants such that they cannot be released even when the soil is swallowed. For example, in rodent feeding studies Gallo and associates showed that dioxin-contaminated soil from Newark, New Jersey, yielded a much smaller proportion of its dioxin content than the sandier soil from Times Beach, Missouri.³⁵ Many risk assessments assume a bioavailability of 100%, a conservative assumption to maximize safety.

Dose and internal dose

Dose refers to how much of a substance reaches a target site in the body. A fundamental principle of toxicology is embodied in the dose–response concept. Simply stated, larger amounts of many chemicals typically produce larger effects. However, the dose–response relationship may be complex. In medicine, dose is measured by the amount that enters the body or gets absorbed into the blood stream, usually measured in mg of substance per kg of body weight per day. Of greater interest, but harder to quantify, is the internal dose delivered to the target tissue, which can sometimes be estimated using physiologically based pharmacokinetic models or by measuring biomarkers.

Thresholds

The first feature of the dose–response relationship that must be determined is whether there is a threshold, some level of exposure below which no effect (and no risk) occurs (see also Chapter 5). The antithesis of the threshold, the so-called no-threshold relationship, is exemplified by ionizing radiation and many other chemical carcinogens. Thus even very low exposures to ionizing radiation produce a finite risk of damage, without a threshold for radiation carcinogenesis.³⁶

Determining a potential threshold in such circumstances is hampered by the practical challenges of directly

studying the biologic effects of extremely low concentrations at which a threshold would exist. The current resolution, in keeping with the two-step model of carcinogenesis, is to treat initiators or genotoxic carcinogens (those which directly alter DNA) as if they have no threshold, and to treat promoters as if they have a threshold.

A second challenge to interpreting dose–response is illustrated in Figure 52.1.1, which compares two chemicals, both of which are shown with a threshold. If one uses the relative thresholds to compare toxicity, B appears to be more toxic than A, with an effect at a lower dosage. However, the midpoint of the curves show that B produces 50% of its effect (response dose or RD-50) at a very similar level to A. At higher doses, chemical A actually has greater toxicity than B, as indicated by the response rate. Hence, even the task of ranking chemicals by relative toxicity can become a difficult process.

CHEMICALS AND MIXTURES

Each individual chemical may exert one or more toxic effects on different target cells, tissues, or organs. For example, benzene, along with many other organic solvents, has general anesthetic properties when people are exposed acutely to high concentrations of vapors. Of greater concern, however, are the myelotoxic properties of

Figure 52.1.1: Dose–response curves showing the relative toxicity of two chemicals. If thresholds are compared, B is more toxic than A, but if the RD-50 is compared, then B appears to have similar toxicity to A. At higher doses, A has greater toxicity than B. (T–threshold dose).

benzene which result in aplastic anemia and leukemia. These effects occur in individuals with long-term exposure to much lower levels of benzene, levels below the odor threshold and below the threshold for neurotoxic effects.

One of the most troublesome features of hazardous waste sites is that the chemicals are present in mixtures, and that the actual composition of the mixtures is seldom fully known. Even when known, there is relatively little experience on how the toxicity of one compound is modified by simultaneous exposure to others. Three types of interaction occur: additive, where the effects of the two compounds together is equal to the cumulative effects both might have if they were administered separately; synergistic, where the two compounds together produce an effect greater than the sum of their individual effects (or at a lower combined dose); or protective, when one compound reduces the effect of the other. Synergistic actions pose the greatest threat, but are particularly difficult to estimate. One of the reasons to adopt an overprotective approach in environmental health is the uncertainty regarding the possibility of synergistic interactions where mixtures occur.

Explosive wastes and ordinance

The specialized task of dealing with ordinance and explosive wastes (OEW) and unexploded bombs, mines, and weapons (unexploded ordinance or UXO) is a specialized area of hazardous waste management. When such materials are identified they are usually dealt with by bomb squads on site, or in some cases transported to US Army facilities for detonation.³⁷

CASE EXAMPLE OF A HAZARDOUS WASTE PROBLEM

On Earth Day 1980, the Chemical Control site in Elizabeth, New Jersey, exploded and burned. The fire raged for days, and many of the more than 40,000 55-gallon drums of chemical waste were damaged and their leaking contents were washed into the adjacent rivers by millions of gallons of fire-fighting water. The smoky plume blew for hours over surrounding neighborhoods. A study conducted by the National Institute for Occupational Safety and Health revealed that many firefighters had suffered measurable respiratory damage, since there was not adequate protective equipment for all of the personnel on site, and in some the damage was still evident five years later. No detailed study was made of the surrounding community (for descriptions and illustrations of the Chemical Control site see USEPA 1980³⁸ and Gochfeld & Burger 1990²⁴).

The Chemical Control Company had operated for more than a decade, receiving waste from diverse chemical companies. In many cases the drums bore little or no labeling information, though many indicated the name of the generator company. Although the company was paid to dispose of the waste in a legal fashion, it merely stored the material on site. Its incinerator was never licensed, and

except for reports of some illegal nocturnal burning, waste continued to accumulate until the State of New Jersey closed the site in 1979 and took it over to begin the cleanup process.

The Chemical Control site was one of the nation's first Superfund sites. Despite the potentially disastrous prospect of a large hazardous waste site in close proximity to residential areas, the cleanup proceeded slowly, and provided insight into the problems that were to confound and retard cleanup and mitigation for the ensuing decade. Despite the fact that there was a hazardous waste incinerator already on site that could have been upgraded to safely dispose of much of the waste, the decision was made not to use it, but rather to ship all material offsite. This required opening every drum, sampling and identifying its contents, relabeling, and manifesting (or cataloging) it.

The process was accelerated when many of the generator companies were ordered to reclaim their identifiable wastes. It was, however, retarded by the difficulties in locating a suitable disposal site in another state and arranging safe transportation. Many of the drums (lab-packs) contained small vials of unlabelled wastes from research laboratories, and months were spent trying to identify and re-pack them. In the year that passed, only a small proportion of the material was moved offsite, prior to the fire and explosion.

The subsequent cleanup, complicated by the fire and rusted drums, required about five years and cost about \$5,000,000 US. The period saw the emergence of companies specializing in hazardous waste cleanup, and one of the first medical surveillance programs instituted specifically for hazardous waste workers. Many of the lessons learned from the Chemical Control experience have shaped subsequent hazardous waste remediation approaches. In 2001 the site was a paved area surrounded by a high chain-link fence, awaiting 'brownfield' re-development.

EVALUATING AND PROTECTING THE HAZARDOUS WASTE WORKER

Protecting hazardous waste workers involves extensive training, determining their fitness to use respirators, careful selection of appropriate protective equipment, establishment of a standard operating procedures manual which includes appropriate safety planning, and medical surveillance. Whereas most of these procedures, including site monitoring by industrial hygienists, represent primary prevention, medical surveillance is secondary prevention (see Chapter 4.2). In addition to assessing early health effects in workers, it serves a quality assurance role, by being able to detect exposures that occur when there is a breakdown or inadequacy of the primary preventive strategies.

Health and Safety Plans

Hazardous waste investigations and remediation operations require a Health and Safety Plan (HASP) which

includes both generic and site-specific components. This is the first step in worker and community protection. A typical HASP includes the following components: site description and layout of zones, hazards present, applicable standards and regulations, public safety, work site safety, site safety officer, chain of responsibility for subcontractors, hazard assessment including substances and amounts likely to be encountered, personnel protection and respiratory protection program, routine decontamination procedures for personnel and equipment, environmental monitoring procedures and equipment.

The HASP must also include provisions for emergency medical care for the site, and must designate employees with first aid and emergency response training. The HASP also identifies the necessary first aid equipment and procedures for emergency decontamination and evacuation, summoning emergency care, ambulance transport and notification of local emergency rooms regarding site hazards and work in progress.

Record keeping is an important part of the HASP. It includes names of all prime and subcontractor employees and visitors to a site, dates of deployment, training and equipment, as well as any exposure and medical monitoring data. The plan should include regular (preferably daily) safety briefings including all contractor, subcontractor, and regulatory personnel, with documentation of attendance and topics.¹² Some components of a HASP are discussed below.

Exclusion zone

Careful layout of a hazardous waste site will facilitate cost-effective operations and afford appropriate levels of protection. The HASP will identify the site zones including a exclusion or hot zone, a contamination reduction zone, and a support or clean zone. Appropriate layout of a hazardous waste site affords the opportunity to allow only adequately trained and protected workers into the most hazardous areas of the site. Other workers are allowed access to certain parts of the sites, i.e., command posts, while being excluded from the center. Staging areas for supplies and equipment, for the shipment of contained wastes, as well as decontamination areas and facilities need to be established and posted appropriately.²⁵

Personal protective equipment

Personal protective equipment (PPE) plays a central role in protecting hazardous waste workers, because of the often unpredictable nature of their exposures. Nonetheless, engineering and administrative controls as well as good work practices remain important. PPE must be selected to be appropriate to possible exposure scenarios and hazards that may be encountered, yet must be sufficiently comfortable that it can and will be worn for the required period. Selection, training, and maintenance of the PPE are an integral part of the HASP. The goal is to provide the appropriate amount of protection. PPE may subject workers to heat stress, requiring adjustment of work practices.³⁹

Respirator fit and fitness

Unlike industrial workers, the use of personal protective equipment plays a prominent role in protecting hazardous waste workers. Respiratory protection must be appropriate to the hazards that may be encountered. Wearers must be tested with their respirator to assure that there is a good fit (no leakage) (see also Chapter 4.1). They must have adequate training, not only in respirator selection, use, and maintenance, but also in hazard recognition and avoidance, i.e., exposure prevention.

There are four levels of protective equipment (Table 52.1.3) determined by the type and degree of contamination that may be encountered. Level D corresponds to requirements imposed on many industrial workers. Level C protection is encountered in industrial settings under special circumstances. In industry, Level B is likely to be used in confined space operations, and Level A primarily under emergency conditions. In hazardous waste activities Level B is not uncommon.

The OSHA Respirator Standard (CFR 1910.134) requires a medical evaluation to determine that there are no medical contraindications to using a respirator or wearing protective equipment. However, the criteria for making this determination are not absolute. Moreover, demographically, individuals applying for hazardous waste work tend to be young and healthy, such that cardiorespiratory contraindications to respirator use are likely to have low prevalence. With the 1998 Revision of the Standard, clearance can be provided simply by completing a questionnaire which can be reviewed by a licensed health provider.

In general, people with significant cardiorespiratory impairment (such as angina or recent myocardial infarction, uncontrolled hypertension, arrhythmias or significant respiratory impairment from lung disease) should not do work that requires respiratory protection. Wearing respirators increases the work of breathing, increases physical workload, and can exacerbate heat stress (leading to peripheral vasodilatation). Rarely, individuals develop anxiety when wearing respirators and other protective equipment, and they should not be placed in locations where regular respirator use is required.

Significantly, the OSHA Standard does not require either chest radiographic studies or spirometry for determining respirator fitness. While it has been argued convincingly that in the absence of a history of cardiovascular or pulmonary disease these tests do not aid the clinician,⁴⁰ workers may be in a medical surveillance program where spirometry is required. Individuals with respiratory symptoms and a moderate decrease in function (e.g., FEU, or FVC 50-65% of predicted) require careful consideration. Such individuals might be cleared for level C, but not for level A or B protection. In jobs where the individual can pace their work, such a restriction may not be essential.

Additional conditions that must be considered, but are not currently regarded as an absolute contraindication for use of respirators, include pneumothorax, ruptured tympanic membrane, and use of contact lenses. While the need for increasing the intrapleural pressure to overcome

Level	Respirator	Body protection
Level D No measurable concentration. No exposure by inhalation or splashes.	None or dust mask.	Work coveralls. Dust mask as needed. Safety goggles. Hard hat/steel-toed shoes as designated.
Level C Known air concentration acceptable for air-purifying respirator. IDLH will not be reached. No skin damage or permeation. No unidentified vapors present.	Air-purifying respirator. Full face-piece.	Light, impermeable outer garment over work clothes.
Level B Air level may exceed capacity of air-purifying system. Unidentified vapor(s) likely to be present. Oxygen <19.5%. Dermal absorption possible, skin contact with head or neck not likely.	SCBA or other air-supplied system.	Full-body, impermeable garment, not encapsulated.
Level A Chemical concentration known to be above safe level or IDLH. Extremely hazardous or unidentified substance likely to be present. High splash potential. Likelihood of dermal absorption.	SCBA or other air-supplied system.	Full-body, encapsulating chemical suit.

Table 52.1.3 Levels of protective equipment for working on hazardous waste sites (IDLH = Immediately Dangerous to Life and Health)

increased dead space raises concern for pneumothorax, there is no evidence that respirator use poses a significant risk. Unless there is a history of a very recent or recurrent pneumothorax, this is not currently considered a contraindication. A ruptured tympanic membrane has been considered a possible route of exposure; however, remains a largely theoretical concern. The use of contact lenses has often been discouraged or forbidden for hazardous chemical work. The rationale is that chemicals might be absorbed under the lens by capillarity, that a soft lens might absorb chemicals, or that the lens might suddenly dislocate, causing the worker to remove their face mask. However, the improved visual acuity and visual field afforded by contact lenses may more than compensate for the risk, and it is reasonable that a person wearing contact lenses have the same eye protection as a person wearing no corrective lenses.

Respiratory protective equipment (RPE) plays an important role in protecting hazardous waste workers, but is not used uniformly. Mandatory fit-testing and training programs can play an important role in motivating workers to use RPE, while concerns about comfort and communication undermine RPE use.⁴¹

Preventing heat stress

A particular problem confronting workers who must exert themselves in chemically impervious protective clothing is heat stress (see Chapter 34). Outdoor work reduces risk for accumulation of hazardous vapors and fumes, but increases exposure to solar radiation. As heat load exceeds dissipation, body core temperature increases, performance declines, accident rates increase, and heat events (heat exhaustion, heat stroke) increase.⁴² Ambient air temperature, radiant temperature, humidity, air motion, and metabolic heat production all contribute to increased heat load.

Acclimatization, work-site canopies, adequate hydration, and scheduling of work are among the approaches to reducing heat stress. Most important is an appropriate rest-work alternation schedule. In sunny areas this may require workers to spend more than 50% of their time at rest. Medical screening, other than a prior history of heat-related events, is of limited use in detecting individuals susceptible to heat stress. Certain equipment, including air-cooled suits, can be very beneficial. Small work sites can be covered by a canopy to exclude solar radiation, fans can be installed to increase air movement.

Decontamination

Decontamination procedures require planning to assure that workers practice the required 'decon' protocols when they move from zone 1 (hot zone) to zone 3. This requires proper removal and disposal of contaminated clothing and equipment, and the washing of non-disposable equipment (e.g., boots), such that contaminants are not tracked into clean areas or carried outside the hot zone. Details for appropriate design of a decon facility and program are provided by Lippitt and Prothero.⁴³ The selection of solvent (usually water), detergent, acid or base (if needed), and the proper drumming and disposal of the waste water are essential.

Training

Appropriate training ensures that workers know the hazards they will encounter and provides knowledge and skills for safe performance of work and protection. Training covers hazard recognition, exposure reduction (including PPE selection, use, and limitations), emergency escape procedures, emergency protocols including decontamination,

and site-specific topics.⁴⁴ The OSHA Standard¹⁴ requires a 40-hour training course with 8-hour annual refreshers, and additional training for supervisors. Actual 'hands-on' performance, including material handling while wearing protective gear, greatly enhances the learning experience, compared to passive classroom lectures.

Environmental monitoring

An important part of a Health and Safety Plan is environmental monitoring, which is a basic industrial hygiene procedure for worker protection. This is necessary to determine the level of protection required for particular tasks or particular parts of the site. In the absence of monitoring, a higher level of protection is required, which may increase the risk of heat stress, impose unnecessary discomfort on the wearer, and increase costs unnecessarily. A variety of monitoring devices are available, including real-time monitors with alarms to indicate the presence of excessive concentrations of volatile chemicals.⁴⁵ Monitoring for combustible gases, carbon monoxide, and for oxygen concentrations in confined space tasks is also essential.

Real-time field monitors have varying sensitivity and specificity. A chemical sensor for volatile organic compounds (VOC) can document underground plumes or air-borne emissions. They can be used as alarm systems. Real-time equipment includes portable gas chromatographs, flame ionization detectors (FID), or photoionization detectors (PIDs). Some are designed to read a particular substance or class of substances. Detector tubes, often used in factory settings, are often less suitable for hazardous waste sites. FIDs indicate total combustibles present, and are not very sensitive to temperature or humidity changes; they are not suitable for chlorinated hydrocarbons. PIDs are durable general purpose detectors that are non-specific and sensitive to humidity. The more expensive Fourier-transform infrared detectors (FTIR) can be tuned to specific substances (when there is a single substance of concern). These monitors do not require oxygen, in comparison with FIDs, and may be used in oxygen-deficient environments.⁴⁶ Confined spaces including buildings, tanks, and trenches represent particularly dangerous environments and require special protocols.⁴⁷ The level of air-borne contaminants present or potentially present determines the level of personal protective equipment required.

Employee job task analysis

A refinement of Health and Safety Plans is the Employee Job Task Analysis (EJTA) which requires supervisors to analyze the tasks required of each worker during every phase of a site investigation and remediation. This involves identifying and documenting critical functions and potential hazards, and links each worker with the appropriate level of training, protection, and medical clearance. The EJTA predicts, characterizes and helps prevent hazardous exposures. It has been initiated at Department of Energy remediation sites, and should extend to all hazardous waste operations.⁴⁸

Medical monitoring for hazardous waste workers

Medical monitoring involves the longitudinal monitoring of workers with actual or potential exposure to workplace hazards (see also Chapter 59). The OSHA published the Hazardous Waste Standard or HAZWOPER,^{14,49,50} which sets forth the requirements for 'medical surveillance' of hazardous waste workers (Paragraph F). There are some important limitations to the Standard. First, it emphasizes fitness rather than needs for surveillance. Second, it sets a threshold of 30 days of exposure above the permissible exposure limit for mandatory surveillance, which does not address individuals with briefer or intermittent high exposure levels and might include those with inadequate training or protection. Fortunately EPA contract specifications usually include comprehensive medical surveillance for all site workers. Finally, while the OSHA Standard leaves the content and interpretation of the surveillance program to the discretion of the physician, it does not stipulate a specific level of medical training or certification.

Medical monitoring of hazardous waste workers has posed many challenges.^{51,52} Since hazardous waste workers with the greatest opportunity for exposure should have a high level of training and protective equipment, few actually experience significant unprotected exposure. This is reflected by studies showing relatively few abnormalities detected among hazardous waste workers.⁵³ On the other hand, workers with a lower level of exposures, but inadequate protection, may be at greater risk, and are less likely to be included in medical programs. Further, white collar hazardous waste workers were 67% more likely than blue collar workers to be in a surveillance program, even though they were less likely to be injured.⁵⁴

Recommendations for medical monitoring programs

The medical monitoring program begins with a preliminary screening examination,⁵⁵ which can determine fitness and provide baseline data for comparison with subsequent evaluations. This is followed by periodic (usually annual) surveillance examinations. The extent, content, and frequency of examination depend on the type of work being performed. Annual examinations are common, but not required. The OSHA Standard gives the examining physician discretion over frequency of follow-up.

The examiner must have a clear picture of each worker's responsibilities and potential exposures; this requires more than a cursory understanding of the specific hazardous waste work. The anticipated task and job requirements should be developed for the EJTA (see above) and provided to the medical examiner in writing. The examiner should review these with each worker to verify the potential exposures.

Workers should complete a general health history form, including an occupational history, supplemented by specific information on past, current, and anticipated exposures. The past and current use of protective equipment should be reviewed, and the examiner should verify

their appropriateness. The questionnaire and/or history should identify the frequency of work in the field, the kinds of sites visited, the substances encountered, the protective gear used, and the problems encountered on the site (including breakdown of operating procedures, explosions, exposures, or acute illness). Each worker should be asked specifically whether they have had mandated hazardous waste training, fit testing and training on their required protective equipment, and understanding of the Health and Safety Plan.

Each new employee should undergo a thorough baseline examination, including a detailed physical examination and blood tests (complete blood count and clinical chemistry profile with liver function testing). Workers who may require frequent exposure to heavy metals or pesticides may have baseline biomonitoring (e.g., blood lead or serum and red cell cholinesterase, respectively). Biologic monitoring was formerly a widespread and expensive component of the examinations, but in most cases has not proven fruitful and has been abandoned by many companies and providers. In some cases, baseline blood samples are archived for future analysis in the event of an exposure. Spirometry is usually performed as part of a respirator fitness examination, but is not required. Electrocardiograms are warranted for workers older than age 40 years or who have a history indicative of an increased risk of heart disease (e.g., family history, chest pain, hypercholesterolemia, hypertension). Stress tests are warranted only if clinically indicated. Audiometry is warranted for heavy equipment operators and others exposed to significant noise.

The periodic examination should include an interim history and targeted physical examination. Further test components depend on the history and exposure. No routine laboratory tests are required, but most examination batteries include spirometry and blood tests. Incident-related examinations are performed when there has been a spill or other exposure, or when a person has become sick as a result of work on a site. This examination depends on reports by the industrial hygienist or site safety officer, who should be able to identify the substance(s) to which the worker was exposed.

Positive results warrant appropriate follow-up, and findings that are believed to indicate chemical exposure must be reported to the health and safety officer as well as the employees, so that additional investigations and protection can be instituted. Usually such exposure occurs only when there is an accident or a breakdown in procedures. Under normal operating conditions, hazardous waste workers should be able to function with no appreciable chemical exposure and no increased health risk. Where health problems are detected, workers should be informed of procedures for filing worker's compensation claims.

Turnover and surveillance

Effective medical surveillance requires longitudinal tracking of the employee, so that current medical findings can be compared to past results. However, hazardous waste work is an industry with high worker turnover, and because each company uses different medical providers, it is

frequently the case that the current examiner has no prior medical record on a particular employee. Accordingly, each hazardous waste worker should receive a complete copy of test results and medical findings. The OSHA Standard requires that they also receive a written explanation of any significant findings. Providing workers with their medical records to take to future providers greatly enhances the value of the medical program.

Quality assurance for medical monitoring

Virtually all medical monitoring of hazardous waste workers is contracted out to physicians. Settings include academic or industrial medicine clinics or private practitioners. Some of these providers are very experienced, while others are unfamiliar with regulations, requirements, and risks. Likewise, some remediation companies lack expertise in identifying required medical services and receive little specific guidance from the OSHA HAZWOPER standard. Some medical companies specialize in providing medical monitoring services, and purchasers of such services must ascertain the experience and credentials of providers, as well as the appropriateness of the services offered. Some hazardous waste remediation firms operate in many states, using local providers for their medical monitoring. Therefore it is essential that the hazardous waste companies institute some form of quality assurance to ascertain that their employees are receiving the appropriate level of monitoring.⁵⁶

Protecting subcontractor workers

As hazardous waste management has developed into an industry requiring increasing specialization, the work-force involved has become more diverse. Many employees are transient, spending only a few days at each site without considering themselves hazardous waste workers. For example, fencing contractors erect fences around sites, road-builders construct access roads and pave pads to support trailers and equipment, and electricians bring power lines to sites. Work on hazardous waste sites may thus represent only a small part of their work activities. Since these workers often do not have to wear respiratory protection for 30 days in a year, most of the subcontractors do not participate in any medical monitoring programs. Nonetheless, where respiratory protection is required, such workforces are required to meet the PPE provisions of the Hazardous Waste Standard as well as the training, fit testing, and fitness provisions of the OSHA Respirator Standard. Unfortunately, such programs are frequently not in place. The evaluation⁵⁷ and auditing⁵⁶ of hazardous waste workers protection should be an ongoing feature of any HASP.

INTERNATIONAL HAZARDOUS WASTE

Although hazardous waste and other environmental and public health issues are addressed in most industrialized nations, they frequently 'take a back seat' to economic development in developing nations. Traditionally, devel-

oping nations have been characterized by numerous small companies, employing few workers, with few resources or staff devoted to occupational or environmental safety and health. Even in countries with environmental regulations, enforcement is limited, due to the decentralized nature of waste generation. El-Fadel et al⁵⁸ demonstrated this with a case study in Lebanon, and warn that the impact of globalization is to superimpose large-scale industrialization on an infrastructure inadequate to deal with current hazardous waste generation. Wastes are disposed of on land and in water with little regard to containment, in a manner reminiscent of the mid-1900s in industrialized nations, without consideration for the much greater costs involved in cleaning up wastes decades in the future.

Assessing hazards at waste disposal sites is an international challenge, and methods have to be generalized to take into account different record keeping practices and cultural exposure patterns.⁵⁹ In some countries large populations live adjacent to or on landfills, and make their living by gleaning recoverable items from the dump. The sale of scrap metal, some of which has had radioactive contamination, has resulted in large-scale radiation exposure in countries such as Mexico, Taiwan, and Brazil. In the future, growing population pressures may require retrieving contaminated sites.

International trade in hazardous waste

Disposing of hazardous waste in compliance with laws has become an expensive process. On the one hand, high cost should be an incentive for pollution prevention and source reduction, including substituting less hazardous materials wherever possible. On the other hand, companies and countries look for less expensive disposal methods that increasingly involve shipping wastes to developing countries with economic incentives. Global environmental treaties are being developed, but are difficult to implement, particularly when hazardous waste is viewed as a commodity protected by world trade agreements.⁶⁰

SOURCES OF INFORMATION

There are many volumes and compendia which provide information on specific hazardous substances. In addition, an increasing number of websites contain such information. The US EPA's Integrated Risk Information System (IRIS) has a web page that documents the scientific literature on which reference doses for non-carcinogens or slope factors for carcinogens are based. The Agency for Toxic Substance and Disease Registry (ATSDR) publishes and periodically updates monographs on specific chemicals commonly found in NPL sites. Fortunately this information is now available on the web at <http://www.atsdr.cdc.gov/toxpro2.html> (verified March 2004), or as CD or hardcopy free from ATSDR.

WASTE MINIMIZATION

A generation ago, Garrett Hardin⁶¹ pointed out that our approach to regulation promoted rather than penalized the

profligate disposal of waste materials, spreading the cost over society as a whole, rather than charging it to the polluters themselves. State and federal efforts to discover and control hazardous waste sites were already well under way by 1982, when Epstein and co-authors published their popular book,⁵ and when medical evaluation approaches for populations exposed to hazardous waste were described.⁶²

The increased cost and regulation of hazardous waste disposal have made waste minimization more attractive, and ultimately an economic necessity.⁶³ In 1984 the Hazardous and Solid Waste Amendments to RCRA stated that 'it is to be a national policy of the United States that, where feasible, the generation of hazardous waste is to be reduced or eliminated'. The Office of Technology Assessment¹⁰ concluded that industry had been slow in achieving waste minimization, even though this may actually reduce costs. Unfortunately, in the ensuing years, progress towards waste minimization has been slow. Nonetheless, there are bright spots, such as a variety of efforts to minimize mercury in the waste stream through elimination of mercury batteries, exchange of mercury thermometers, and removal of mercury switches from automobiles.

52.2 Community Hazardous Waste Exposures

Michael Gochfeld

Many of the facts and principles regarding hazardous waste reviewed in Chapter 52.1 apply to community exposures as well. The impetus for the Resource Conservation and Recovery Act 1976 (RCRA) and the Comprehensive Environmental Response, Compensation and Liability Act 1980 (CERCLA), the statutes that govern hazardous waste management, was protection of public health by preventing community exposure. Residential and community exposure can occur from a variety of sources, including proximity to operating or abandoned industrial sites or landfills, from air-borne or water-borne contamination, from leaking pipelines or underground storage tanks, from transportation accidents, as well as uncontrolled releases such as fires and explosions. Several exposures, such as to medical and composted waste discussed in the previous chapter, can also affect community residents. Evaluating long-term, low-level exposures, including complex mixtures, poses a challenge to physicians practicing environmental medicine.¹

HAZARDOUS WASTE VS HAZARDOUS MATERIALS EVENTS AND RELEASES

This chapter focuses on community exposure to hazardous waste. Communities can also be exposed to hazardous chemical and radioactive substances through uncontrolled industrial releases, transportation spills, fires, and explosions. For the most part these events are beyond the scope of this chapter. In the state of Washington alone, between 1993 and 1995, an estimated 1269 such events were recorded, of which 294 involved human victims.² Title III of the Superfund Amendments and Reauthorization Act of 1986 (SARA Title III) established a new approach to managing chemical hazards, requiring industries to report the identity and amount of hazardous chemicals. SARA Title III also established local governmental boards to receive such data and evaluate hazards to the community, developing local emergency response plans where needed. However, implementation has been variable and often incomplete, in terms of both obtaining and processing data.³

EXPOSURE PATHWAYS

While the proximity to hazardous substances in waste sites is certainly a potential risk to health, there are two critical intervening factors: exposure pathway and biologically available dose. In order for people to become ill there must be a completed pathway of exposure involving contamination of air, water, food, soil, or dust, and entry into the body through inhalation, ingestion, or dermal routes. Proximity to a site is a major, though not essential aspect of this pathway. In general, air-borne contaminant concentration declines as the inverse square of distances from the source, although stack height, wind direction and velocity, physiologic features (terrain, buildings), and physical properties

of the contaminant (e.g., density compared to air) greatly influence this pathway. Ground water contamination can operate over relatively long distances when an entire aquifer is contaminated. About a third of the sites on the National Priorities List have documented complete pathways of exposure.⁴

The Agency for Toxic Substances and Disease Registry (ATSDR), a branch of the CDC, has the responsibility for evaluating health risks to communities with actual or potential exposure to hazardous wastes. This agency can perform public health assessments (Table 52.2.1), a primary purpose of which is to characterize pathways from contaminated environmental medium to human receptors. Community studies by ATSDR focus attention initially on the existence of a completed exposure pathway, from source, to environmental medium, to absorption route, to target organ. When such a pathway is documented, it is important to estimate the dose that can be transmitted, and how such a dose compares with known dose-response data for that substance. Seldom is there complete information on all components, and many uncertainties exist in estimating risk.

Marshall and colleagues⁵ considered four pathways of exposure: air vapor, air particulates, ground water ingestion, and ground water inhalation (e.g., soil ingestion by toddlers). In studies of community exposure to industrial or hazardous waste sites, arbitrary cutoff distances have been used to distinguish an exposed from a non-exposed population. Areas were classified within one mile of each site according to (1) the probability of exposure to solvents, metals, and pesticides, and, if available, (2) the relative concentration of contaminants. The probability of exposure (low, medium, or high) for air vapor and particulates depends on the evaporation and soil retention potential of the contaminants, degree of containment, predominant wind direction, size of the contaminated area and amount of contaminant at the source, as well as any remediation or interventions. The probability of exposure for ground water ingestion and inhalation depends on whether there are water supply wells or affected basements within one mile, solubility of the contaminants, direction of ground water flow, and ground water sampling results. Relative concentration is based on sampling results for the appropriate environmental media.

EVALUATING COMMUNITY EXPOSURE TO HAZARDOUS WASTES

Inadequacy of exposure data (mainly retrospective) often represents a challenge in assessing the public health significance of hazardous waste. Such data are essential (1) to support epidemiologic studies of workplace and community exposure, (2) to conduct risk assessments, (3) to determine the utility of medical monitoring,⁶ (4) to guide

remediation and risk management activity,⁷ and (5) to support litigation, remedial investigations, and cleanup. Many studies rely on proximity or distance to a source, but in order to make this a meaningful surrogate for exposure, the spatial resolution must be improved, requiring smaller areas with better characterized sampling strategies.⁸

Although many hazardous waste sites are former industrial properties, or landfills, and may be in rural areas away from densely populated areas, there are many sites that have residences within close proximity. In many cases, residential housing has been built on former industrial facilities, abandoned waste sites, or former manufactured gas plants, and many other sites have residential properties immediately abutting the property line. In some cases direct soil contamination of backyards has occurred due to runoff from the industrial sites, while in other cases concern may arise in a community downwind from a site. Other communities have had private or municipal wells contaminated by industrial waste.

The basic principles of exposure apply to community residents as well as to workers. Materials can move off-site through air, soil, water, and the food chain. People can be exposed through inhalation (air, dust), through dermal contact (soil, water), and through ingestion (soil, water, food). The picture is complicated frequently when communities have used abandoned waste sites for recreation.

Environmental media of concern and routes of exposure

Table 52.2.2 is an exposure matrix illustrating how material can move from the environment into the body. Air, soil, water, and food are the primary environmental media that can be contaminated. In addition to toxic vapors, air-borne dusts or smoke from waste incinerators carry toxic particulate matter. Surface runoff or leachate through the soils may lead to contamination of surface or ground waters. In many cases, people actually enter the sites, experiencing direct contact with contaminated soil. This is particularly true in the case of children, who may ingest soil from their fingers after play. The problem is compounded by recreational use of abandoned sites. For example, dirt-bikes generate dust that can be inhaled or ingested. Once the soil and water are contaminated, there is opportunity for certain chemicals to be taken up by plants or plankton and thereby enter the food chain, with exposure to humans who may consume contaminated fish or wildlife.

The matrix (Table 52.2.2) has proven useful for demonstrating these relationships to policy makers and the public. It identifies the components that must be included in a risk assessment and those that are subject to remediation. For example, 'fallout' or air-borne deposition on the skin may not be important at a hazardous waste site, but may be significant in evaluating a proposed incinerator. Secondary interactions can also be incorporated in the matrix (e.g., air-borne deposition on edible portions of plants). The routes of exposure include ingestion, inhalation, and dermal absorption (injection is rarely applicable). In general, air-borne materials are inhaled, while contaminated water and food are typically ingested. Contaminants may become bioavailable through a combination of these routes.

Please refer to the printed publication.

Table 52.2.2 Exposure matrix for human exposure to environmental pollutants (Strength of pathway: + = Weak; ++ = moderate; +++ = prominent)

Soil contamination with hazardous materials is widespread. Some contaminants are taken up from soil by garden plants. The contaminants in soil may leach into ground water, contaminating drinking water supplies. However, the main pathway of concern is the direct ingestion of soil by toddlers. The bioavailability of contaminants in soil is highly variable. They may be bound tightly to organic compounds, may exist in insoluble forms, or may be freely accessible when ingested. Various approaches have been used to estimate bioavailability, including the use of simulated gastric juice to extract lead and chromium compounds from soil. The bioavailability varied for lead from 39% to 70%, 41–66% for arsenic, and 34% for chromium.⁹

Community vs individual exposure

Most exposure investigations consider the community as a whole, particularly where air or ground water contamination is involved. This is sufficient to determine whether remediation is required or whether medical monitoring will be beneficial. It may also be the basis for litigation. However, for epidemiologic studies or where single households are affected, it may be important to determine exposure for individual families or even specific family members. This will also be essential in the screening phase of a medical monitoring program (see below).

Ongoing vs historic exposure

If exposure is ongoing or current, it is relatively easy to sample the relevant environmental media (e.g., drinking water, or indoor air in basement, showers, and bedrooms), ascertain behavioral patterns for family members, conduct 'market basket' analyses of food, and measure biomarkers of exposure in individuals. It is useful to narrow the assessment to one or a few agents that are suspected to have reached a family. Whereas the initial investigation (see Chapter 52.1) may seek to identify dozens of compounds, usually only about ten are found to be present in large quantities in a waste site; often only one or two of these are suspected of being significant for a household. For example, with leaking underground storage tanks from an adjacent gas station, the exposure evaluation may focus on petroleum hydrocarbons and benzene. Proximity to a chromium dump will focus attention on trivalent and hexavalent chromium.

It is often the case that exposure to hazardous materials ceased years previously and exposure can only be inferred

by historical analytic data (air, soil, ground water), and by reconstruction of places and years of residences. In a New Jersey community where municipal wells were contaminated by a chemical company, several communities drank contaminated water for 10–20 years, but their exposure ceased in 1985. Medical monitoring, however, did not begin until 2002, by which time only residential information could be used to stratify the group by historical exposure probabilities.

Behavioral aspects

Often overlooked is the importance of individual behavior in determining or modifying exposure. The number of hours an individual spends at home, the amount of tap water consumed, the apportionment of time between different rooms, the amount of time and frequency of showering, the reliance on homegrown foods compared with commercial foods, the amount of fish consumed, are important variables. For children, especially toddlers, the amount of time spent at home compared with school, indoors compared with outdoors, crawling on floors and engaging in hand-to-mouth behavior are extremely important. Where soil is contaminated, the cover of playing areas (bare soil vs grass or pavement) and the activities on the soil are important.

Biomarkers

Some hazardous wastes such as heavy metals or polychlorinated organics persist in the body for long periods of time, stored in organs or fat, with slow excretion. These can be measured relatively non-invasively in blood or urine, and less effectively in the case of metals with hair and nails. Some exposures may be detected months or even years after exposure has ceased. Many small organic compounds, however, are quickly metabolized, and they or their contaminants can only be measured in the body if exposure is ongoing or relatively recent (days or weeks).

HIERARCHY OF EXPOSURE DATA AND SURROGATES

The National Research Council¹⁰ identified a variety of exposure metrics and ranked them from best to poorest. This hierarchy of exposure-related data is presented in Table 52.2.3.

Quantified personal measurements
Quantified area or ambient measurements in the vicinity of residence or other sites of activity
Quantified surrogates of exposure (e.g., estimates of drinking water use)
Distance from site and duration of residence
Distance from site or duration of residence
Residence or employment in reasonable proximity to site where exposure can be assumed
Residence or employment in defined geographic area (e.g., county) of the site

Table 52.2.3 Exposure metrics as ranked by the National Research Council from best (top) to poorest (bottom)

Quantified personal measurements are virtually never available, even with recent or current exposures. Area measurements may have been obtained as part of surveys or compliance investigations. Surrogates of exposure such as distance and/or duration of residence are frequently used. The last measure, namely co-occurrence of site and receptor in the same geographic area, is also frequently used and is usually referred to as 'an ecologic study'. The NRC list is consistent with use of biomarkers as a quantified personal measurement. Kharrazi et al¹¹ successfully used odor complaints as a marker of exposure.

There have been several epidemiologic studies based on approximate distance between residence and source. Different authors used different distance criteria, based either on data constraints or on a priori judgments about significant distances. In an Australian study, distances of 300 m and 1000 m were used.¹² A 1994 study by Sosniak and colleagues¹³ used one mile, measuring distance from the center of the zip code region to the center of the nearest site; such an approach may result in substantial misclassification of distance, requiring large numbers to assess an effect (see below). A very large study comparing adverse birth outcomes among populations within 2 km of British landfills, compared with reference populations showed very small, but statistically significant increases of all congenital anomalies, neural tube defects, hypospadias/epispadias, and low birthweight. The relative risks were all less than 1.1 except for gastroschisis (1.19). Conversely, heart defects were slightly but significantly lower among the exposed. No mechanism was identified to account for these findings.¹⁴

Many authors have concluded that enhanced availability and use of biomarkers to document exposure will advance environmental epidemiology. One common way to sample various biomarkers is through blood tests for a pollutant or its metabolites. However, exposure levels and the timing of exposure may not produce detectable signals of any biomarker in blood. ATSDR studied various analytes in blood in people living near to and far from an industrial complex, and found little difference in commonly encountered industrial volatile chemicals. The authors concluded that blood volatile organic compound (VOC) 'testing should be limited to populations living near sites where environmental testing has shown recent, elevated VOC exposure, or where unusual circumstances of illness may be attributed to VOC exposure'.¹⁵

HEALTH SURVEYS

When a community learns about a significant exposure to hazardous wastes, it is likely to request a health survey. In contrast, public health agencies may voice reluctance about such surveys, and are often not able to conduct a formal epidemiologic study. Such studies could include surveys and questionnaires, but might also include studies of birth or death certificates, data from birth defects or cancer registries, emergency room visits or hospitalizations, or comparisons of disease incidence or mortality in the affected community with that for a comparable

community or the state. Unfortunately, in the absence of more detailed exposure data, one can rarely determine the exposure status of the individuals who become ill, and such studies are very likely to be inconclusive.

The importance of accurately determining exposure is that it will reduce the likelihood of misclassification errors (see Chapter 6). If an exposed person has a health problem, but is erroneously misclassified as an unexposed referent, or if a referent with no health problem is erroneously classified as exposed, the likelihood of detecting a difference in health status is compromised. Thus misclassification errors bias a study towards the null, reducing the likelihood of identifying an effect, even when an effect exists.

The ATSDR is charged to develop large-scale community health surveys. Surveys may involve little more than questionnaires or may involve extensive medical examinations and testing. In some cases, laboratory testing may be done as an exposure screening tool, as in urine testing for chromium, or breast milk screening for organochlorine compounds.

Health surveys may be aimed at estimating exposure, or may actually focus on the prevalence of particular disease endpoints. Careful attention must be given to designing such studies, particularly to the manner in which either negative or positive outcomes will be explained to the community, to government, and to responsible parties. Inadequately planned surveys may fail to uncover significant exposure, may provide spurious results that later undermine the community's efforts, and may discourage community and public health officials alike. However, since in many cases future exposure is terminated, a health survey, if it is to be conducted, should be undertaken in a timely manner, before evidence of exposure becomes diminished or lost.

One of the major difficulties with such health surveys and epidemiologic studies is the potential for bias and the difficulty of obtaining appropriate reference groups. By the time the study gets initiated, community members frequently have concerns regarding adverse health effects. Participants in health studies may be self-selected, introducing sources of bias and complicating interpretation of findings. However, it is essential to remember that the potential for selection bias does not mean that people have not been exposed or affected.

Self-reported exposures

Epidemiologists are divided over whether self-reported exposure can be relied on for hazardous waste studies. Dunne et al¹² found that people who believed that they had been exposed showed more symptoms than those who believed they had not. They attributed the difference to the effect of belief as advanced by Roht et al.¹⁶ Ozonoff et al¹⁷ likewise found an association between belief and self-reported findings. Since many aspects of exposure, visual and olfactory, are readily detectable by the exposed persons, it is likely that those who believed they were exposed actually had higher exposure than those who did

not believe they had exposure. Indeed, Kharrazi et al¹¹ found that lower birth weights were associated with higher levels of odor reports.

Pets as sentinels

In some cases a sickness or death of a pet that has recently swallowed or drank from a mud puddle has called attention to local soil contamination. A study of pet dogs living near Superfund sites showed a higher frequency of micronuclei than in control dogs, suggesting actual exposure.¹⁸ The rate of sinonasal cancer in pet dogs was more highly correlated with exposure to carcinogens in indoor air rather than outdoor pollution.¹⁹

NATIONAL EXPOSURE REGISTRY

ATSDR has established a National Exposure Registry (NER) as mandated by Superfund legislation. The purpose of the Registry is to assess and evaluate the potential relationship between adverse health effects and exposure to hazardous wastes, particularly the relationship between chronic health effects and long-term, low-level chemical exposures. The NER's trichloroethylene (TCE) subregistry has been used to demonstrate increased rates of hearing impairment and other conditions associated with historical exposure to TCE,²⁰ and offers one approach to identifying exposed individuals.

EPIDEMIOLOGIC STUDIES OF COMMUNITIES

There have been many attempts to identify or estimate the health impacts of community exposure to hazardous wastes, often by studying people in proximity to hazardous waste sites. Like many aspects of environmental epidemiology, the health risks of hazardous waste are often subtle and invariably complex. For some cancers there is a long latency between exposure and outcome. Even with events such as the Minamata disease outbreak (methylmercury poisoning in Minamata, Japan), where the health impacts were widespread and catastrophic, years elapsed before the causal agent was identified. Occupational health consequences lend themselves more readily to epidemiology, because populations are more circumscribed and exposures more quantifiable. However, the industrial hygiene literature indicates that substantial, and at times monumental, efforts of historic dose reconstruction may be required. There are classic studies of communities exposed to hazardous waste; these include reproductive and developmental effects near the Love Canal (Niagara Falls, New York²¹) and leukemia (Woburn, Massachusetts²²).

The importance of exposure estimates, misclassification bias, and power

Investigations of community exposure present problems of defining populations at risk, establishing reasonable refer-

ence populations, documenting pathways, and estimating concentrations and dose. The increasing mobility of society complicates the task of identifying populations at risk. The identification of suitable biomarkers of exposure and effect has greatly facilitated epidemiologic studies; improved exposure monitoring, spatial mapping, and statistical methods are also valuable. Nonetheless, many studies may yield wide confidence intervals due to small sample sizes; elevated risk ratios for disease may thus be difficult to interpret.

Although epidemiologic studies are often population based, the units of measurements are typically based on individuals and their disease outcomes. Thus it is necessary to have individualized exposure estimates that, as indicated above, may be challenging to ascertain. Most epidemiologic studies rely on surrogates of exposure or membership in a class. The inherent danger of such reliance is misclassification bias. If individuals with low or negligible exposure are included among those with high exposure (i.e., misclassification), the possibility of detecting an exposure is compromised. Once the potentially exposed population has been identified, usually based on some a priori distance assumption, a reference population is chosen. Sometimes the reference population is contiguous to the exposed one, and sometimes at a greater distance, including use of national reference populations. However, members of the reference population may also have been exposed to the same or similar hazards.

Within the exposed population, some individuals are more highly exposed than others, and these are presumably the ones likely to manifest the adverse health effect. However, by pooling these people with less exposed individuals, there is dilution of the effect being sought. This *invariably* reduces the power of any study to detect an adverse health effect. Yet, if a study attempts to stratify by exposure, the result may yield few people in an arbitrary 'high exposure' category, reducing power to detect effects.

Statistical power and hypothesis testing

The tradition of hypothesis testing and statistical significance arose in other disciplines and has been transferred directly to epidemiology, usually without critical consideration of its limitations (see Chapter 6). While setting an α (or 'P-value') of 0.05 may make sense in the context of many scientific investigations, it may be an unrealistic criterion for community-based epidemiologic studies, particularly since people do not need to be 95% confident when making health decisions or avoiding exposures. Studies of community exposure are limited by the size of the community, often in the hundreds, so that most studies begin with low power and can only detect a 'significant' a dramatic increase in the rate of disease.

Reference populations and confounders

Defining an appropriate reference population is a challenging aspect of designing studies in environmental settings. The reference population should be similar to

the exposed population with regard to age, gender, ethnic, socioeconomic, and occupational characteristics, all of which are important risk factors for disease in general. Occupational exposures to hazardous materials would be especially confounding in a community study of the same hazards. Such matching represents a challenge that may not be achievable. Neighborhoods are often subtly structured, particularly with regard to socioeconomic factors. Even in a highly mobile society, people living close to an industrial facility are more likely to be employed there than those further away. People living close to a hazardous site are also more likely to be poor than those living further away, even within the same town.

Published studies appropriately identify the possibility of confounding. However, just because confounding may exist does not mean that it explains the findings. If a study has been undertaken to detect adverse health effects associated with a hazard, and observes a statistically significant positive association, it is important to strongly consider that that association is likely, even when the possibility of confounding is real. Only if the confounder can be shown to be a more likely cause of the outcome than the exposure should confounding be adduced as the primary explanation, and even then the exposure should not be disregarded. Interactions between confounders and the exposure (e.g., smoking and asbestos) may also represent an important causal factor.

Small area statistics

There are many challenges in performing environmental epidemiologic studies to evaluate exposure, risks, and health effects attributable to hazardous waste. These have been identified by many authors.²³ Small area statistics are a widespread problem in trying to study a single workplace or community. Characterizing populations living in proximity to (and at varying distances from) hazardous waste sites requires special statistical techniques. A general weakness is the lack of direct exposure measurement. An increased prevalence of self-reported health symptoms such as fatigue, sleepiness, and headaches among residents near waste sites has been reported in numerous studies. It is difficult to conclude whether these symptoms are an effect of direct toxicologic action of chemicals present in waste sites, an effect of stress and fears related to the waste site, or an effect of selection, recall, or reporting bias.

Although a substantial number of studies have been conducted, risks to health from landfill sites are challenging to quantify. There is often insufficient exposure information, and effects of low-level environmental exposure in the general population are by their nature difficult to establish. More interdisciplinary research can improve understanding of risks to human health related to hazardous waste disposal sites. As Vrijheid and colleagues emphasize, research needs to include 'epidemiologic and toxicologic studies on individual chemicals and chemical mixtures, well-designed single- and multisite landfill studies, development of biomarkers, and research on risk perception and sociologic determinants of ill health'.²³

From cluster to waste site

Although most studies of health effects of hazardous wastes have examined populations living in proximity to known waste sites, some studies exemplify the reverse approach, beginning with an occurrence of similar disease among individuals. Best known, perhaps, is the investigation of a cluster of leukemia cases eventually attributed to drinking water contamination in Woburn, Massachusetts. A cluster of childhood brain cancer cases in Monmouth County, New Jersey, reported to the State Health Department by the local community, resulted in intensive environmental and epidemiologic study. The cluster has been linked to drinking water contamination, apparently by a novel and hitherto unrecognized contaminant from a nearby chemical plant.²⁴ Although controversy may continue to surround the current explanation or understanding of causation of these clusters, they remain important examples.

Detection of a cluster (an occurrence in time and space considerably above background levels) is not trivial. What seems like a cluster to a community may be coincidence when examined statistically,²⁵ yet actual clusters are important potential clues to environmental hazards.²⁶ A survey in 1990 indicated that about 1500 'clusters' are reported each year to state health departments. Some are followed up in detail, while some respondents emphasize the coincidental nature of apparent clusters.²⁷ Media coverage of clusters is uneven, but can both stimulate and interfere with subsequent investigations.²⁸ Some public health officials doggedly investigate reported clusters while others prefer to provide reassurance to the community that they are artifacts or coincidences.

Non-responders

Environmental epidemiologic studies often have a high rate of non-responders. Some of these are people who refuse to be interviewed ('refusers') while others are people who could not be contacted ('movers'). A study comparing these two types of non-responders to responders around a hazardous waste site showed no demographic difference between responders and refusers. Concern that refusers might be those who are healthy or unconcerned was refuted by the finding that refusers actually had somewhat higher levels of concern. By contrast, movers differed demographically, particularly in shorter residence and renting rather than owning,²⁹ that presumably allowed them to be more mobile and leave the area of hazardous exposure. People in this group, who may leave based on health-related symptoms, represent an important bias towards the null. (i.e., not detecting an effect that actually exists).

SPECIFIC HEALTH OUTCOMES

A variety of health effects are associated with hazardous material exposure. Communities are most concerned about long-term cancer risk or adverse reproductive outcomes. Some exposures may induce cytogenetic, neurobehavioral,

hepatic, renal, pulmonary, endocrine, or dermal changes. In many instances however, non-specific symptoms are increased. Self-reported cases of disease, even physician-diagnosed events, are not always reliable. A cluster of 'ovarian cysts' reported in a contaminated university building included mostly cases of Bartholin cysts.³⁰ A study of medical records versus self-reported cancers showed a 15% over-reporting by participants living in a community with a hazardous waste processing facility.³¹

Cancer

Although cancer is one of the greatest concerns of communities near hazardous waste sites, few studies have directly investigated cancer, usually because of the long latency. The Knox study³² did show an approximate doubling of childhood cancer risk for children living within 5 km of incinerators, with no relationship to landfills. In an Australian study, no relationship was found between exposure to mining wastes and cancer rates.¹²

Controversy has surrounded the reported cluster of childhood cancers, particularly leukemias and lymphomas, at Seascale, in the vicinity of the Sellafield nuclear reprocessing plant in the United Kingdom. However, one study found that the cancer cluster did not appear to be temporally related to the period of intense nuclear activity at Sellafield,³³ with population mixing potentially contributing to the observed lymphomas.³⁴

Adverse reproductive outcomes

A variety of reproductive endpoints have been examined in populations with known or suspected hazardous waste exposure, and studies have been conducted on both local and national scales. Several occupational studies have shown that maternal exposure to certain chemicals is associated with lowered birth weight. A data linkage study between EPA's NPL and the National Maternal and Infant Health Survey found no excess of low birth weight, prematurity, infant mortality, or congenital malformations to mothers living within approximately a mile of hazardous waste sites.¹³ About 80% of the British population lives within 2 km of a landfill. A study of populations around all 9565 landfills yielded 43,000 stillbirths and 124,000 congenital anomalies. There was a small excess of congenital anomalies and low (< 2500 g) or very low (< 1500 g) birthweight infants close to landfills, although no mechanism was demonstrated.¹⁴ The confounding issue of whether populations at increased risk for low birthweight infants are more likely to reside close to landfills is an important one. Environmental justice studies (see below) indicate a higher proportion of minority and low income families living in proximity to environmental hazards.

Studies in New York³⁵ and California³⁶ also showed some excesses in specific congenital abnormalities associated with hazardous waste sites. A higher miscarriage rate was reported among people living close to old mining waste sites in Australia.¹² Thus there are some studies reporting miscarriages, low birth weight, and congenital

anomalies around hazardous waste sites. Interpretation is limited because the type of anomalies are not the same from study to study, nor are the specific exposures.

Families living near New Jersey's Lipari landfill (the highest priority on the Superfund list) had higher rates of low birthweight babies during the 1971–1975 period, than those more than 1 km from the site, and this excess was mainly due to a fivefold increase of low birthweight in homes immediately adjacent to the site.³⁷ This finding provided evidence that direct runoff and contamination was more likely a problem than air-borne contamination; the 1971–1975 period was temporally associated with the period of greatest runoff, and birthweights rose slowly after that time.

Elaborate study designs and detailed protocols have been developed for evaluating male and female reproductive function in exposed populations.^{38,39} Depending on the magnitude of exposure, a tiered approach of (1) questionnaires, diaries, and review of parent and infant medical records; (2) cross-sectional biologic sampling for hormone levels, and (3) extensive prospective sampling linked to diaries has been proposed.³⁹ Five adverse outcomes, namely, structural anomalies, mutations, mortality, functional deficits, and impaired prenatal and postnatal growth, are amenable to investigation, beginning with questionnaires and medical records, and proceeding to neurodevelopmental testing and karyotyping. The highest level of investigation would include DNA adducts.⁴⁰

Spatial mapping of birthweight data on a large sample initially posed computing challenges requiring novel approaches (e.g., Wartenberg et al⁴¹), which can be greatly facilitated by use of Geographic Information Systems (GIS).⁴² However, selection of scale and sample size still pose problems, and despite increased availability of GIS, little progress has been made in incorporating it into environmental epidemiology.

Symptom prevalence studies

Many studies and reports indicate that people living in proximity to hazardous waste sites or other Locally Unwanted Land Uses (LULUs) have more symptoms than reference populations. Since such symptoms can be generated by events surrounding the site, by media coverage, lawsuits, controversies, and stress, symptom prevalence studies are potentially subject to bias and/or confounding. Lipscomb et al⁴³ attempted to provide a general estimate of background symptom prevalence in communities that could serve as an additional reference rate for future studies. A study of two Louisiana communities identified both hypochondriasis and respondent opinions as important contributors to reported symptoms.¹⁶ Not surprisingly, they note that respondents who held a negative opinion of the site were two to three times more likely to identify symptoms. However, the converse interpretation – people with symptoms are more likely to form negative opinions – must also be taken seriously.

Based on a study of communities around five California waste sites, Neutra et al⁴⁴ concluded that neither classic

exposure pathways and toxicology nor mass psychogenic illness accounted for increased symptom reporting. They suggested that 'environmental anxiety' be taken seriously as a stressor producing physiologic changes manifest as symptoms. Studies usually seek to compare rates in the target (putatively exposed population) with rates in some unexposed reference population. Rarely is it documented that the reference population is free of some other exposure sources.

A study of the BKK landfill (Los Angeles, CA) showed that the frequency of odor complaints statistically predicted lower birth weight.¹¹ Those reporting high odors had babies about two days earlier and 59 grams lighter than the reference population. The study cannot distinguish whether this observed effect is because odor produced anxiety and stress, or because odor was a good surrogate for exposure.

Mine, mill, and smelter waste

Children exposed to lead mining waste exhibited elevated blood levels, while rates of miscarriages were also higher near mine waste sites.¹²

ENVIRONMENTAL RISK ASSESSMENT

Public health assessments are often only qualitative in nature. When it comes to prioritizing risks or comparing hazards, more quantitative approaches such as 'risk assessment' have become popular. Although engineers have long been familiar with risk assessment in the design of structures, the concept was adopted in environmental health in the mid-20th century, and became prominent in the 1980s. The importance of improved information on hazardous waste sites was highlighted by the National Research Council, which recommended improvements in the system for setting remediation priorities – reducing expenditures on sites which posed minimal hazards and improving the identification and cleanup of highly hazardous sites.¹⁰ The study noted the lack of toxicologic data on many hazardous waste components and the need to clarify the significance of long-term low-level exposures.

The risk assessment paradigm

The original approach to risk assessment included four phases that have been given various names.

Hazard identification involves identifying the specific hazard and its biologic effects. For a hazardous waste site this may involve characterizing the waste and identifying dozens of chemicals that may potentially contaminate surrounding communities. For each of these compounds, one or more endpoints are selected based on significance. At hazardous waste sites this is accomplished during the initial site discovery and the remedial investigation.

Dose-response assessment requires a review of the epidemiologic and toxicologic data base concerning the identified

Figure 52.2.1: A typical dose-response curve showing the sigmoid curve typical (or assumed typical) of two toxic chemicals A and B with different toxicities. The linear no-threshold curve, which represents the dose-response relationship for a carcinogen, is represented by Line C.

hazards in order to determine at what levels exposed populations may experience adverse health outcomes. A typical dose response curve is 'S-shaped' with a flat subthreshold component, a steep effect component, and a plateau where maximum response is reached (Fig. 52.2.1). For cancer, however, a linear 'no threshold' dose-response curve is usually assumed (e.g., line C).

Exposure assessment involves a determination of how much, how long, and by what routes individuals may be exposed. Each potential exposure pathway must be examined and the quantities of material measured or estimated.

Risk characterization is the process of combining the above information to determine a 'safe' or 'de minimus' exposure level, above which an unacceptable public health risk may exist, and below which continued exposure is believed to have no significant health consequences. Various mathematical models have been employed to extrapolate downward from the high doses used in toxicologic experiments or encountered in occupational epidemiologic studies, to the much lower doses anticipated in residential or community exposure scenarios.

Over the past 20 years there has been an evolution in risk assessment. In the early 1980s the main debate was over which mathematical model was most appropriate for the various biologic processes involved in carcinogenesis. In the late 1980s it became apparent that exposure assessment data were notoriously lacking, and this scientific discipline enjoyed a renaissance. In the 1990s the toxicologic basis of risk assessment came under scrutiny, as analysis of epidemiologic data was refined. Subsequent attention focused on the 'uncertainty' in risk assessment. The mathematical results given to several decimal places and compared to a 'one in a million' (10^6) risk level convey an impression of mathematical precision which may not be justified by the data and assumptions employed. Often, errors in the dose-response analysis may be multiplied by errors in the exposure analysis, such that the resulting risk

estimate may differ from the unknown reality by orders of magnitude. Default assumptions used in risk assessment have also come under scrutiny. Attempts to individualize exposure and risk are being investigated.

Risk assessment has engendered substantial controversy regarding all of these phases, particularly since the outcome of a single risk assessment may impose major cost burdens on polluters; conversely a low risk estimate may allow a community to be exposed to hazards that the residents find unacceptable. Risk assessment has become a common method for prioritizing hazardous waste exposure problems, and determining levels of exposure where intervention is necessary.⁴⁵ Given the uncertainties inherent in risk assessment, coupled with broad assumptions and sometimes conflicting data, the process is certainly vulnerable to controversy.

Risk assessment is currently used to determine whether a population exposed or potentially exposed to a hazard has sufficient risk of adverse outcomes to require intervention. Risk assessment provides information that risk managers can use to prioritize interventions. Originally it was considered critical that the estimations of risk be independent of the influence of cost or political considerations, which enter the risk management decision process. However, more recent approaches integrate the scientific/toxicologic risk assessment into a broader context that includes input from a large variety of stakeholders.⁴⁶

Exposure scenarios for risk assessment

If a risk assessment is to be performed, one must develop a series of scenarios regarding potential exposure. These are sometimes labeled 'realistic' or 'worst-case' scenarios. One can consider this a sensitivity analysis; if the worst case scenario estimates a lifetime risk that is acceptable, then it is likely that few, if any, individuals in the community will have an unacceptable risk. Problems arise when the realistic scenario produces acceptable risk, but the worst case produces unacceptable risks. Controversy arises when a risk acceptable to the government may not be acceptable to the community or individuals. Regulatory agencies may use risk assessment to refuse or justify permits, or determine whether a cleanup is required. Since the decision over what scenarios to use is a policy decision rather than a scientific decision, and since scientists argue vehemently on both sides of the issue, the role of science in influencing policy is often clouded. Clinicians should be aware of these considerations when discussing policies and risks with patients, regardless of whether they are providing warnings or reassurance.

Some of the assumptions that are made in evaluating potential risk to a community are indicated below with some extreme examples.

House occupancy component:

- A newborn baby who will live in a house for 70 years, sitting on the front porch without ever leaving.
- A 5-year-old who will live in a house 16 hours a day until age 17, then leave and never return.

- An adult who will live in a house 16 hours a day, for 45 years.

Dietary component:

- People will obtain 100% of their food from locally caught fish or locally grown milk, meat, and produce.
- A realistic estimate of the contribution of locally grown produce and fish to overall diet is about 10%.

Childhood soil ingestion:

- An average child consumes about 50–100 mg of soil per day (for 4–6 months/year).
- In the South, where children might play outdoors all year, a malnourished child with pica might consume 1000 mg soil/day for 12 months/year.

Vulnerability of the population:

- A maximally exposed individual (MEI) is one who spends all their life at the point of maximum impact of air-borne and water-borne contamination, eating contaminated food. Specially susceptible groups include small children, the elderly, and the infirm.

Stealth farmer scenario:

- In planning for the indefinite storage of radioactive wastes on sites which are fenced, assume that a family climbs the fence and lives on top of the waste storage site, drinking well water, and growing crops and livestock in contaminated soil.

As described above, the role of risk assessment is currently debated, but the EPA at present accepts the formalized process of risk assessment as a basis for setting policy and making site-specific decisions. Environmental risk assessments are not designed to be predictive for individuals, but are intended to protect virtually all individuals. Risk assessments are limited by considering mainly cancer as an endpoint; by ignoring ecologic, aesthetic, and convenience values; and by making major, sometimes untestable, assumptions.

The Presidential/Congressional Commission on Risk Assessment and Risk Management

Throughout the 1990s, there was an increasing involvement of stakeholders in the risk assessment process. In addition to people who are exposed to hazardous waste, the term 'stakeholder' also refers to the generators, regulators, and local governments. Rather than endorsing the rigid separation of risk assessment and risk management, the Commission set risk assessment in a much larger risk management context, with stakeholder involvement at the center (Fig. 52.2.2). Stakeholders are to be involved in the decision of whether, when, and how to conduct a risk assessment, including what factors to consider and what assumptions to use. They are involved in discussions of how to interpret risk estimates, which remediation options (including the null option) to choose, and in the evaluation

Figure 52.2.2: The model of a comprehensive risk management process as developed by the Presidential/Congressional Committee on Risk Assessment and Risk Management.

of interventions (i.e., whether risk has been reduced to an acceptable level).

Cancer risk assessment

Most of the attention in risk assessment has focused on carcinogens. The EPA has developed cancer slope factors that provide an estimate of the number of increased cancer cases per unit increase in lifetime dose. After selecting appropriate toxicologic studies, the linearized multistage model is applied to back extrapolate from the observed data to the dose that would correspond to one excess cancer death per million people exposed. To add an additional conservative step, the slope factor is designated as the 95th percent confidence limit around the point estimate of that dose. This represents a conservative estimate, not generally subject to verification epidemiologically. Since the average rate of cancer mortality is about 20% or 200,000 per million people, the one in a million excess corresponds to 200,001 cancer deaths per million (or one person dying of cancer who would otherwise have died of some other cause). Since even 10% increases in incidence are hard to detect in epidemiologic studies, the 1 in a million or (10^6) excess mortality is only a theoretical construct.

Armed with the EPA slope factor, a risk assessor needs to estimate the lifetime exposure for the population and apply the slope factor to estimate the excess cancer mortality. Although the 10^6 'one in a million' risk is considered the de minimus risk, many decisions are made using the less protective 10^5 level; for occupational exposures the 10^4 level is frequently used. Estimates of the lung cancer risk for radon conclude that the 4 pCi/l remediation standard corresponds to an excess cancer mortality risk that may exceed 10^3 . This would be unacceptably high if it were not for the fact that the radon occurs naturally and cannot be eliminated, although exposure can be interdicted.

Non-cancer risk assessment

In contrast to cancer endpoints, a threshold for risk is assumed for non-cancer endpoints. Using risk assessment approaches, the EPA sets reference doses (RfDs) for inhalation or ingestion, by selecting appropriate studies and identifying a no observed adverse effect level (NOAEL). Unfortunately, this level depends on the doses that were originally chosen for studies, most of which aimed at identifying the 50% effect (or 'ED-50') level rather than the NOAEL. In many studies, the only dose with no effect is the control or zero dose. In that case, the lowest observed adverse effect level (LOAEL) is selected. Since the threshold must be somewhere below the LOAEL, it is usually assumed to be one-tenth of the LOAEL, consistent with a safety or uncertainty factor (UF) of 10. If the base study is in animals, a tenfold UF is used to account for interspecies extrapolation. This is not always appropriate, since in some cases humans turn out to be less sensitive than the experimental animal.

Since risk assessment is concerned with lifetime risk, it is desirable to base the RfD on an animal study with lifetime exposure. In some cases, only shorter term studies are available, in which case another tenfold UF is incorporated to extrapolate from short-term to lifetime dose. This extrapolation accounts for accumulation in the body, and a longer opportunity for the endpoint to occur.

Whereas experimental animals are inbred to reduce individual variability, humans vary considerably, both genetically and in health status. Therefore a tenfold factor is introduced to protect the most sensitive individuals of a population. In some cases a threefold factor is used, but often even a tenfold factor may be inadequate to protect outliers.

Additional uncertainty factors may be used to account for multigenerational effects or for inadequacies in the underlying studies. The reference dose (RfD) is then calculated as follows:

$$\text{RfD} = \text{NOAEL}/(\text{UF1} \times \text{UF2} \times \text{UF3})$$

or if there is no NOAEL:

$$\text{RfD} = \text{LOAEL}/(\text{UF1} \times \text{UF2} \times \text{UF3} \times \text{UF4})$$

The RfD is typically reported as micrograms (μg) intake per kg body weight per day. The exposure assessment then calculates the actual intake for an individual (usually averaged over a long period) and compares this to the RfD to achieve a hazard quotient (HQ).

$$\text{HQ} = \text{daily intake}/\text{RfD}.$$

An HQ less than 1 is considered acceptable, since the RfD itself has built in uncertainty factors. Where there are mixed exposures and several components can be analyzed at once, the HQ is calculated for each substance individually, and the HQs are summed to give an overall hazard index (HI). If the HI exceeds one, the exposure is considered

unacceptable. This can be used as a basis for eliminating the hazard through cleanup, changing the water supply, or evacuation to a safer location.

Susceptibility

A major advancement in the 1990s was been the recognition of the importance of variation in susceptibility of human populations to various hazards. Whereas laboratory animals are inbred to reduce genetic variation and variance in response to an exposure, human populations have no such constraint. There is, however, no general rule to determine by what factor the most susceptible individuals differ from the population mean. Generally a tenfold correction factor is assumed to cover this difference. Much of the variation is presumed to have a genetic basis; in the 1990s there was a focus on genetic polymorphisms, particularly in metabolic enzymes such as the P450 group. A particular genotype may result in the underactivity or absence of an enzyme that normally speeds up the metabolism of a toxic compound, thereby increasing susceptibility. Conversely, if that enzymic conversion changes a parent compound into a more toxic metabolite, absence of the enzyme may favor direct excretion or an alternative pathway that reduces cancer risk.

This focus on genetic polymorphism research has been very fruitful; however, it is likely that many of the variations in susceptibility are polygenetic, involving the interaction of numerous gene loci. Moreover, genetic variation may interact with diet or other health conditions to modify the body's response to a particular toxicant.⁴⁷ Understanding the complexity of susceptibility is still in its infancy.

Precautionary principle

School children learn that in our legal system a suspect is considered innocent of a crime until proven guilty by a jury of peers. Unfortunately, in many countries chemicals are also considered 'innocent' of hazard until 'proven' hazardous, and skeptics set a very high barrier for proving hazard. An opposing view, now articulated as the Precautionary Principle, has been stated in various ways and contexts. Fundamentally, it recognizes that where there are threats of serious or irreversible damage, lack of full scientific certainty shall not be used as a reason for postponing measures to prevent environmental degradation. In other words, public health officials must not wait for every last bit of evidence before taking steps to reduce population exposure to potentially hazardous materials or situations. Even skeptics recognize the value of this principle, while arguing that it should be applied selectively.

The Precautionary Principle seems particularly applicable to hazardous waste, because of the difficulties in performing epidemiologic studies and conflicting published results. The National Research Council's Committee on Environmental Epidemiology concluded:

'Whether Superfund and other hazardous-waste programs actually protect human health is a critical ques-

tion with respect to federal and state efforts to clean up hazardous wastes. To answer this question requires information on the scope of potential and actual human exposures to hazardous wastes and about the health effects that could be associated with these exposures. Based on its review of the published literature on the subject, the committee finds that the question cannot be answered. Although billions of dollars have been spent during the past decade to study and manage hazardous-waste sites in the US an insignificant amount has been devoted to evaluate the attendant health risks. This has resulted in an inadequate amount of information about the connections between exposure and effect.'¹⁰

BALANCING RISK: WORKERS VS COMMUNITIES

For nearly two decades, environmental remediation proceeded on the widespread assumption that any reduction in risk was good, and that reducing risk as close to zero as possible was desirable, if not feasible. The assumptions in many of the risk assessment scenarios were worst-case exposures, involving maximally exposed individuals. In such analyses, the countervailing risks to workers (or to communities exposed at a distance due to transportation accidents or exposures at the waste-receiving site) were conveniently ignored. It must be emphasized that reducing risks to workers is essential, particularly since such risks are usually more predictable than those hypothesized for the community.

Faced by the large sums of money expended on hazardous waste site remediation, to avert a relatively few resident deaths predicted by risk assessments, several researchers have called attention to the fact that the workers involved in remediation are at risk of death, and that such deaths are real (rather than theoretical) and may offset the number the cancer deaths averted. One study has shown that the years of life lost through injury or illness among hazardous waste remediation workers match or exceed the hypothetical cancer deaths to exposed residents if the site were not remediated.⁴⁸ A hypothetical example of "Years of Potential Life Lost" among 500 hazardous waste workers exceeded the years saved for the residential population of 5000 exposed to the site. Hoskin et al⁴⁹ quantified the mortality risk to workers using Bureau of Labor Statistics data for three different occupations often utilized in hazardous waste operations. These studies demonstrate that traumatic and traffic deaths, rather than chemical exposures, are the main problem for workers.

RISK COMMUNICATION AND RISK PERCEPTION

The important topic of risk communication is covered in Chapter 59 (see also Slovic⁵⁰ and Tinker⁵¹). Individuals vary greatly in their willingness to accept risks. Radiation and chemical workers tend to be more tolerant of these hazards than clerical employees in the same industries. Familiar and

voluntary risks, or those carrying a perceived benefit, are frequently tolerated. In contrast, risks of similar magnitude that are unfamiliar and involuntary are rarely perceived as acceptable. The media often emphasize hazards without attempting to communicate levels of risk.^{52,53}

Risk communication involves interpreting the nature and magnitude of health risks to communities and providing information on how to reduce further risks. Unfortunately, to some, risk communication involves reassuring the public that hazardous wastes will not hurt them, but in reality the task is very complex. Too often professionals assume that the public is not sophisticated enough to understand risk, but since risk decisions are a common occurrence in life, such condescension is unwarranted. If the risk communicator has enough information to present a clear picture of alternative risks, then individuals are likely to make informed choices. The choices, however, may not always appeal to health professionals or the risk manager.

Some communications resort to risk comparisons, comparing the lifetime cancer risk from a hazardous waste site to smoking so many packs of cigarettes a day, or to the probability of an asteroid striking earth.⁵⁴ Although seemingly sensible, such comparisons do not always have their desired effect since smoking, for example, is viewed as voluntary. An asteroid strike (high impact/low probability) differs categorically from waste exposure that is viewed as ongoing (therefore high probability).

Goldstein et al⁵⁵ extended the risk comparison approach by calculating that the lifetime risk of an individual on the ground being killed by an airplane was 4 in a million, and emphasized that people don't change their mode of living in response to such a small risk. People living near airports may well be less reassured than those living far away, particularly if there has been a recent air crash with community fatalities.⁵⁶

Another approach is to convert a lifetime risk into an estimate of how many lifetimes it would take to experience one toxic-related cancer in a population of a given size. Weinstein et al⁵⁷ provide examples where cases would occur at intervals of centuries, and suggest that some audiences may find this informative or reassuring.

Patients and community residents can superimpose their own knowledge and belief systems on the messages imparted to them, allowing them to come up with their own, often unique interpretations. Faced with uncertainties in the data and various underlying values of audiences, physicians must develop a repertoire of approaches to communicating risk to the public and to other stakeholders.⁵⁸

Risk perception and 'popular epidemiology'

It has long been apparent that professionals and lay persons have different perceptions of risk. Many papers have explored how people perceive risk. One reason for the different perceptions is in the kinds of data that communities utilize in conducting cursory epidemiologic assessments, often on an informal basis. They differ from professionals in how they gather and evaluate data, how

they weigh possible confounders, and how they interpret results, thereby leading to different perceptions.⁵⁹

REDUCING COMMUNITY EXPOSURE

In the case where a risk assessment identifies an elevated or unacceptable risk, or where there is frank contamination, intervention is required. In extreme cases where an emergency exists, residents may be required or encouraged to evacuate. This will be a severe stress in itself, particularly if the exposure has been ongoing for a long time. A household or community may be warned or ordered to discontinue using water for drinking, cooking, and even for bathing or showering. Communities with well water may have emergency hook-up to municipal water, but when municipal water is contaminated, an alternative source for the water must be obtained. If the water is contaminated with non-volatile substances, then residents may continue to shower, but must obtain or be provided with bottled water for drinking and cooking. Long-term remediation may involve actual pumping out of aquifers, some form of chemical treatment, and replenishment. This is notoriously slow, inefficient, and costly. Point-of-entry treatment systems using ion exchange and filters may be used for some contaminated well water. When food is contaminated, advisories are issued banning fishing (or the consumption of fish) from certain bodies of water, ordering people not to consume certain garden crops, or even condemning certain sources of food.

Air-borne contamination that jeopardizes health is more likely to occur from incinerators or ongoing industrial activities. In the case of volatiles or dust blowing from a hazardous waste site, emergency containment or capping is called for.

Soil contamination poses more vexing, longer term challenges for reducing risk. Different agencies have different guidelines for identifying contaminated soil. Low-level contamination may be remediated in situ by some form of capping. Certain plastic geotextiles covered with clean fill may prevent people from contacting the contaminated soil. In some cases paving or planting of grass may be deemed sufficient.

When soil is contaminated above a certain level, it must be treated (either by chemical treatment in situ or by removal) to lower the level to a certain set standard (which is not always the same level that is considered hazardous). In many cases, companies must completely remove the top layer of soil (anywhere from 18 to 36 inches or more, depending on depth of contamination) from nearby residential communities, and replace it with clean topsoil, followed by extensive re-landscaping.

Household hazardous waste

Many households have hazardous wastes of their own half-used paint and solvent containers, pesticides, and cleansers. In some cases these may release volatiles into

the home. In other cases they are a fire hazard, or a source of environmental contamination if disposed of improperly. Although the amount in a single home is small, the total amount in a community can be substantial. Many communities or counties have introduced household hazardous waste days or collection sites to facilitate the safe disposal of such wastes. Wastes are collected, chemicals are poured into bulk containers, and solid wastes are channeled either to special incinerators or landfills. However, occupational exposures at such sites can be significant, particularly to benzene and to mercury in broken fluorescent bulbs.⁶⁰

BROWNFIELDS REDEVELOPMENT

A brownfield is an abandoned, idled, or under-used industrial or commercial facility where expansion or redevelopment is complicated by real or perceived environmental contamination. Residential risk is particularly problematic, and drives more extensive cleanup than redevelopment for industrial or commercial purposes. Development of industrial sites is not new. Many former manufactured gas plants were subsequently developed for housing; the school and adjacent properties at Love Canal represent another example of a brownfield. The costs of complete cleanup can sometimes be averted, or even amortized by new industrial development. Failure to develop such lands has become a national urban blight, while developing compatible remediation/redevelopment plans remains challenging.⁶¹ New technologies for inactivating certain types of waste offer one possibility.⁶² It has even been proposed that some hazardous waste sites be developed as museums to demonstrate how contamination occurs and its actual and potential impacts.⁶³

THE ROLE OF MEDICAL SURVEILLANCE FOR THE COMMUNITY

A medical surveillance program must be predicated on the early detection of the effects of an exposure, at a point where intervention can prevent disease or disability. Where significant exposure to one or more toxic agents has occurred, medical evaluation can detect pathophysiologic changes. Where exposure is deemed not to be significant, appropriate reassurance may have greater benefit than the prolonged uncertainty associated with recurrent medical examinations. ATSDR has concluded: 'medical monitoring should be directed towards a target community identified as being "at significant increased risk for disease" on the basis of exposure. Significant increased risk will vary for particular sites depending upon such factors as the underlying risk of the outcome of concern, the risk attributable to the exposure, and the presence of sensitive subpopulations.'⁶⁴

The decision regarding medical surveillance would be easier to make if risk assessments offered better precision, or if medical surveillance had better sensitivity and specificity. Legal action taken on behalf of communities or indi-

viduals exposed to hazardous waste often includes claims for ongoing medical surveillance as part of the damages sought. This places a unique burden on the medical community. Where exposure is likely to be negligible and the prevalence of toxic effects thereby low, the predictive value of even a sensitive screening test might be low.

Although medical surveillance is warranted in appropriate cases, it is certainly prudent to develop a registry of all residents in a community, including information such as dates and location of residence, data on soil and water contamination, age, time spent in home, and current health status. Maintaining a registry allows for the identification of potentially exposed residents at a future date, when more is known about the hazard, or when individuals show signs of illness. In the case of significant exposure to a toxic agent, baseline medical testing is often valuable. If the agent is one that can produce disease at a later date (e.g., carcinogens, reproductive toxins), follow-up examination may be warranted. However, where these conditions have a very low prevalence (i.e., where the risk is low), the predictive value of even a positive test may be low.

Criteria for inclusion in a medical surveillance program

The efficacy of any medical surveillance or screening program depends on the underlying prevalence of the endpoint being sought. Where this endpoint lies in the future, its prevalence can only be estimated. Therefore medical surveillance programs in industry or for communities depend on some assessment of the underlying prevalence of significant exposure, such that risk of adverse health effects in the future is increased.

Various approaches used to assess individual exposure (see above) can provide information for determining which individuals will benefit from medical surveillance and which will not. Ongoing medical surveillance can be justified where (1) there is or has been significant exposure to a hazard with documented exposure pathways, (2) when serious health consequences may occur, (3) when there is a substantial benefit from early diagnosis (or reassurance), and (4) when the onset of disease may be long delayed after exposure ceases. Where there is substantial anxiety, a one-time cross-sectional screening program may be appropriate, the results of which can serve to reassure the community or individuals, or can serve as the baseline for follow-up surveillance activities.

Screening versus surveillance

A medical monitoring program should include two phases: the initial or screening phase and the long-term surveillance phase. In the screening phase, the clinician obtains information on the past (or ongoing) exposures, and determines whether the participant is in a low, medium, or high exposure group. The former can be given reassurance that their risk of long-term health consequences is not appreciably increased, and that periodic follow-up examinations (surveillance phase) are not required. For individuals with

high exposures, a close follow-up or surveillance (perhaps with annual examinations) is required. For individuals in the medium category, examinations can be performed less frequently (e.g., every 3–5 years).

The appropriate duration of the surveillance phase should address practical issues of latency. Since the longest latencies for cancer are of the order of decades, it may be reasonable to plan long term surveillance following termination of exposure.

COMMUNITY HAZARDOUS WASTE SOURCES

Household hazardous waste

Many households contain waste materials that are potentially hazardous, particularly flammable and volatile materials. Household hazardous waste is exempt from RCRA and CERCLA. This includes material collected, transported, stored, treated, disposed, recovered, or reused (RCRA 40 CFR 261.4). Such materials represent sources of exposure for the households in which they occur, as well as those who collect, process and dispose of them. Many communities have established household waste days to collect paints and stains, paint thinners, automotive wastes, antifreeze, cleaning agents, batteries, and pesticides. Medical wastes (bandages, syringes) are usually not collected in this manner. In a community survey, most householders try to use up materials where possible, but much is brought to the hazardous waste collection sites. However, because there may be few days a year when the sites are open, and because they are not conveniently located for everyone, much of this waste is disposed of as garbage, particularly when a house is being vacated for sale.

Solid waste incineration

The National Research Council estimates that the US has more than 100 municipal solid waste incinerators, 1600 medical waste incinerators, and 200 hazardous waste incinerators. Emissions of concern include particulates, metals, dioxins, and furans. The development of continuous emission monitors would allow incinerator operators to shut down or alter conditions when emissions are high. The Committee on Health Effects of Waste Incineration concluded that there were few studies effectively assessing health effects of incinerator emissions, particularly delayed effects.⁶⁵ The Committee made recommendations about improving future epidemiologic studies and exposure measurements.

ISSUES OF ENVIRONMENTAL JUSTICE

In the early 1990s, environmental justice emerged as a major ethical and public health issue (see Chapter 58),

spearheaded by Robert Bullard's 'Dumping on Dixie'. Bullard and others have demonstrated that minority and poor communities are disproportionately exposed to hazardous waste sites, as well as industrial facilities and other locally unwanted land uses.^{66,67} Whether this situation arises because the communities have little political influence or representation, making it easier to site such facilities, or because property values and rents are likely to be lower in such 'undesirable' neighborhoods does not change the fundamental relationship between poverty and exposure risk. Even in non-urban areas, minority populations may be at risk. In rural South Carolina, black fishermen consume substantially more fish than white fishermen, and are at higher risk from pollutants in the fish tissue,⁶⁸ while in the vicinity of a nuclear research laboratory (Los Alamos, NM), Hispanic populations had higher exposure from recreational activities than whites.⁶⁹

Minority and poor families disproportionately live in communities with landfills, hazardous waste facilities, incinerators, industrial plants, and old housing with poor indoor air quality and lead-based paint, and children in these families are at risk of becoming the 'unwitting target of environmental injustices'.⁷⁰

Environmental justice is a US governmental remedy that requires the application of fair strategies and processes in the resolution of inequality related to environmental contamination. The US response resulted in the establishment of offices of environmental justice within the EPA and ATSDR, and passage of important legislation and policies such as the Community Planning and Right-to-Know Act of 1986, Executive Order 12898 (Federal Actions to Address Environmental Justice in Minority Populations), and Executive Order 13045, a parallel order to protect low-income and minority children from actual and potential environmental hazards.

INTERNATIONAL TRADE IN HAZARDOUS WASTE

Closely linked to the issue of environmental justice is the international trade in hazardous waste. Developing nations concerned with balance of payment and international monetary debt generally pay more attention to short-term cash flow than to long-term environmental consequences.⁷¹ Many countries have expressed a willingness to accept transboundary shipments of hazardous waste as a source of income, arguing, in some cases persuasively, that if short-term economic support is given to basic public health needs, this will have a salutary effect on health that offsets the long-term risks from the waste itself. Waste shipped from Taiwan to Cambodia was reported to have had short-term health consequences to people who reside near the site where the waste was dumped.⁷² Highly industrialized countries that have been economically disadvantaged also have a serious hazardous waste legacy, as exemplified by a number of countries in Eastern Europe (e.g., Zejda et al⁷³).

ECOLOGIC RISKS FROM CONTAMINATED SITES

Ecosystems and other natural resources of biologic, economic, recreational, or aesthetic value to humans can also be contaminated by hazardous wastes. Ecologic risk assessment has developed as a separate discipline,⁷⁴ emphasizing new methods to assess the effects of chemicals on ecosystems.⁷⁵ Runoff and leachate from landfills into adjacent ground or surface water of surrounding ecosystems is one means of contamination. Many habitats that have been used for disposal continue to maintain viable ecosystems that may develop some degree of tolerance for contamination. Although beyond the scope of this chapter, ecologic risk assessment has important parallels with human health risk assessment,⁷⁶ and it also influences how agencies responsible for hazardous waste, such as the US Department of Energy, provide for the long-term stewardship of sites that cannot be completely remediated with current technology.⁷⁷

Chapter 53

Environmental Aspects of Food Safety

Mark R Cullen

INTRODUCTION

The major importance of food to health relates to nutrition. In developing countries, many of the common causes of morbidity and mortality relate to inadequacy of caloric or protein intake, deficiency in dietary components, or inadequacy of sanitation. In developed countries, and an increasing number of regions crossing through health 'transition', chronic diseases owe much of their origin to maldistribution of dietary elements and, increasingly, overconsumption and obesity. The fraction of all cardiovascular disease and cancer attributable to diet suggests it is on a par with, or possibly exceeds, tobacco as the major preventable cause of premature death in such societies.¹ These issues fall into the province of nutrition, crucial in the practice of general preventive medicine as well as virtually every clinical discipline, but beyond the scope of this text. Similarly beyond the scope of this chapter are the clinical problems of traditional food allergy and food intolerance, such as those to milk and lactose, and infectious enteropathies.

The past few decades, however, have witnessed changes in society and in the food supply which have thrust certain aspects of food safety directly into the purview of environmental medicine. Such matters as the contamination of the food chain with industrial chemicals such as mercury or polychlorinated biphenyls (PCBs); the intentional use of food additives (colorants, preservatives) and nutritional supplements; the unintended residues of pesticides, hormones, and antibiotics used in growing animal and vegetable products; and the dramatic incursions of new chemical and biologic products of biotechnology into the food chain (e.g., genetically modified [GM] organisms) have heightened concerns about the healthfulness of many foods above and beyond the traditional nutritional medicine or infectious disease concerns. These issues have been further thrust into the spotlight by the increasing recognition of food-borne infections associated not with poor sanitation per se but with modern food processing, such as 'mad cow disease' (also beyond the scope of this chapter). This is not to suggest that any of these environmental factors – even including the infectious risks – compete in importance with nutritional matters, nor that any major contribution to the risk for cardiovascular disease or cancer attributable to dietary behaviors is best explained by these environmental factors. But sufficient evidence of harm has been demonstrated to awaken unprecedented political and regulatory efforts around the world to re-evaluate food from an environmental perspective.

The goal of this chapter is to outline the major categories of environmental risk and/or concern associated with food (other than infectious and nutritional aspects), and provide a framework for clinical evaluation of patients with food-related exposures or concerns.

CHANGES IN SOCIETY, FOOD PRODUCTION, AND THE ENVIRONMENT WHICH MAY CONTRIBUTE TO RISK AND PERCEIVED RISK OF ADVERSE HEALTH

A complex constellation of societal changes has contributed to heightened environmental concern about the food we eat.

- Compared with earlier eras, most people eat a far higher fraction of their meals away from home. In the US, this fraction is approaching 50%, a reflection of modern worklife and lifestyle, enhanced by developments in food processing and service allowing unprecedented variety and convenience to support the cultural shift. As such, individuals and families have increasingly less control over the actual source of food and handling than previously.
- Because of changes in technology, single locations can process food for wide distribution. Once local, the food processing industry has become regional, national, and, increasingly, international business, providing more opportunities for environmental contamination and greater opportunity for a single mistake to affect large numbers of people.
- At the same time, the marketplace for raw and other minimally processed foods has markedly expanded. The increased demand for fresh food year round, concomitant with the technology for food distribution systems to satisfy this demand, has fostered increased importation of foods from regions of the world with less well regulated food-handling practices.
- Changing dietary and social eating patterns have led to the introduction of new waves of food additives – such as non-absorbable fats and artificial sweeteners – as well as inclusion of natural nutrients (e.g., vitamins and herbals) as supplements at concentrations not previously in foods per se, some of which have never been tested at concentrations that could be consumed unwittingly and over long periods of time.

- Although many of the worst persistent polluting chemicals in the environment, such as PCBs and organochlorine pesticides, have now been banned from sale in many parts of the world, these have nonetheless persisted in the food chain and even spread to areas where they were never used. Other contaminants, such as mercury, are biologically magnified in the food chain, resulting in contamination covering the entire globe in unprecedented and unanticipated patterns, potentially causing risk remote from the original sources of contamination.
- In order to enhance production, agriculture (including for the purposes of this chapter both plant and animal production) has become increasingly mechanized and reliant on agrochemicals such as pesticides, hormones, and antibiotics. The wide variations in dietary behaviors present the possibility that exposure dose to some agents by some individuals could be substantial.
- The effectiveness of modern medicine in increasing the lifespan, allowing individuals with various immunologic and other biologic impairments to live for long periods, raises new questions about subsets of the population that may be at enhanced risk for food-borne illnesses and contamination.
- To meet the rising demand for fresh and nutritionally satisfactory foodstuffs, a panoply of GM vegetables – and, possibly in the near future, animal products – are entering into the marketplace, often without label or notice. Strategies for assuring the safety of these products have lagged behind the staggering pace of their development, currently the source of considerable political furore, especially in Europe.
- Emerging patterns of health and disease in highly developed societies have refocused concern on the possibility for a contribution of diet to such disorders as attention-deficit disorder, asthma, breast and prostate cancers, and endocrine disruption.

In the sections that follow, we shall review the following major areas of concern to environmental medicine practice.

- I. Chemical contamination of foodstuffs
 - Accidental chemical contamination
 - Residues of agricultural products – pesticides, hormones, and antibiotics
 - Biopersistent or biomagnified contaminants
- II. Food additives in processing
- III. Contamination of food from packaging, cooking, and serving
- IV. GM foods and related ‘technologies’

CHEMICAL CONTAMINATION OF FOOD

Accidental contamination

Many of the most spectacular outbreaks of human exposure to hazardous chemicals have involved food. Most episodes have occurred when fresh staple foods, such as oil, rice, or other grains, have been contaminated during their growth or processing by industrial materials or waste. The best studied include the following.

Epping jaundice

In 1965, a small community near London experienced an epidemic of acute-onset jaundice following contamination of flour in a bakery with methylene dianiline (MDA or diaminodiphenylmethane). Victims developed gastrointestinal symptoms and fever over several days, with high levels of alkaline phosphatase in blood and milder rises in hepatic transaminases. Most recovered; long-term follow-up of 84 persons who were traced revealed no evidence of long-term sequelae, although the sample size was small.²

Minimata

In the late 1950s, an epidemic of a central nervous system (CNS) disease appeared in the region of Minimata Bay in Japan. Some adults were affected with tremor, ataxia, dysarthria, and visual disturbances – despite relatively well preserved cognition and memory. The impact on newborns was more profound, with motor disturbance and major developmental anomalies.³ The cause was eventually attributed to consumption of large sea fish contaminated by mercury dumped in the bay from a factory manufacturing vinyl chloride; the mercury was biotransformed in the aquatic food chain to the highly neurotoxic methyl mercury. Interestingly, none of the systemic signs seen in inorganic mercurialism, such as dermal, salivary, or renal changes (see Chapter 39.8), were noted. A similar outbreak occurred 15 years later in Iraq, where imported grain seeds that had been fumigated by organic mercurials were consumed rather than planted, with similar consequences.⁴ These two outbreaks have formed the foundation for concern about the increased contamination by methyl mercury in fish throughout the world (see below).

Yusho

About a decade after the Minimata disaster, the Yusho prefecture in the western part of the Japanese archipelago was blighted by another – contamination of rice oil by PCBs, a now-banned class of industrial oils (see also Chapter 45). Up to 1800 people were affected by a syndrome initially recognized by ungainly skin and nail discoloration, cheesy ocular secretions, and chloracne.⁵ Extensive evaluation as part of the so-called Yusho study revealed that peripheral nerve complaints and dysfunction were common, as were intractable headaches and lipid disturbances. Newborns were demonstrably affected to a greater degree than their mothers. Signs and symptoms persisted for years after resolution of the exposure, consonant with knowledge of the biopersistence of the causal agents; to date there has been no confirmation of increased cancer risks in the population.

An almost identical outbreak occurred in 1979 in Taiwan, dubbed Yucheng.⁶

Itai-itai

Long-term contamination of rice by cadmium in yet another part of Japan was recognized in 1971; the source was ground water carrying the metal from a mine tailing. Although renal dysfunction characteristic of poisoning with this metal was universal among heavily exposed subjects (see Chapter 39.4), the most common presenting

clinical feature was pathologic fracture and extreme bone pain (which gave the outbreak its name – ‘ouch-ouch’), primarily in middle-aged and elderly women, as a consequence of urinary calcium depletion. Much of our current knowledge of the consequence of industrial poisoning with this metal has resulted from extensive clinical and epidemiologic studies conducted on this population.⁷

Toxic oil syndrome

A spectacular epidemic of pneumonia with eosinophilia occurred in Madrid in May 1981. Thousands were affected; hundreds died while others went on to manifest chronic signs, including neuromuscular and visceral organ involvement. Investigations by local authorities, with the assistance of the Centers for Disease Control and Prevention (CDC), traced the outbreak to contamination of rapeseed oil (canola) by an aniline derivative – whose precise identity remains obscure after 20 years of research – hence the designation toxic oil syndrome (see Chapter 44). These oils had been sold via an informal market network over a several week period preceding the epidemic, which immediately petered out when the source was contained.^{8,9} The clinical picture bears a strong resemblance to the eosinophilia-myalgia syndrome which occurred in epidemic form several years later in the US, and was eventually attributed to contamination of L-tryptophan sold as a herbal medicine for sleep in health food stores; studies revealed traces of aniline derivative in that outbreak as well, although again, the precise chemical structure of the causal agent remains obscure.⁹

Pesticides

Over the past 60 years there have been dozens of similar outbreaks caused by gross inadvertent application of agrochemicals to food. Virtually every class of pesticide has been implicated, and virtually every region of the world, developed and developing, has been affected. These episodes are cogently reviewed by Ferrer and Cabral.⁴

Residues of agricultural products in food (see Table 53.1)

Increasing use of chemicals to produce foodstuffs results in inevitable residues in products that come to market, only some of which can be ‘washed off’ or ‘cooked away’. Although there has been an increasing pressure in developed countries to limit use of the most toxic agents, concern about long-term health consequences of residues persists for several reasons.

- Testing of many agricultural chemicals remains incomplete, especially as regards newer health concerns such as immunotoxicity or endocrine disruption.
- Agrochemicals are typically regulated individually, but multiple agents are present simultaneously in the typical food basket, with overlapping, possibly additive or synergistic, toxicities.
- Even for compounds regulated with established endpoints (such as cancer) taken into account, safety factors may not consider the impressive heterogeneity

Residue	Health concern	Most affected food(s)
Pesticides	Direct toxicity (especially in infants and children) Cancer Endocrine disruption Immunologic effects	Fruits, vegetables
Antibiotics	Drug-resistant flora Allergy Superinfection	Poultry
Hormones	Cancer Endocrine disruption	Dairy products, meat

Table 53.1 Residues of agricultural chemicals in human food

of dietary choices, especially among young children whose behavior may defy ‘normative’ assumptions used in establishing limits.¹⁰ Recent evidence, for example, suggests that total organophosphate pesticide exposure of most children exceeds the current US recommended dietary levels, and a non-negligible fraction exceed even decade-old guidelines.

Despite these concerns, the following must be borne in mind. Ecologic studies comparing populations over time and from country to country¹ have not suggested the likelihood that residues in food explain much of the link between diet and cancer. For the pesticides in particular, best evidence suggests that overall, consumption of diets highest in raw fruits and vegetables confers protection from cancer despite possible contamination. Moreover, despite the theoretical concern, few empiric data have been generated to suggest that additive effects among related pesticides have contributed to measurable health effect, clinically or in populations.¹¹ Nonetheless, interest in this issue remains high, and the final verdict is still awaited.

There is growing evidence that the very widespread use of antimicrobial agents, especially for raising poultry, beef, and pork, has been responsible for emergence of resistant bacterial strains in the environment, and consequent human infection.^{12,13} Consumers of treated meat are not necessarily at greater risk than others, since the spread of resistance through the ecosystem is complex; this is more a public health issue than individual health concern at the present time. A possible exception may be workers in the industry, who may be heavily colonized with such organisms (Silbergeld E, unpublished communication). Notably, neither allergic reactions nor other untoward side effects have been reported as a consequence of food ingestion per se, likely owing to the relatively trivial doses remaining in the final marketed products.

Likewise, although there remain substantial theoretical concerns about the use of hormones (see Chapter 27.1), the most widely used agent, supplemental bovine growth hormone in cow’s milk, is essentially inert for humans.¹⁴ Growth hormone-induced growth factors, which are biologically active for humans, are not secreted in the milk. The theoretical possibility that some fragments of these hormones would induce other endocrine responses remains unproven.

Finally, although there may be many reasons for consumer preference for so-called organic foods – grown or

raised without the use of any of these chemicals – there remains no empiric evidence that they confer any better measure of health than comparable commercially grown products. Part of the problem has been wide variability in the interpretation of the designation ‘organic’, hence heterogeneity in the products.¹⁵ However, because of widespread interest in these food alternatives, and the commercial pressures to expand their production, it is likely that further regulation of the industry will occur, as well as further scientific study attempting to delineate potential differences in health risk associated with their consumption.

Biopersistent contaminants in food (see Table 53.2)

Biopersistent organic chemicals, primarily polyhalogenated heterocyclic compounds like DDT and PCBs, and biomagnified metals, primarily methyl mercury, have created a hazard not previously envisioned. Unlike the residues discussed above, these agents have entered the food chain not primarily by virtue of the way food is raised or processed, but because of more profound contamination of the biosphere. An exception might be farmed salmon, in which PCBs have been attributed recently to feeding methods. As such, there are no ‘organic’ swordfish to be found, nor animals raised without trace dioxin content. Moreover, the dispersal of these contaminants throughout the world due to movements of air and water, and their persistence both in nature and biota, has extended the threat to much of the globe, even areas extremely remote from the original sources, such as the polar ice caps. Although the risk of acute effects or outbreaks from such contamination is slight, the public health consequences are potentially vast – in view of the magnitude and underlying health status of populations potentially at risk – and intractable, since the hazards are already widely disseminated and irremediable in the short term. The hazards of greatest concern are briefly discussed below, and in relevant exposure chapters elsewhere in the text.

Methyl mercury

As noted above, metallic or other forms of inorganic mercury are metabolized in the aquatic food chain to methyl mercury, which in turn is stored in muscle tissue of fish and not further excreted. Since this process continues for the lifespan of the fish, concentrations in the animals

increase with their age, rendering large (old) catch a far greater potential risk to human health than crustaceans or fish consumed early in their lifespan. As discussed in Chapter 39.8, the greatest concern in populations with obligatory fish consumption (e.g., islanders) or individuals who consume large quantities by dietary preference is risk for in-utero absorption, since fetal brain is far more susceptible to injury than adult. For this reason, consumption of swordfish, tuna, and other similar species is recommended in modest quantities during pregnancy, although the extent of risk at currently extant levels worldwide is hotly disputed: some investigators believe the risk has been proven to be effectively nil¹⁶ while others dispute this.¹⁷

PCBs

Although worldwide production of these oils has ceased, their persistence in the environment is such that levels are easily detected in the fatty tissue of mammals and many fish throughout the world. Recent studies from the Great Lakes and elsewhere suggest the possibility that small increments above the lowest background levels may induce measurable developmental effects in children, from either in-utero exposure or postpartum exposure in breast milk.¹⁸ Study of the problem has been confounded by coexistence in fish of mercury, and methodologic difficulties teasing out relatively subtle differences in CNS performance of children, given the number of relevant covariates.

Dioxins

These cyclic organochlorines result from a range of industrial processes and from high-temperature oxidation of organic material such as fuels, plastics, and waste in the presence of chlorine. As discussed in Chapters 45 and 48, dioxins are the most potent synthetic toxins known, with carcinogenic, immune, and other systemic toxicities at picogram-per-kilogram (i.e., very low) doses. The human impact of background contamination in the food chain is the subject of intense speculation.¹⁹ High-level environmental exposure is already suspected to cause diabetes mellitus, based on studies in Seveso, Italy, where a large community exposure occurred after an accident in 1976, and from Vietnam, where dioxins contaminated Agent Orange and other defoliants used in war.^{20,21} Occupational exposures have been deemed carcinogenic.

FOOD ADDITIVES IN PROCESSING

An extraordinary array of synthetic chemicals is used by the food processing industry for various purposes, including sweetening (saccharine, aspartame), flavoring (nitrites, glutamates, papain, amylase, casein), preservation (BHT and BHA, sulfites), adding bulk and texture (polydextrose), packaging (polyglycerol), and coloring (tartrazine, azo dyes). In general, these compounds have been subjected to substantial toxicologic scrutiny because of the greater legal and regulatory requirements for food safety compared to other industrial uses. Nonetheless,

Chemical	Effects	Most affected foods
Polychlorinated biphenyls (PCBs)	Cancer Endocrine disruption Developmental toxicity	Fish (fresh water)
Organic mercury	Neurotoxicity Developmental toxicity	Fish (especially large game fish)
Organochlorine pesticides, dioxins, and related compounds	Cancer Endocrine disruption	Dairy products, meat

Table 53.2 Biopersistent contaminants in food

because exposure is so widespread and the possibility of idiosyncrasy so difficult to establish by traditional laboratory testing strategies, there has been substantial speculation and investigation regarding health effects. Current best evidence regarding these major additive groups is summarized below; detailed discussion of this extensive subject is beyond the scope of this chapter.

Overt clinical manifestations ascribable to dietary additives are uncommon, with estimates between three and 15 per 10,000 persons; the rates in children are higher, possibly approaching 1%–2%.²² Far and away the best characterized reactions are allergic in nature, including asthma (with *sulfites* and *protein additives*), urticaria, and dermatitis, primarily in atopics. It is estimated that as many as 5% of asthmatics are sensitive to *sulfites*, though the reactions are typically mild when challenge tested.²³ Because of the occasional role of macronutrients in seizure disorders and migraine syndromes, it has been speculated that additives such as *tartrazine* might also be important triggers in some cases; blinded challenge studies have yielded at most equivocal evidence to support this.^{24,25} *Nitrites* and *monosodium glutamate* (MSG) have each been implicated in the syndromes of flushing and headache, often related to consumption of Chinese food, but double-blind studies tend to refute the association.²⁶ More troublesome are data regarding attention-deficit disorder and behavioral disturbances in children, such as aggressive behavior in adolescents. Although the mechanisms remain highly conjectural, evidence does support an important role for dietary additives in a small minority of cases.²⁷ Strategies for identifying and documenting the relationship between these additives and clinical manifestations are discussed at the end of the chapter.

In addition to rare clinically recognizable consequences, carcinogenesis and endocrine disruption have been concerns, since some of these agents demonstrate adverse activity in in-vitro or whole-animal models. For example, *nitrites*, in theory, may be converted by flora in the gastrointestinal tract to the highly potent carcinogen group nitrosamines. Likewise, the preservative *potassium bromate* has proven positive for renal carcinoma in various assays, as, of course, has *saccharine*. Best evidence, however, suggests any effects due to these additives are dwarfed by effects – some harmful, some beneficial – of the foodstuffs to which these chemicals are added. It is worth mentioning, in this regard, that the most widely used preservatives, the phenolic antioxidants *BHT* and *BHA*, are likely anti-carcinogenic in practice, based on large population studies.¹

CONTAMINATION OF FOOD FROM IRRADIATION, PACKAGING, COOKING, AND SERVING

Beyond the factors that food might be exposed to during growth and production, there remains concern about

irradiation and chemicals leached from packaging, cooking or serving materials.

Irradiation of fresh foods, especially poultry and meat, has become an increasingly common practice in response to concerns about bacterial pathogens such as salmonella. Unlike the complex and controversial subjects discussed above, there is neither a theoretical nor empiric basis for the belief that this practice may be harmful. Levels of radiation are too low to induce even trivial contamination by radionuclides and the energy transferred too low to modify substituents chemically. It is most likely that popular worry about this practice represents fallout from legitimate concerns about ionizing radiation exposures in other contexts.

The issue of chemical leaching is far less trivial. Canned and wrapped foods often accumulate higher levels of the material in which they are packed, and cooking adds still further to that burden. *Aluminum*, used for both purposes, has been prominent among concerns in this regard, especially since aluminum is an established neurotoxin in animal models, and in the setting of renal failure in humans, i.e., dialysis dementia which occurred when aluminum was added to dialysis solutions (see Chapter 39.1). Although there is speculation implicating this ubiquitous metal in degenerative disorders of the CNS, the evidence for such an effect remains weak; avoidance of such cookware or packaging for healthy individuals is without foundation at present. It might be argued theoretically that patients with renal failure should avoid aluminum exposures when possible, but there are no data to inform such a position.

Phthalates in plastic containers and wrapping can also leach into some foods. In vitro, these plasticizers have been shown to have a small estrogen-like effects only at doses exceeding those present in plastic-stored food.²⁸ Nonetheless, consideration is being given to substitutions based on risk assessment models.

More worrisome is the possibility of leaching from cookware made in regions of the world where environmental controls are limited. Most notorious in this regard is *lead*, used in glazes for pottery and crockware throughout the developing world because it is cheap and available. Heavy body burdens and even overt lead poisoning have been described from this route of exposure, rendering this an important component of history taking when lead poisoning is a consideration (see Chapter 39.7).

Finally, there is the issue of contamination of food by the products of combustion of fuel in cooking. The greatest concern is accumulation of *polyaromatic hydrocarbons* (PAHs) (see Chapter 44) on foods that are smoked or charcoal grilled. Exposure to these potent carcinogens in this setting has been documented;^{29,30} excess risk due to consumption of these foods has not, although dermal and respiratory exposures to the same compounds industrially are associated with cancers of the lung and bladder. At present, the best dietary advice is to limit the fraction of overall consumption of food prepared by this route, but refinements in nutritional epidemiology may lead to strengthening or relaxation of such guidance in the near future.

GENETICALLY MODIFIED VEGETABLE AND ANIMAL PRODUCTS

The newest and most rapidly emerging environmental concern about food relates to GM plants and animals (see also Chapter 18.1). A number of such plant products have been introduced over the past decade. Consequently, substantial proportions of potatoes, corn, soy, and certain fruits are now produced from seeds into which genes from other species have been transfected and selected out, for purposes including pest resistance, climatologic hardiness, prolonged shelf-life, improved appearance or palatability, higher crop yields, and nutritional augmentation.

Most of the new products involve the insertion of vegetable or bacterial genes that produce well-characterized – and, generally, well-studied – structural proteins or enzymes. However, based on the pace of the technology, there will be countless variations in the near future, foreseeably including foods of animal origin as well.

There is evident concern in the community about the implications of this for the economy of agriculture as well as the control of the food chain in the hands of a few manufacturers implicit in the approach. Also, reasonable and as yet not fully addressed ecologic and environmental health concerns have surfaced, including:

- unforeseen selection pressures on ecosystems when large fields of plants with altered genes intrude;
- the possibility that genes could be transfected by natural vectors or otherwise recombine with plants in neighboring fields or even other species;
- the possible increased use of some herbicides for selection of genetically altered species over wild types, since, in order to select the new variants, genes are typically linked to genes for tolerance to herbicides, which are then sprayed on the fields to kill the wild types.

There are legitimate occupational issues raised for both the laboratory and field workers exposed to the GM products and their production (see Chapter 18).¹ The focus of this discussion, however, is the risk associated with consuming GM food.

Despite the vituperations and claims of some opponents of GM foods, the risk from consumption of these products appears modest. No outbreak or even case of systemic poisoning from consumption has been documented. Nonetheless, there are some credible concerns. An early one was the use of antibiotic-resistance genes to aid in the process of distinguishing the successful transgenic seeds from wild type.⁵ Typically, kanamycin- and neosporin-resistance genes are employed for this purpose, most likely with no adverse human consequence of serious risk for emergence of polyresistant bacterial strains.³¹ The best-founded concern relates to the possibility of increased allergy associated with altered or newly introduced proteins. Although theoretical information can be cited to exclude proteins that are *likely* to be antigenic – i.e., glycosylated proteins; those stable to temperature, pH, and protease degradation; and homologues of known antigens

– the possibility remains that post-transcriptional or other molecular modifications in the whole plant could render toxicologic predictions too imprecise to prevent allergic reactions from occurring.³²

Another possibility is that a transgenic product could be toxic, especially if expressed in very large quantities in the edible portions of the plant as would be necessary for the new protein to change the taste/appearance/stability of the marketable product.³³ In general, these intentionally introduced proteins can be tested like any other potential chemical considered as a food additive. More problematic are the so-called *pleiotropic* effects of new genes. This refers to alteration of the expression of *other* plant genes or metabolism as an unanticipated consequence of the genetic modification, hence the overall composition of the food. For example, expression of a novel gene in potatoes was shown to enhance expression of certain potent plant alkaloids that caused an outbreak of food poisoning after conventional breeding experiments.³⁴ Another possibility is alteration in the distribution of native gene products by the new gene, such as expression in the fruit of cucubitracin, a bitter cucumber protein normally expressed only in stems and leaves. This problem is particularly vexing because meaningful toxicity testing would require testing the whole plant, not just the gene product itself, since the possibilities are limitless and unpredictable. To achieve this would require identifying some test animal species capable of consuming sufficient doses of the plant. The most obvious choice would be the livestock that normally consume such plants, but practical issues aside, such animals digest quite differently from humans, rendering such an approach very problematic, especially for conduct of long-term testing for chronic effects.

FOOD SAFETY IN CLINICAL ENVIRONMENTAL MEDICINE PRACTICE

As a matter of public health practice, the issue of diet concerns all practitioners. However, the possibility that contaminants in the food we generally eat, like the air we generally breathe and the water we generally drink, may contribute to background risks for chronic disease is not, in or of itself, an issue for clinical practice, except possibly in the management of those with unusual disorders or sensitivities. There are, however, four distinctive settings in which the issue of environmental food contamination might arise in clinical practice:

- in the workup of a patient with a cryptogenic illness – acute, episodic, or progressive – suspected possibly to have an environmental basis, such as urticaria, asthma, encephalopathy, migraine syndrome, or behavioral change;
- in the search for a ‘source’ when a patient – symptomatic or asymptomatic – is discovered to have a high body burden of a potentially toxic chemical, e.g., a metal or pesticide;
- in the evaluation of patients with multiple chemical sensitivities or other related conditions in which

gastrointestinal and systemic symptoms are perceived to be occurring in temporal relation to exposure to dietary constituents;

- in the evaluation and management of asymptomatic patients concerned about risk from exogenous exposures or classes of exposures, e.g., in a pregnant patient or a resident in a community in which a known source of contamination exists.

The approach to history taking, exposure assessment, and management in these settings and in general environmental medicine practice is briefly outlined below.

The dietary history in environmental medicine practice

It has not been routine in most occupational and environmental medicine practices to take detailed dietary histories. However, given the range of exposures that may be relevant to clinical evaluation, at least some information about diet should be included in every clinical assessment, along with work history, and home and ambient environments. Unless there is particular reason for concern based on the clinical issues listed above, however, this should be limited, and should not be confused with the dietary history that forms the foundation for nutritional medicine practice, general prevention-oriented primary health-care, or the management of patients with chronic diseases to which diet has been proven to contribute – e.g., obesity, diabetes, lipid disorders, hypertension, etc. In those settings, the purpose of the dietary history is to establish a basis for nutritional modification, and considerable detail about food preferences and consumption is obligatory. In routine environmental medicine practice (excluding the specific settings listed above), on the other hand, the focus of the basic history is to discern whether *any aspect of dietary behavior might place an individual at unusual risk for an unsuspected environmental exposure or risk*. The elements of concern are:

- whether any food or class of foods is eaten in unusual proportion compared to normative behaviors; for example, does the patient consume fish at every meal, or extraordinary quantities of particular processed foods?
- whether ‘unusual’ foods are consumed which are known to have specific additives, such as herbs or supplements (a good context to inquire about any directly consumed in pill or other forms); and
- whether any foods are obtained from non-traditional sources, e.g., imported by family members, purchased from catalogues or other non-local suppliers, home-grown or processed, which could be locally contaminated, etc.

Negative responses to queries are probably sufficient as a screening procedure unless subsequent suspicions warrant greater detail.

The search for the ‘source’ for an elevated level of a potential toxin requires a more extensive evaluation. Overwhelmingly, the first matter is to confirm the evidence that the toxin has, in fact, accumulated in the body to excessive amount. Unfortunately, the proliferation of available laboratory assays and laboratories, combined

with substantial ignorance on the part of some practitioners who may order tests without appreciating the subtleties of their interpretation (see Chapter 3), has resulted in many ‘false positives’. This situation is compounded in some areas by non-traditional practitioners, espousing unproven theories, who may order poorly standardized tests or large batteries such as hair analysis for metals and organic chemicals. Suspicion that a test result may not represent meaningful or conclusive evidence of an intoxication confers a crucial clinical obligation to resolve the issue clearly for the patient. Extensive investigation for a ‘source’ of the suspect toxin should *follow*, not precede, confirmation of the evidence at hand. However, once the evidence for an excessive burden of a toxin has been confirmed, then a careful exploration for possible sources must be conducted, and ingestion becomes an integral part of that search. In this regard, information must be sought regarding such matters as food preparation (e.g., cookware, utensils, or dishes from which metals could theoretically leach, sources of water used for cooking, seasonings or other materials used in food preparation), providers of food outside the home, foods consumed during travel, and even the remote possibility of foul play – surreptitious or intentional poisonings.

In the workup of acute, episodic or progressive symptoms, the temporal relationship between dietary behaviors and sources and the clinical problem is most important, as in the occupational history when workplace exposures are suspect. For example, in a progressive neuropathy, the onset in relation to change in diet would be noteworthy; for migraine, the nature of ingestions preceding headaches compared to other times. The task is most straightforward in presentations of acute disease, in which the approach to history taking parallels that for suspect food poisonings of any kind, with emphasis on most recently consumed meals and the pattern of symptoms among those who may have consumed the same items.

Patients with suspect multiple chemical sensitivities often complain about reactions to certain foods (see Chapter 49). In some cases, the reactions are limited to abdominal discomfort, and may mimic irritable bowel syndrome, a commonly associated illness. In others, however, foods are perceived as triggering diverse systemic, CNS, dermal, or other symptoms, similar to reported responses to air-borne exposures to irritants and odors. Recognizing that detailed knowledge of such patterns rarely contributes to elucidation of the underlying problem nor simplifies decision making, review of foods which trigger symptoms is preferable to frustratingly exhaustive searches or elimination diets that such patients often undertake by themselves under the misapprehension that the effort will reveal the unique ‘cause’ of their symptoms, if only they are diligent enough.

Finally, for the patient at special risk for exposure, or especially concerned – for example, regarding organic mercurials during pregnancy – the history should focus on known sources of such contaminants. This may require specific knowledge about local food sources, such as whether fish or game in the area are known to be contam-

inated (see below), coupled with a more detailed profile of what the patient consumes, at least semi-quantitatively, and where it comes from.

Establishing food-borne exposures

To a greater degree than in other aspects of occupational and environmental medicine practice, confirmation of exposure relies on use of biologic markers in the patient, most often direct levels in blood, urine, or hair; rarely, other body tissues. Although this does not pinpoint the source, it is often the only way to meaningfully estimate the amount of exposure that has occurred. Sometimes this is not possible, especially in situations where the chemical identity remains unknown, as in the case of toxic oil syndrome for example. In such cases, the pattern of symptoms among family members or others consuming the same foods is the best tool for clinical investigation.

Pinpointing the specific food-borne source of the contaminant may be substantially more challenging than confirming the presence of the toxin. Although in theory it might be possible to measure the suspect toxin in a food, this is rarely feasible – either the food is no longer present, the chemical is present in too low a concentration to easily measure, or the chemical identity is not adequately characterized. Even if measurable, normative values for comparison are generally lacking. As an alternative, the source may be identified by combining a dietary history with available data on food constituency or contamination. For example, an elevated blood mercury level might be ‘confirmed’ by combining a history of consumption of a given quantity of swordfish per week with data on average levels of mercury in swordfish in the community. Likewise, the presence of a food additive, such as MSG, or an herbal ingredient could be confirmed by food suppliers or preparers.

Another approach is to assess exposure levels and/or effects among other individuals with the same diet. For example, a working adult with an unexplained elevation of blood lead might be evaluated by checking lead levels of his or her spouse or children. Likewise, in suspect acute contamination, one would generally expect others who have consumed the same item(s) to be similarly affected, albeit not necessarily to comparable degree because of differences in the amount eaten or host variability.

Diagnostic evaluation: associating symptoms with foods

For the subset of cases where the possibility is raised that acute or recurrent symptoms might be induced by specific ingestions, elimination and/or challenge diets can have an important diagnostic role. The fundamental concept is straightforward, and similar to removal and rechallenge for workplace exposures (see Chapter 3). However, unlike the workplace, where few comparable exposures are likely to confound such ‘trials’, successful conduct of dietary challenges requires thoughtful guidance, especially if the suspect culprit is a food additive or contaminant that

could be present in a high fraction of items typically consumed. Rarely, a biologic marker may be helpful, such as skin or radioallergosorbent testing (RAST), most typically in pursuit of classic allergenic effects.

Managing environmental exposures/effects from food-borne sources

Once there is evidence that exposure has occurred, and reasonable knowledge about its source, there are two components to management. First, the toxic effects themselves need to be managed, depending on what they are. For example, organophosphate or lead poisoning from a food source would be treated as a similar poisoning from any source.

Second, the exposure should be eliminated. Fortunately, this is generally easier than in other occupational or environmental poisoning situations as long as dietary alternatives and the resources to utilize them exist. Food substitution is, in every case, the best solution. The major problems occur when there is no access to uncontaminated food; for example, in parts of the world where mercury-contaminated fish constitute the only source of protein, or when cultural or religious reasons make food substitution difficult. Even where confirmation is less certain – for example, in childhood behavioral disturbances or allergies arguably related to food additives – substitution can generally be undertaken by elimination diets without adverse social, economic, or other health consequences.

CONCLUSION

Far more testing is performed on the food supply, and far more attention paid to it, than either the ambient or workplace environment. Despite this, and despite centuries of experience, environmental aspects of food continue to cause risk to human health. The rapid intensification of agricultural production methods has necessitated larger, not smaller, reliance on chemicals and biologic products such as hormones and antibiotics. Moreover, the application of new genetic techniques to foodstuff, still in its developmental infancy, guarantees continued and novel challenges in the decades ahead.

Chapter 54

Occupational and Environmental Exposures to Waterborne Microbial Diseases

Mansour Samadpour, Peter S Evans, Karin D E Everett, Prajakta Ghatpande, Gregory J Ma, Robert R Miksch

INTRODUCTION

Diseases caused by waterborne microbial agents continue to be a leading environmental concern, and are responsible for human morbidity and mortality throughout the world. Freshwater microbes annually are responsible for four billion cases of diarrhea (2.2 million deaths), according to the World Health Organization (WHO). Poor hygiene that is associated with use of unclean water has resulted in an estimated 200 million schistosomiasis infections, with six million cases of blindness worldwide.¹ Freshwater sources, historically, have been associated with epidemics: during the 1800s in the United States there were eight major cholera outbreaks (caused by *Vibrio cholerae*) and three typhoid outbreaks (caused by *Salmonella typhosa*).

The fear of historically important waterborne infectious diseases like cholera and typhoid fever has been eliminated or substantially reduced in developed countries today, mostly due to sewage treatment and implementation of water treatment and delivery systems. However, even chlorinated drinking water is not sterile, and many people work in occupations with considerable exposure to water containing wastes. In addition, molecular diagnostic methods and DNA-based biodiversity studies are revealing that old pathogens are causing new problems, and novel microbes are being discovered in every setting. Epidemiologic reports have led to the recognition of emerging waterborne pathogens. As part of its regulatory role, the Environment Protection Agency (EPA) Office of Drinking Water prepares a list of 25 priority pollutants for scrutiny and research. In March of 1998, the agency published its Drinking Water Contaminant Candidate List in the Federal Register.² It was notable that ten of the 25 pollutants of concern were micro-organisms: *Acanthamoeba*, Adenoviruses, *Aeromonas hydrophila*, Caliciviruses (Norwalk and Norwalk-like viruses), Coxsackieviruses, *Cyanobacteria* (blue-green algae), Echoviruses, *Helicobacter pylori*, Microsporidia (e.g., *Cyclospora cayetanensis*), *Mycobacterium avium* and *Mycobacterium intracellulare*.

Humans and animals are exposed to microbes throughout their lives in work, home, and recreational environ-

ments. To be responsible for disease in humans or other animals, any one of these agents must be present in sufficient concentration to produce disease (infectious dose) and a susceptible host must come into contact with contaminated water.³ Those that are waterborne are transmitted by drinking/eating, dermal/mucosal contact, or aerosol inhalation. Waterborne pathogens can also become foodborne when food is grown or prepared using water containing pathogenic microbes. Foodborne disease organisms are tracked by the Centers for Disease Control (CDC) Foodborne and Diarrheal Branch.⁴ Eleven of the 16 foodborne diseases under surveillance by the CDC are also waterborne microbes.

Waterborne microbial pathogens belong to three major groups: bacterial, viral, and eukaryotic. These microbes cause a wide variety of diseases, including acute gastrointestinal, upper and lower respiratory, meningitis, myocarditis, dermatitis, cirrhosis, bacteremia, hemolytic uremic syndrome, and thrombotic thrombocytopenic purpura (see also Chapter 22). Because diseases vary greatly in severity, the US characterizes pathogens as Notifiable, Select, or Foreign Animal Disease (FAD) agents. Notifiable agents require notification of state public health physicians; the specific agents reported may vary from state to state. Waterborne Notifiable disease agents include *Cryptosporidium parvum*, enterohemorrhagic *Escherichia coli*, *Giardia intestinalis*, *Legionella pneumophila*, *Vibrio cholerae*, Poliovirus, and agents such as *Shigella sonnei*, which causes dysentery.⁵

GENERAL US POPULATIONS AT RISK

Outbreaks of waterborne illness in the USA

The US EPA and the CDC conduct surveillance for waterborne outbreaks in the USA.⁶ In the distant past, waterborne outbreaks were caused by agents associated with disease in developing nations such as *Vibrio cholerae* (cholera), *Entamoeba* (amebiasis), *Shigella* (dysentery), and *Salmonella* (typhoid fever). In more recent years, outbreaks

Etiologic agent	Community outbreaks	Cases	Non-community outbreaks	Cases	Individual outbreaks	Cases	Cumulative outbreaks	Cases
AGI	11	10,162	36	4717	11	246	58	15,125

Data from MMWR Surveillance Summaries 1993, 1996, 1998, 2000, and 2002.

Table 54.1 United States outbreaks by etiologic agent in drinking water, 1991–2000 by water system type

have been linked to newly identified pathogens such as *Campylobacter*, *Cryptosporidium*, *E. coli* O157, *Giardia*, hepatitis A, *Legionella*, *Naegleria*, *Acanthamoeba*, Norwalk virus, *Pleisiomonas shigelloides*, *Pseudomonas*, and *Schistosoma spindale*. Improvements in sanitary infrastructure, including waste water treatment and drinking water protection, have drastically reduced the burden of waterborne disease, as well as the number of outbreaks. However, massive waterborne disease outbreaks continue to occur. The largest recent waterborne outbreak involved more than 400,000 cases of cryptosporidiosis in Milwaukee, Wisconsin, in 1993.⁷ Another waterborne outbreak in Washington County, New York, in 1999⁸ resulted in 148 cases of *E. coli* O157:H7 and *Campylobacter jejuni* infections. Outbreaks of waterborne illness have been associated with drinking water as well as recreational exposure to swimming pools, and natural water (bodies containing fresh and salt water).

Agents posing the greatest waterborne disease potential are transmitted through the fecal–oral route (Table 54.1). Consequently, prevention from diseases associated with these organisms is accomplished by protecting drinking water sources and recreational waters from contamination with human or animal waste. On the other hand, a limited number of waterborne pathogens (e.g., *Legionella* spp., *Vibrio* spp., *Aeromonas hydrophila*, and *Pseudomonas aeruginosa*) are indigenous to the water environment. Control of these agents and their potential infections is dependent on controlling exposure to water containing these organisms or by treating the water to remove or inactivate the infectious agents.

Drinking water

During the period 1991–1998, there were 81 outbreaks of waterborne disease associated with drinking water.⁶ Of these, 41 were described as ‘acute gastrointestinal illness’ (AGI) of unknown etiology. The flagellated protozoan

parasite *Giardia* was the leading causative agent for 15 of the remaining 40 outbreaks. *Giardia* was the leading cause of waterborne outbreak in the preceding ten-year period as well. Another eukaryotic parasite, *Cryptosporidium parvum*, was the next leading cause (Table 54.2), accounting for ten of the 40 outbreaks. However, *C. parvum* accounted for the largest number of cases due to waterborne pathogens, mainly due to the Milwaukee outbreak that involved more than 400,000 cases. *Shigella sonnei* and *E. coli* O157:H7 each was responsible for four outbreaks. Two outbreaks were attributed to *Shigella flexneri* and the remaining five outbreaks were attributed one each to: *Salmonella typhimurium*, *Pleisiomonas shigelloides*, non-O1 *Vibrio cholerae*, hepatitis A, and a ‘small round structured virus’. The low number of waterborne outbreaks of infectious disease is a tribute to the success of water treatment processes, especially the final disinfection and maintenance of residual disinfectant in the distribution systems. It is to be mentioned that while bacterial and viral pathogens are controlled effectively by the current disinfection processes, a successful control regimen for pathogens such as *Giardia* and *Cryptosporidium* involves the use of alternative disinfection technologies, such as ozonation and ultraviolet treatment, prolonged contact time with chlorine, and efforts to protect the source waters from resistant pathogens.

Recreational waters

The larger list of agents associated with recreational water outbreaks reflects the higher diversity of organisms present in untreated, natural waters (Table 54.3). In the period 1990–1998, 14,962 cases of disease associated with recreational water exposure were reported to the CDC.^{9–12} *Pseudomonas* spp. were consistently reported every year during this period as a causative agent in 607 cases. However, the largest number of cases, 10,269, were

Table 54.3 United States outbreaks by etiologic agent, for the period of 1991–2000 in recreational waters

attributed to *Cryptosporidium parvum* in seven of these eight years. *Shigella sonnei* was also reported in seven out of eight years as an etiologic agent in 1190 cases. Acute gastrointestinal illness (AGI) of unknown etiology and *E. coli* O157:H7 were both reported in five out of the eight years, for 253 and 257 cases respectively. *Giardia* and *Naegleria* were both reported in four of the eight years for 252 and 17 cases respectively. Three organisms, *Leptospira*, Norwalk virus and *Legionella*, were reported in three of the eight years for 375, 48, and 45 cases respectively. The following six causes were mentioned in one year each out of the eight-year period: adenovirus 3 (595 cases), *E. coli* O157:H7 and *Shigella sonnei* mixture (80 cases), *Shigella flexneri* (35 cases), unknown etiology (33 cases), chemical (26 cases), and *Salmonella* serotype Java (3 cases). The primary settings for recreational water associated outbreaks are swimming pools, lakes or ponds, and hot tubs⁹⁻¹³ (Table 54.3). Microbial hazards associated with marine and estuarine environments are discussed in the next section.

The risk associated with recreational exposure to pathogens has been assessed in epidemiologic studies by comparing disease or symptom incidence rates for swimmers versus non-swimmers, or swimmers exposed to recreational waters with varying levels of microbial pollution. Pruss¹⁴ reviewed 22 published epidemiology studies and concluded that there was agreement in a strong association of gastrointestinal (GI) symptoms and exposure to waters containing enterococci, fecal streptococci, thermotolerant coliforms, and *E. coli*. Pruss' conclusion, based on evaluating epidemiologic designs, was that enterococci and fecal streptococci were the most reliable indicator organisms for GI symptoms associated with exposure to marine and fresh waters; and that *E. coli* was a reliable indicator organism in fresh water and nearly as reliable as enterococci in marine waters. The observed illness threshold values described in the studies evaluated by Pruss were low for the enterococci and fecal streptococci and higher for the thermotolerant coliforms.¹⁴⁻¹⁶ As a practical matter, the methodologies for recovery of these indicator organisms are not precise when applied to environmental water samples. Consequently, the higher threshold values for the *E. coli* and thermotolerant coliforms¹⁷⁻¹⁹ are a more pragmatic yardstick for predicting the causal relationship between swimming and illness.

Swimming pools are frequently the setting for infectious disease outbreaks. Factors determining microbiologic water quality of swimming pools include the free chlorine concentration and pH, as well as the rate of water filtration and recirculation. Wading pools used by infants and other children prior to toilet training are often the site of disease transmission. The shallow depth and relatively low water volume in these pools leads to faster disinfectant depletion rates (due to the effects of ultraviolet light) and a higher concentration of organic matter following accidental bowel movements.²⁰

A variety of eukaryotic, viral and bacterial pathogens are transmitted through swimming pools. *Cryptosporidium*, one of the most important waterborne pathogens of the past decade,⁹⁻¹³ is a frequent cause of recreational water-

borne outbreaks²¹ (Table 54.2). The persistence of *Cryptosporidium* oocysts in swimming pools is due to the extreme resistance to inactivation by chlorine and inadequate filtration by conventional pool filters.²² Outbreaks of conjunctivitis due to a variety of Adenovirus serotypes, gastroenteritis due to exposure to Norovirus, Enterovirus, or enterobacteria such as *Shigella* spp. and *Escherichia coli* are often linked to inadequately chlorinated pools.

Marine waters

Exposure to a diverse group of micro-organisms, including diatoms, dinoflagellates, microalgae, as well as blue-green algae (a bacterial species), has been linked to mild to severe neurologic and gastrointestinal complaints in coastal and estuarine environments throughout the world. Marine micro-organisms may be free-living, or associated with a variety of fish and shellfish species. Clearly, foodborne transmission for these agents is an important means of exposure, but the role of recreational or occupational exposure to these micro-organisms has been suspected and is being evaluated.

Scromboid, amnesic shellfish poisoning (ASP), diarrhetic shellfish poisoning (DSP), paralytic shellfish poisoning (PSP), and ciguatera fish poisoning (CFP) follow the ingestion of fish or shellfish contaminated with marine micro-organisms. In these diseases, microbial contamination leads to the accumulation of toxic compounds producing a variety of neurologic and gastrointestinal symptoms. The diseases are encountered throughout the world, at a low rate. The CDC estimates 30 cases per year and one fatality per four years in the USA.⁴ Diagnosis is usually based upon symptoms and history of shellfish consumption. In most cases, treatment is limited to supportive care; however, specific therapies are available for scromboid and CFP.

Individuals exposed to coastal waters risk contact to marine micro-organisms through recreational or occupational exposure to the environment. Marine micro-organisms or their toxins may be ingested or contact skin and mucous membranes. Air-borne transmission of aerosolized microbes or toxins is also possible. Environmental exposure may play a role in the transmission of neurotoxic shellfish poisoning (NSP) as well as possible estuary associated syndrome (PEAS).

NSP is primarily thought of as a foodborne illness associated with the consumption of shellfish caught during red tides, which are blooms of a marine dinoflagellate, *Karenia brevis* (formerly *Gymnodinium breve*), that regularly occur along the Gulf of Mexico and Atlantic coasts of the USA. A *K. brevis* toxin, brevetoxin, is responsible for NSP symptoms, which include altered sensations in the mouth and extremities, dizziness, loss of co-ordination, muscle aches, and gastrointestinal symptoms. Brevetoxin may also be aerosolized when it is released from cells by lysis or excretion and incorporated into marine aerosol by wind and breaking surf along the coast.²³ Air samples taken during red tide conditions along the Atlantic and Gulf coasts of Florida, as well as the Atlantic coast of North Carolina,

were measured at 160–180 ng/mm².²³ The CDC is currently conducting a study to assess the health effects of exposure to aerosolized red tide agent.⁵

Another disease in which recreational or occupational exposure is thought to be potentially involved is PEAS, which is associated with two species of marine dinoflagellate, *Pfiesteria piscicida* and *P. shumwayae*. *Pfiesteria* has been implicated in massive fish kills occurring in estuaries along the southeastern Atlantic coast of the USA. Fish and shellfish located at the site of *Pfiesteria* blooms are lethargic, disoriented, and contain ulcers.²⁴ Although water-soluble *Pfiesteria* toxins are hypothesized to exist, none have been isolated and characterized in the laboratory, or detected in the environment, and a recent report challenged the notion that *P. shumwayae* even has the capacity to produce dinoflagellate-like toxin.²⁵ Studies documenting the effects of *Pfiesteria* species on humans originated with observations of respiratory, gastrointestinal, optical, and neurologic symptoms following exposure to aerosol in a laboratory.²⁶ Subsequent retrospective epidemiologic investigations have compared the health status of symptomatic individuals in contact with *Pfiesteria* blooms to controls.^{27,28}

Mild flu-like illness as well as learning and memory difficulties were reported to be associated with exposure, but exposure assessments other than self-report were not possible. A large prospective study was unable to identify health issues in a cohort of individuals with recreational or occupational exposure,²⁹ and a cross-sectional study comparing the health of watermen working either in estuaries (site of *Pfiesteria*-associated fish kills) or the ocean failed to find significant differences upon medical, neurologic, neuropsychologic, or neurobehavioral evaluation system 2 (NES-2) evaluation, but did note a significantly reduced visual contrast sensitivity among the estuarine watermen.³⁰ Further studies, especially those that specifically measure exposure to *Pfiesteria* or its toxins, are needed to establish PEAS as a human disease.³¹

OCCUPATIONAL POPULATIONS AT RISK

Individuals are exposed to pathogens by virtue of their occupational responsibilities. A good example is exposure of physicians and allied healthcare professionals to viruses (e.g., hepatitis B, C, D, and human immunodeficiency virus) present in blood and other clinical specimens. Likewise, some workers are routinely exposed to waterborne pathogens present in natural waters, as well as sewage and aerosols.

Workers exposed to cooling towers, industrial water conditioning, and water supplies

Closed water management systems, such as those used for water cooling, conditioning, and supply, are difficult to maintain, and often accumulate biofilms. These biofilms

provide a protective niche for many waterborne protozoa and bacteria. From a medical perspective, an important inhabitant of biofilms is *Legionella* spp., the causative agent of legionnaire's disease. This bacterial pathogen may be associated with single-celled protozoa; when growing inside the protozoan, it is unaffected by relatively high levels of biocides.³² Aerosols containing *Legionella* bacteria are created when the bacteria are shed into water, which is then sprayed or splashed. In this way, *Legionella* gains access to the respiratory systems by inhalation. Free-living *Legionella* spp. have also been isolated directly from waters and soils. *Legionella* bacteria have been recovered from water samples taken from cooling towers,³³ cooling systems,³⁴ and hospital water supplies,^{35,36} and inhabit water fittings, pipework, and materials in hospital hot-water systems.³⁷ Large outbreaks have been associated with these water supplies.^{38–40}

Waste water workers

Waste water is a complex mixture of potentially hazardous organisms and chemicals in water, and workers may be exposed to pathogens through ingestion, contact with the skin or mucosal surfaces, or by aerosol inhalation. The purpose of waste water treatment is to protect public health by collecting, transporting, and treating waste water. This treatment has greatly reduced the frequency of water-associated disease in the United States, but continues to have an enormous worldwide impact on populations.

Despite the seemingly high potential for hazardous exposures to waste water treatment workers, many reports suggest that the risk of infection, as measured by pathogen loads or seroprevalence, is similar to other segments of the working population.^{41–44} Questionnaire-based prevalence studies have documented illness rates in waste water treatment workers. For example, Thorn and colleagues found an elevated risk of non-specific respiratory, gastrointestinal, and central nervous system symptoms among 1394 Swedish municipal sewage workers, compared to controls that were unexposed, or partially exposed to sewage.⁴⁵ Using factor analysis, Douwes and colleagues defined four symptom clusters reported by 147 Dutch sewage workers.⁴⁶ Two clusters ('flu-like illness' and 'neurological symptoms') were statistically significantly associated with exposure to sewage. Other studies^{47,48} did not find significantly higher illness rates among sewage workers, although Pahren and Jakubowski did find that the rate of gastrointestinal illness in inexperienced waste water workers was 2–4 times higher than in experienced workers or the control group.

Although the results of epidemiologic studies are mixed, the potential for exposure to disease agents cannot be discounted. Samples taken from municipal sewage treatment plants or conveyance systems can potentially contain any or all of the pathogenic micro-organisms from the community served by the plant. Waterborne microbial pathogens relevant for sewage treatment workers can be divided into those causing respiratory tract, cutaneous, and enteric diseases. The etiologic agents may be bacteria,

viruses, protozoans, or helminths. These organisms typically enter human hosts by ingestion, inhalation, or direct contact with dermal or mucosal surfaces.

Respiratory tract pathogens

Aerosolized waste water can transmit viral and bacterial microbes to the lungs of workers. Aerosols may also be deposited on food or the surfaces of objects (fomites). The microbes described below may become etiologic agents of respiratory disease. *Legionella* species can be found in waste water, but there is little published information about waste water workers' potential risk of infection. One reported outbreak of Pontiac fever (non-pneumonic legionellosis) demonstrates that treated industrial waste water from a food manufacturer may have contributed to their common infections with *Legionella* based on their antibody titers.⁴⁹ Notably, the *Legionella* serotype isolated from five workers matched that isolated from sewage sludge during the same time period, and a sludge centrifugation process was identified as a potential source of the aerosol.

Mycobacterium spp., bacteria which cause tuberculosis and skin ulcerations, have been identified from waters and waste water treatment plants, and aerosols created in those environments may offer a previously unexpected source of infection.^{50,51} Additional waste waterborne organisms cause respiratory disease in other countries. One of these, *Burkholderia* (*Pseudomonas*) *pseudomallei*, causes a pneumonia known as melioidosis in sub-tropical Australia and tropical southeast Asia.⁵² As waste water treatment plants modernize and become more enclosed for odor control, aerosols become a more important exposure route.

Cutaneous pathogens

Gram-negative bacilli constitute the largest group of aquatic pathogens causing skin infections.⁵³ Skin infections and rashes have been reported for a variety of organisms not typically considered to be associated with waste water, but these reports underscore the importance of the combination of exposure, agent, and susceptible host. *Staphylococcus*, *Enterococcus*, *Streptococcus*, and *Clostridium* have a clinical history of causing cutaneous infections, and in some instances, serious tissue necrosis. *Mycobacterium ulcerans* has been epidemiologically linked to skin ulcerations through contact with waste water.⁵⁴ *Pseudomonas* spp., *Aeromonas hydrophila*, and *Flavobacter* are other bacteria causing non-enteric diseases, typically rashes, but sometimes associated with toxin production and secondary sequelae.⁵²

Enteric pathogens

Enteric bacteria are the predominant, pathogenic infectious agents in waste water, and a large variety of pathogenic and opportunistic bacteria can be detected (Table 54.4). Enteric bacteria commonly cause gastrointestinal disorders, but some cause health effects beyond the gastrointestinal tract. Over the last 20 years in the USA, pathogenic forms of *E. coli* (enterotoxigenic, enteropathogenic, enterohemorrhagic, and enteroaggregative) have been found in waste water.^{55–57} Enterohemorrhagic *E. coli*

O157:H7 causes not only bloody diarrhea, but also hemolytic-uremic syndrome in children, which is characterized by renal failure and a high case fatality rate. In the USA, *Salmonella* and *Shigella* bacteria are responsible for infection associated with foods that have been irrigated with waste water.⁵⁸ However, the most severe form of salmonellosis, typhoid fever, is rarely seen in the US.

Pathogenic species of *Leptospira* can be acquired from water contaminated with the urine of infected animals, causing vomiting, high fever, severe headache, chills, and muscle aches, and may include abdominal pain, diarrhea, jaundice (yellow discoloration of skin and sclerae), red eyes, or a rash. Severe infections result in liver and kidney dysfunction and a high mortality rate.⁵⁹ Rodents, particularly rats, are common hosts of infection, but a variety of wild and domestic mammals can be infected. The organisms can survive for months in water, and isolation from waste water is not uncommon, particularly in tropical and semi-tropical climates.⁶⁰ Fewer than 100 cases of leptospirosis are reported each year in the United States.⁸ Other bacteria causing gastrointestinal ailments include *Campylobacter*, *Helicobacter*, and *Arcobacter*.⁶¹

The most commonly detected viruses in waste water belong to the *Enterovirus* group of the Picornaviruses, which consists of small single-stranded RNA viruses and includes *Poliovirus*, *Echovirus*, and *Coxsackievirus*. Other viruses associated with waste water and fecal contamination include *Adenovirus*, *Aichi virus*, *Astrovirus*, hepatitis A and E, *Calicivirus*, and *Reovirus*. *Rotavirus* (a member of the *Reoviridae*) is the most infectious of all the enteric viruses and should be considered a high risk in waste water.⁶²

Protozoan parasites such as *Entamoeba histolytica*, *Giardia intestinalis*, and *Cryptosporidium parvum* are recovered from waste water more frequently than from other environmental sources. These parasites are also recovered from natural fresh and estuarine waters in the USA and worldwide.^{63–67} *Toxoplasma gondii* and *Cyclospora* are also frequently recovered from waste water. *Entamoeba histolytica* causes amebiasis (amebic dysentery), and more serious extraintestinal disease affecting the liver. *Giardia intestinalis* (*lamblia*) and *Cryptosporidium parvum* have been implicated in waterborne cases of diarrhea, with flatulence and greasy stools, primarily from drinking surface water and inadequate treatment systems. Non-human animals serve as secondary or carrier hosts. The recurring contamination of water and cycling of these organisms to humans creates an almost endless source of infection. Helminth parasites (worms) found in waste waters include *Ascaris lumbricoides* (roundworm), *Necator americanus* (hookworm), *Trichuris trichiuria* (whipworm), *Toxocara canis* (canine roundworms), and *Strongyloides stercoralis* (the agent of strongyloidiasis). These worms all have life cycles that are dependent on a host during part of the reproductive cycle, and produce infective cysts, the form likely to be encountered in waste water. Helminthic eggs/cysts that make it past the waste water treatment process may survive in soils and sludges for up to ten years.⁶⁸

Type	Disease or syndrome caused	Amount in waste water	Infectious dose
Bacteria		Med to High	High
<i>Aeromonas hydrophila</i>	Enteritis (inflammation of the intestine)		High
<i>Burkholderia pseudomallei</i>	Melioidosis		High
<i>Campylobacter</i>	Enteritis, diarrhea		High
<i>Clostridium perfringens</i>	Enteritis (indicator)		High
<i>Escherichia coli</i> , pathogenic	Enteritis, diarrhea		High
<i>Francisella tularensis</i>	Tularemia		High
<i>Leptospira</i>	Jaundice, meningitis, Weil's disease		High
<i>Listeria monocytogenes</i>	Listeriosis		High
<i>Mycobacterium</i>	Tuberculosis, skin ulcers		High
<i>Pseudomonas</i>	Skin, ear infections		High
<i>Salmonella</i> (1700 types)	Enteritis, typhoid		High
<i>Shigella</i> (4 species)	Enteritis, diarrhea		Low*
<i>Staphylococcus aureus</i>	Skin infections		High
<i>Vibrio cholerae</i> and <i>V. parahaemolyticus</i>	Cholera, skin infections		High
<i>Yersinia enterocolitica</i> and <i>Y. pseudotuberculosis</i>	Enteritis		High
Helminths		Low	Low
<i>Ascaris lumbricoides</i>	Ascariasis		Low
<i>Ancylostoma duodenale</i>	Hookworm infections		Low
<i>Trichuris trichiura</i>	Trichiuriasis		Low
<i>Taenia</i> (tapeworm)	Taeniasis		Low
<i>Toxocara</i>	Abdominal pains		Low
<i>Strongyloides</i>	Abdominal pains		Low
Protozoa		Low to Med	Low
<i>Entamoeba histolytica</i> and <i>Entamoeba coli</i>	Enteritis, chronic diarrhea, dysentery, liver abscess		Low
<i>Giardia intestinalis</i>	Giardiasis, enteritis		Low
<i>Cryptosporidium parvum</i>	Enteritis, diarrhea		Low
<i>Ballantidium coli</i>	Enteritis, diarrhea		Low
<i>Naegleria fowleri</i>	Meningoencephalitis		Low
<i>Acanthamoeba</i> spp.	Meningoencephalitis		Low
Viruses		Med to High	Low
Poliovirus (3 types)	Paralysis, meningitis		Low
Echovirus (34 types)	Meningitis, diarrhea		Low
Coxsackievirus A and B (30 types)	Meningitis, conjunctivitis, chronic fatigue syndrome, myocardia, diabetes		Low
Hepatitis A and E viruses	Epidemic 'infectious' hepatitis		Low
Enterovirus 68–71	Meningitis, conjunctivitis		Low
Rotavirus (+4 types)	Enteritis		Low
Reovirus (3 types)	Enteritis, respiratory		Low
Adenovirus (+40 types)	Enteritis, eye and respiratory		Low
Norwalk and Norwalk-like viruses	Gastroenteritis		Low
Calicivirus and Astrovirus	Enteritis		Low
Coronavirus	Enteritis		Low
Parvovirus (2 types)	Enteritis, respiratory in children		Low

* Low infectious dose means only a few viral particles/cells/cysts/eggs are required to cause infection; high indicates many are required to cause an infection.
Data from Feachem et al. 1983²⁵⁶ and Payment 1991.⁵⁰

Table 54.4 Diseases associated worldwide with pathogens in waste water and their relative loading

Agricultural workers

In 2002, people working in agriculture, forestry, fishing, hunting, and mining accounted for 1.8% of the US workforce.⁶⁹ These individuals may be exposed to disease sources having natural reservoirs in animals (zoonoses), may be specific for humans, may produce toxins, or may be commensals that have acquired genetic elements that express pathogenic traits. The risk posed by transmission of waterborne disease from the agriculture watershed to the population is substantial.⁷⁰ Virulent bacteria and parasites can remain viable in the watershed environment, become amplified by agricultural practices, or contaminate the food supply with toxin (as in the case of algal blooms) or pathogens. Surveillance of farm workers has demonstrated that water quality is a serious occupational

hazard.^{71,72} Drinking water may be contaminated in the farm environment with pesticides, other agricultural chemicals, and microbes. Agricultural waste containing pathogens such as *Salmonella* spp., *E. coli* O157:H7, *Campylobacter*, *Cryptosporidium parvum*, and many others, can contaminate surface and ground water that is used as sources for drinking water, or for recreational contacts.

Manure and agricultural waste water

Agricultural workers are exposed to many waterborne organisms through their contact with animals, animal feces, and fecally contaminated soil and water. The principal fecal sources are livestock and poultry, followed by wildlife and companion animals.⁷⁰ Manure from cattle, horses, pigs, and poultry is routinely processed and used as farm and commercial fertilizer. An additional source of

agricultural exposure to infectious agents is the use of biosolids (sludge) from municipal waste water treatment plants,⁷³ where pathogens surviving sewage treatment are a potential health threat. Protozoan cysts can survive in water as long as 180 days; helminth (worm) ova can survive in soil seven years; bacteria and viruses may live up to a year.^{74,75} Additionally, fecally contaminated water from animal feeding operations may leach into surface or ground water. On-farm recycling can also release pathogens into the environment. Manure contains numerous eukaryotes (protozoa), as well as anaerobic, aerobic, and facultatively aerobic bacteria that contribute to the decomposition of manure.⁷⁶ For this reason, manure is stored and decomposed as an aerated liquid slurry concentrate. Sludge and lagoon water are removed periodically and applied to farmland. Unprocessed sewage may be carried from lagoons and storage ponds into overland flow or subsurface water. Obviously, the occupational hazards of waste water workers would also be applicable in these situations.

Waterborne hazards in the agricultural watershed include protozoa, bacteria, viruses, and helminths. *Cryptosporidium parvum* and *Giardia* spp. are the protozoal pathogens of primary concern. Of lesser concern are *Entamoeba histolytica*, *Toxoplasma gondii*, and *Balantidium coli*.^{9-13,70} Anaerobic and facultatively anaerobic bacteria make up the bulk of the feces. In a study of bacteria obtained from chicken intestines, 70% of the contents of the ileum were related to the *Lactobacillus* genus, and the rest were related to *Clostridia*, *Streptococcus*, and *Enterococcus*.⁷⁷ In the cecum, clostridial relatives comprised 65%, and the remainder were related to *Fusobacterium*, *Lactobacillus*, and *Bacteroides*. Facultatively aerobic organisms belonging to genera *Escherichia*, *Klebsiella*, *Enterobacter*, and *Citrobacter*, among others (fecal coliforms), are used as measures of fecal contamination in the environment because they are easily cultured and nearly always present in fecal matter.

Pathogenic bacteria are also transmitted in the feces, and these include *Escherichia coli* O157:H7, *Streptococcus* spp., *Enterococcus* spp., *Campylobacter* spp., *Salmonella* spp., *Yersinia enterocolitica*, *Brucella* spp., and *Leptospira*.⁹⁻¹³ Parasitic worms transmitted by feces include platyhelminths and *Ascaris* spp.⁷⁰ Human viruses present in human sewage include *Adenovirus*, *Astrovirus*, *Hepatitis*, *Noroviruses*, *Rotavirus*, and *Coxsackievirus*.⁷⁸ However, most viruses, unlike many bacteria, parasites and helminths, are host specific. Viruses present in animal feces having zoonotic potential include hepatitis E, and influenza virus.

Contamination of crops

One of the major causes of water- or food-borne outbreaks associated with the agricultural sector is the use of contaminated irrigation water. The use of partially treated or untreated waste water introduces waterborne pathogens into the irrigation system.⁷⁹⁻⁸¹ Additionally, pathogens may enter the watershed through the application of manure or other biosolids to the land.^{70,82,83} In the USA, use of these biosolids is regulated by the EPA Part 503 Biosolids Rule. However, these regulations may not be stringent enough to remove thermally tolerant viruses.^{84,85}

After waste water or biosolids are applied to land, waterborne pathogens may persist and contaminate vegetation and crops. The life cycle of waterborne parasites may be supported by intermediate hosts found in irrigation canals.⁸⁶ Pathogens may contaminate crops by adhering to leaf or root surfaces.^{87,88} Additionally, recent studies have shown that *E. coli* O157:H7 can migrate to internal edible parts of the plant tissue and become inaccessible to disinfectants and surface cleaning.^{82,83}

Other occupational hazards

Stojek and Dutkiewicz⁸⁹ investigated the possibility of *Legionella* infection among outdoor gardeners in eastern Poland. They found that potting soil as well as the aerosolized water from the sprinklers was contaminated with *Legionella*, and could pose a threat.

In healthcare settings *Legionella* bacteria were found in the water of dental units sampled from 28 dental facilities in six US states.⁹⁰ The *Legionella* spp. levels observed in the dental unit waters was 1000/ml or more in 36% of the samples collected, and 10,000/ml or more in 19% of the samples. In an investigation of *Legionella* infection in a dental office, Atlas and colleagues identified high levels of *Legionella* spp., *L. pneumophila* and *L. longbeachae* in the dentist's operating area, suggesting that aerosols from dental units were the source of the *Legionella* infection.

WATERBORNE BACTERIAL PATHOGENS

Bacteria represent a diverse group of microbes that live in a wide variety of environments. Depending on the taxonomic subgroup, they may produce spores, survive in distilled water, remain alive for centuries in salt deposits, live endosymbiotically in protozoa, fungi, or insects, or synthesize toxins that in tiny amounts can cause substantial human illness or death.

Aeromonas

Introduction

Aeromonas species are free-living, facultatively anaerobic, gram-negative rods found in fresh water and sewage. *Aeromonas hydrophila* causes illness in fish, reptiles, amphibians, ducks and other water birds, and mammals, including humans.^{91,92} Some *A. hydrophila* strains may produce a toxin that can cause diarrheal symptoms in patients.⁹³ *A. hydrophila* cultured from stool specimens grows readily on the differential media used to culture enteric gram-negative rods, and can easily be confused with the enteric bacteria.⁹⁴

Clinical symptoms

Two distinct types of gastroenteritis have been associated with *A. hydrophila*: a cholera-like illness with watery diarrhea, and a dysenteric illness characterized by loose stools containing blood and mucus.⁹¹ It also causes cellulitis and

other primary or nosocomial infections.^{91,94} *A. hydrophila* can be found in blood of individuals with seriously impaired host defenses or endocarditis. It is occasionally isolated from the feces of patients with diarrhea.⁹⁴

Mode of transmission

Aeromonas hydrophila is a motile rod commonly isolated from water, soil, or food, and occasionally from the human intestinal tract. It can cause freshwater wound infections.⁹⁴ Transmission may be via water, food or, more rarely, person to person.

Control measures

Most *Aeromonas* strains are susceptible to tetracyclines, aminoglycosides, and cephalosporins that can be used for the treatment.⁹⁴

Escherichia coli

Introduction

Escherichia coli belongs to a large bacterial family, the Enterobacteriaceae, which lives in the intestinal tracts of animals. *E. coli* is a facultatively anaerobic gram-negative rod that adheres to mucus overlying the inside of the large intestine. It is acquired orally shortly after birth from other individuals, foods, or water. Many strains are sensitive to antibiotics. *E. coli* is a consistent inhabitant of the human intestinal tract and so its presence in nature is used as an indicator of fecal pollution and water contamination. Despite its role as a commensal organism in humans, *E. coli* is sometimes responsible for three types of infections: intestinal diseases (gastroenteritis), urinary tract infections (UTI), and neonatal meningitis.

The serotype O157:H7 of *Escherichia coli* has emerged as a significant pathogen from the enterohemorrhagic *Escherichia coli* (EHEC) group. Though commonly associated with foodborne illnesses, waterborne occurrence is also observed. Two potent toxins involved in the clinical complications of EHEC infection are Shiga-like toxins I and II. Shiga-like toxin I is identical to the cytotoxin produced by *Shigella dysenteriae*.⁹⁵ Antibiotic resistance genes are also frequently present in pathogenic strains. Drinking unchlorinated well water or accidental swallowing of water while engaging in recreational activities has been responsible for hundreds of cases.^{96,97} Cattle are the primary reservoirs of EHEC. Humans can also act as a reservoir in the cases of human-to-human transmission. The pathogen can be shed for a week or less in adults, though three weeks is the common excretion period observed. A prolonged carriage is comparatively infrequent.⁹⁵

Clinical symptoms

Pathogenic *E. coli* strains are classified as localized, diffuse, or aggregative, and typically cause fever, abdominal cramps, nausea, vomiting, and diarrhea. Diarrhea is often bloody. The incubation period for the illness ranges from one to ten days, with a median of 3–4 days. The pathogen is typically shed for a week or less in adults, but may be

found for up to three weeks. Clinical complications of the illness include hemolytic-uremic syndrome and thrombotic thrombocytopenic purpura. Uropathogenic *E. coli* colonize from the feces or perineal region and ascend the urinary tract to the bladder, causing typical urinary tract infection symptoms of dysuria, urgency, and frequency; the urine may be cloudy, foul smelling, and bloody.

Mode of transmission

Cattle are a primary reservoir of EHEC. Consumption of insufficiently cooked meat previously contaminated with *E. coli* O157:H7 during slaughter is one of the major causes of *E. coli* O157:H7 outbreaks. Humans can act as reservoirs in human-to-human transmission. A fecal–oral route of transmission is observed, with transmission from the diarrheal stools of an infected person to others, if inadequate personal hygiene is followed. Other common sources of infection include contaminated sprouts, lettuce, salami, unpasteurized milk, juice, sewage-contaminated water, and swimming in water contaminated with *E. coli* O157:H7.

Susceptibility and resistance

The infective dose of *E. coli* O157:H7 appears to be less than ten organisms. *E. coli* O157:H7 is susceptible to heat. Thus cooking meat or boiling water will help prevent transmission. Strains that have acquired pathogenicity factors may be resistant to tetracycline, ampicillin, erythromycin, trimethoprim-sulfamethoxazole, and amoxicillin/clavulanate.

Control measures

Drinking pasteurized milk, juice, or cider will help prevent the transmission of the pathogen. Chlorine or other commercially used disinfectants can kill *E. coli* O157:H7.

Helicobacter pylori

Introduction

Helicobacter pylori (formerly *Campylobacter pylori*) is a spiral-shaped bacterium found in the gastric mucous layer or adherent to the epithelial lining of the stomach. *H. pylori* causes more than 90% of duodenal ulcers and up to 80% of gastric ulcers. It is estimated that over half of the world's population may be infected with *H. pylori*. In the United States, *H. pylori* is most prevalent among older adults, African-Americans, Hispanics, and lower socioeconomic groups.⁹⁸

Clinical symptoms

H. pylori causes chronic active, persistent, atrophic gastritis, as well as duodenal and gastric ulcers in adults and children. Infected persons have a 2–6-fold increased risk of developing gastric cancer and mucosal-associated lymphoid-type lymphoma compared with uninfected counterparts. The most common ulcer symptom is gnawing or burning pain in the epigastrium, most severe when the stomach is empty, between meals, and in the early morning hours. Other ulcer symptoms may include nausea, vomiting, loss

of appetite, and bleeding; prolonged bleeding may cause anemia, weakness, and fatigue. Bleeding may be associated with hematemesis, hematochezia, or melena.⁹⁹

Mode of transmission

It is not clearly understood how *H. pylori* is transmitted or why some patients become symptomatic while others do not. The bacteria are most likely spread from person to person through fecal–oral or oral–oral routes.¹⁰⁰ Possible environmental reservoirs include contaminated water sources.¹⁰¹ Iatrogenic spread through contaminated endoscopes has been documented, but can be prevented by proper cleaning of equipment.¹⁰²

Control measures

Therapy for *H. pylori* infection consists of ten days to two weeks of a regimen of effective antibiotics, such as amoxicillin, tetracycline (not to be used for children <12 years), metronidazole, or clarithromycin, plus either ranitidine bismuth citrate, bismuth subsalicylate, or a proton pump inhibitor.¹⁰³ Acid suppression by the H₂ blocker or proton pump inhibitor therapy in conjunction with the antibiotics helps alleviate abdominal pain and nausea, heal gastric mucosal inflammation, and enhance antibiotic efficacy against *H. pylori* at the gastric mucosal surface.

Legionella pneumophila

Introduction

The research so far has identified more than 30 species and at least 14 serogroups of *Legionella pneumophila*. The most common strain responsible for more than 90% of known infections is the Pontiac sub-type (MAB2).¹⁰⁴ The *Legionella* species have often been observed to inhabit soil, rivers, and lakes. These organisms can colonize man-made water handling and storage systems. *Legionella* are often observed to inhabit cooling towers, evaporative condensers, showers, water storage, distribution systems, and other aquatic systems such as whirlpool spa baths.¹⁰⁴ *L. pneumophila* was shown to grow intracellularly in amoebae, like *Acanthamoeba*, *Hartmannella*, *Valkampfia*, and *Naegleria* spp., and in other protozoa, like ciliates of the *Tetrahymena pyriformis* group.^{105–110} Not only do these hosts provide nutrients for *Legionella* organisms, they also protect them from adverse environmental conditions.¹¹¹ Legionellosis has two distinct presentations: legionnaire's disease, the more severe form of infection, which includes severe pneumonia; and Pontiac fever, a flu-like illness without associated pneumonia.¹¹¹

Clinical symptoms

Common symptoms include pneumonia with fever, chills, cough with variable sputum, prominent myalgias, headache, tiredness, loss of appetite, and diarrhea.^{94,103} Persons with Pontiac fever experience fever and myalgias, but do not have pneumonia. They generally recover in 2–5 days without treatment. Incubation periods for legionnaire's disease and for Pontiac fever are 2–10 days, and 5–66 hours, respectively.¹⁰³

Mode of transmission

Legionella spp. have often been observed to be associated with cold and hot water distribution systems, heaters, pools, and spas.¹¹¹ Persons may be exposed to these mists in homes, workplaces, hospitals, or public places. Legionellosis is not passed from person to person,¹⁰³ and there is no evidence of persons becoming infected from auto air conditioners or household window air-conditioning units.

Control measures

High dose erythromycin is the antibiotic currently recommended for treating persons with legionnaire's disease. In severe cases, a second drug, rifampin, may be added. Other drugs such as newer macrolides, clarithromycin, and azithromycin are also found to be effective.¹⁰³ Pontiac fever typically has a self-limited course, even without treatment. Improved design and maintenance of cooling towers and plumbing systems to limit the growth and spread of *Legionella* organisms are the foundations of legionellosis prevention.

Leptospira

Introduction

Leptospire are obligate aerobes that may be stained using carbol fuchsin counterstain. They produce both catalase and oxidase and have an optimum growth temperature of 28–30 degrees C. These tightly coiled, thin, flexible spirochetes are 5–15 µm long with very fine spirals 0.1–0.2 µm wide.⁹⁴ One end of the microbe is often bent into a distinctive hook and there are two internally located flagellar bundles for translational motility. Leptospirosis is a zoonosis of ubiquitous distribution, caused by infection with pathogenic *Leptospira* species passed in animal urine. The complex taxonomy of leptospire, previously based on serology, has been modified by genotypic classification.¹¹²

Clinical symptoms

Leptospirosis is particularly common in tropical regions. The spectrum of human leptospirosis ranges from subclinical infection to a severe syndrome of multi-organ infection with high mortality (Weil's disease). The incubation period ranges from four to 19 days.⁹⁵ Disease can develop in two phases: the first acute phase lasts about a week and includes fever, chills, headache, myalgias, vomiting, diarrhea, and occasionally skin rash. The second or immune phase produces antibody response and shedding of *Leptospira*.¹¹³ Other symptoms may include aseptic meningitis, with intense headache, stiff neck, and pleocytosis in the cerebrospinal fluid.¹¹⁴ Uveitis is a well-known late complication of systemic leptospirosis.

Mode of transmission

Rats, mice, wild rodents, dogs, swine, and cattle have been identified as the primary sources of zoonotic *Leptospira* infection, passing it through urine. *Leptospira* is ingested with contaminated food or water or can enter through skin lesions and mucous membranes.¹¹⁴ Transmission can occur

through contact with contaminated water, moist soil, vegetation, animals, or urine.¹⁰³ US military personnel serving in tropical regions are at risk for infection.¹¹²

Control measures

The epidemiology of leptospirosis is influenced by changes in animal husbandry, climate, and human behavior.¹¹² Once contracted by a person, the treatment of choice is antibiotic therapy (doxycycline, penicillin or tetracycline).⁹⁴ Control consists of preventing exposure to potentially contaminated water and reducing contamination by rodent control.

Plesiomonas shigelloides

Introduction

Plesiomonas shigelloides is a ubiquitous, facultatively anaerobic gram-negative rod with a polar flagellum. It is found in wells and unfiltered, untreated surface water. *P. shigelloides* is most common in tropical and subtropical areas. Most isolates from humans have been from stool cultures of patients with diarrhea. *P. shigelloides* grows on the differential media used to isolate *Salmonella* and *Shigella* from stool specimens. Some *Plesiomonas* strains share antigens with *Shigella sonnei*, so cross-reactions with *Shigella* A and C antisera do occur.⁹⁴

Clinical symptoms

Symptoms usually occur within 48 hours of exposure. *P. shigelloides* produces self-limited diarrhea with blood or mucus, abdominal cramps, and vomiting or fever.¹¹⁵

Mode of transmission

Plesiomonas shigelloides is transmitted by drinking or preparing food with untreated water, eating uncooked shellfish, or traveling to developing countries.^{116–118} It has been isolated from freshwater fish and this has been postulated as a source of transmission as well.¹¹⁹

Control measures

Routine testing for total fecal coliform bacteria, turbidity, and chlorine residual may enable early detection of fecal contamination and rapid decontamination. Disinfection with chlorine and filtration of potable water systems have substantially reduced waterborne outbreaks and subsequent morbidity and mortality. Agricultural runoff should not be used for drinking or food preparation.

Pseudomonas aeruginosa

Introduction

Pseudomonads are gram-negative, motile, aerobic rods, some of which produce water-soluble pigments. They are ubiquitous in soil, water, plants, animals, and moist environments such as hospitals.⁹⁴ Of the two million nosocomial infections in the US each year, 10% are caused by *P. aeruginosa*.¹²⁰ It is a common cause of pneumonia in inten-

sive care unit (ICU) settings. *Pseudomonas* infections can be spread within hospitals by healthcare workers, medical equipment, sinks, disinfectant solutions, and food.¹²⁰ Multidrug-resistant (MDR) *Pseudomonas aeruginosa* infection has been widely described in cystic fibrosis patients; some hospital units have MDR *P. aeruginosa* rates as high as 40%.¹²¹ MDR *P. aeruginosa* occurs in isolated outbreaks in intensive care units, hematologic units, and among immunocompromised patients, including oncology and HIV patients.¹²¹ *Pseudomonas aeruginosa* is both a frank pathogen and an opportunist, dependent almost entirely on the host susceptibility.

Clinical symptoms

P. aeruginosa infects skin, soft tissues, urinary tracts, eyes, ear, central nervous system, bones, joints, heart, and lung. Infection causes a similarly large range of symptoms, consistent with bacteremia: fever, inflammation, rash, myalgias, swelling, and other organ-specific symptoms (e.g., respiratory symptoms of dyspnea and cough). Wounds and burns can give rise to meningitis through hematogenous spread. *P. aeruginosa* invasion of the blood stream can lead to fatal sepsis. Hemorrhagic necrosis of skin (ecthyma gangrenosum) occurs often in sepsis due to *P. aeruginosa*. *P. aeruginosa* exotoxin A causes tissue necrosis that can be lethal.⁹⁴

Mode of transmission

Pseudomonas is primarily a nosocomial pathogen, and it may be passed person to person or environmentally. The organism thrives in moist environments, including sinks, water baths, showers, hot tubs, and other wet areas.⁹⁴ It may be indigenous to water supplies or distribution systems if chlorine residuals are inadequate, or if water in long runs of distribution pipe is inadequately circulated.

Susceptibility and resistance

The most active antimicrobial agent against *P. aeruginosa* isolates is amikacin, in a study of 10,361 isolates at centers in the United States during 1995–2000.¹²² It is important to assess sensitivities given the toxicity of aminoglycoside therapy. MDR *P. aeruginosa* and some other pseudomonads may be non-responsive to ciprofloxacin, ceftazidime, imipenem, gentamicin, and piperacillin.¹²¹ Three-drug combinations are sometimes the only effective treatment.

Control measures

Pseudomonas infections should not be treated with single-drug therapy, as the bacteriocidal response rate is low with such therapy, and organisms can rapidly develop resistance for a single drug.

Shigella sonnei

Introduction

Shigella are gram-negative, non-motile, non-spore forming rod-shaped bacteria. Approximately 18,000 cases of shigellosis are reported in the United States every year.¹²³ *Shigella*

sonnei (serogroup D) accounts for two-thirds of these. *Shigella sonnei* may be differentiated from the other *Shigellae*; however, the other species cannot be separated without serotyping, including *Shigella dysenteriae* (serogroup A), *Shigella flexneri* (B), and *Shigella boydii* (C).¹²⁴ In the CDC surveillance period 1991–2000, approximately 1700 people in the US developed shigellosis infection; one-third of these were due to contaminated drinking water and the remainder were associated with recreational water sources. Shigellosis accounts for less than 10% of the reported outbreaks of foodborne illness in the USA, and is frequently found in water polluted with human feces.

Clinical symptoms

Shigellosis involves the large and distal small intestine, and is characterized by diarrhea, fever, vomiting, stomach cramps, occasional toxemia, and tenesmus. Illness can be self-limited, and in some cases only a watery diarrhea occurs. More frequently, stools contain blood and mucus (dysentery) as a result of mucosal ulceration and confluent colonic crypt microabscesses. The incubation period ranges between 12 hours to one week, and lasts for about 4–7 days. Convulsions are an important complication in young children.⁹⁵

Mode of transmission

Direct or indirect fecal–oral transfer is the primary route of transmission. Flies can facilitate transmission of the pathogen from feces to food. Drinking or swimming in contaminated water is another form of transmission.⁹⁵

Susceptibility and resistance

A recent retrospective study found that most *Shigella* isolates are susceptible to ceftriaxone, ciprofloxacin, and gentamicin, but resistant to ampicillin and trimethoprim-sulfamethoxazole.¹²⁵

Control measures

Improved hygiene in food handling, bathing in hot springs, and chlorine disinfection of potable water systems will reduce person-to-person transmission, outbreaks, and subsequent morbidity and mortality.

Salmonella typhimurium

Introduction

There are numerous pathogenic serotypes of *Salmonella*, although *Salmonella typhimurium* and *salmonella enteritidis* are the most common serotypes in the United States.¹²³ The vast majority of the more than 2500 serovars belong to one species: *S. enterica* (formerly *choleraesuis*¹²⁴). *Salmonella* infections are common throughout the world. The incidence rate is highest in infants and young children. About 60–80% of cases are sporadic, though large outbreaks can be associated with hospitals, restaurants, and institutional settings, including nursing homes and orphanages. The common reservoirs of salmonellosis are domestic and wild animals, including poultry and fowl (including eggs),

swine, cattle, rodents, and pets such as iguanas, tortoises, turtles, terrapins, chicks, dogs, and cats. Mild and asymptomatic human cases can also act as a carrier.¹²⁶

Clinical symptoms

The typical clinical symptoms include frequent fever, headache, abdominal pain, diarrhea, nausea, and vomiting. Severe dehydration frequently occurs in elderly and infant cases. Anorexia and diarrhea may be experienced for several days. Septicemia and focal infection can develop as the illness progresses beyond the phase of acute enterocolitis,⁹⁵ including septic arthritis, cholecystitis, endocarditis, meningitis, pericarditis, pneumonia, pyoderma, pyelonephritis, and tissue abscesses. The incubation period ranges from six to 72 hours, with a median of 12–36 hours. An exposure dose of 100–1000 organisms is generally required, although for some highly virulent strains the infectious dose (ID) is thought to be as few as ten organisms.⁹⁵ A temporary carrier state is often observed for months in infants.

Mode of transmission

Salmonella inhabit the intestinal tracts of humans, animals, and birds, therefore the fecal–oral route is the most common. This is often mediated by water and food.

Susceptibility and resistance

HIV infected persons are at a higher risk of non-typhoidal *Salmonella* septicemia.

Control measures

Measures that will help reduce the risk of *Salmonella* transmission include pasteurization of milk, treatment of municipal water supplies, improvements in farm and animal hygiene, and wider use of egg pasteurization.¹²³

Campylobacter jejuni

Introduction

Campylobacter jejuni belongs to the group of spiral shaped bacteria. Ninety-nine percent of the human illnesses of campylobacteriosis are caused by *Campylobacter jejuni*.¹²⁷ The common reservoirs for the pathogen are poultry, cattle, puppies, kittens, other pets, swine, sheep, rodents, and birds.¹²⁸ *Campylobacter* grows best at the body temperature of birds (40–42 degrees C), but some important species (e.g., *C. jejuni* var. doyle) will not grow at 42 degrees C, but rather at 37 degrees C.¹²⁹

Foodborne campylobacteriosis is more common than waterborne campylobacteriosis. A waterborne outbreak at the Washington County Fair in New York in 1999 is one of the significant outbreaks of *Campylobacter jejuni*, where a total of 781 cases were identified in conjunction with *E. coli* O157:H7.¹³⁰

Over the period of 1991–2000, a total of five outbreaks affecting 340 people, and one outbreak affecting six people, were reported in association with drinking water and recreational water, respectively.^{9–13}

Clinical symptoms

Campylobacteriosis is characterized by diarrhea, cramps, abdominal pain, and fever. The stools may be bloody, with mucus and WBCs in diarrheal stools. Occult blood can also be observed in the stools. A typhoid-like syndrome, with reactive arthritis, febrile convulsions, Guillain-Barré syndrome, and meningitis can also occur.¹²⁷ Severe gastroenteritis may mimic acute appendicitis. The onset of illness is usually observed between 2–5 days after exposure, though it can range between 1–10 days. Clinical illness usually lasts 2–5 days but in prolonged cases may last up to ten days.¹³¹

Mode of transmission

Birds, especially chicken flocks, are the most common reservoir of the pathogen. The organism is easily spread from bird to bird through a common water source or contact with the infected feces.¹³¹ Primarily transmission can occur by handling raw poultry, or eating raw or undercooked poultry meat. Previous studies have reported that larger outbreaks are associated with drinking unpasteurized milk or contaminated water.¹²⁷ Infection can also be facilitated by contact with stools of an infected animal.

Susceptibility and resistance

The organism cannot survive drying, and tolerates poorly an oxygen-rich environment.

Control measures

Simple prevention measures can help control *Campylobacter jejuni* transmission, including avoiding consumption of uncooked meat or consumption of unpasteurized milk and untreated surface water.

Mycobacteria

Introduction

Mycobacteria are rod-shaped, non-spore forming, aerobic bacilli with thick, multi-layered lipid-rich walls. Mycobacteria are fastidious extracellular bacteria requiring special culture conditions, supplemented media, and prolonged incubation time. Nonetheless, they cause disease in a wide variety of vertebrates, including humans, livestock, birds, and fish. A number of *Mycobacterium* species are waterborne, including but not limited to *Mycobacterium avium*, *Mycobacterium intracellulare*, *Mycobacterium scrofulaceum*, *Mycobacterium marinum*, and *Mycobacterium chelonae*. *Mycobacterium avium* and *Mycobacterium intracellulare* grow in natural water sources and drinking water over a temperature range of 10–45 degrees C.¹³² Mycobacteria species may be both saprophytic and pathogenic. Their growth rates are much slower than those of most other bacteria.

Clinical symptoms

Symptoms depend on the route of infection. In respiratory infection, symptoms include those associated with pneu-

monia as well as wheeze, bronchitis, and asthma.¹³³ Cutaneous infection results in granulomatous lesions of the skin.⁵³

Mode of transmission

Cell surface hydrophobicity permits adherence to solid substrates (e.g., pipes or leaves) in aquatic environments, which results in Mycobacteria's persistence and resistance to being washed away.¹³³ Mycobacteria can colonize dental units and drinking water sources. Pulmonary illness and infection have been a consequence of exposure to aerosols generated by hot tubs, spas, and coolant baths, including hypersensitivity pneumonitis in occupants of water-damaged buildings, swimming pool attendants, and workers exposed to metal working fluid.

Susceptibility and resistance

Immunocompromised individuals and the elderly are particularly susceptible to mycobacterial infection.

Control measures

Mycobacterium are very resistant to the disinfectants used in water treatment, including chlorine and ozone.¹³³ Water filtration removes particulates that carry Mycobacteria; their numbers can be reduced using UV light or high temperatures (e.g., 40 degrees C), surfactants, or detergent-like disinfectants.

Vibrio cholerae

Introduction

Vibrio species are among the most common bacteria in surface waters worldwide. They are curved, gram-negative, aerobic rods, and are motile, possessing a polar flagellum. They do not form spores. *Vibrio cholerae* serogroup O1 and related Vibrio species cause cholera in humans, while other Vibrio species may cause sepsis or enteritis. Vibrio species are members of the family Enterobacteriaceae, including the medically important species *V. cholerae* serogroup O1, *V. cholerae* serogroup non-O1, *V. parahaemolyticus*, *V. mimicus*, *V. vulnificus*, *V. hofisae*, *V. fluvialis*, *V. damsela*, *V. alginolyticus*, and *V. metschnikovii*.⁹⁴

Clinical symptoms

After an incubation period of less than a day to five days, depending on size of the inoculum,¹³⁴ there is a sudden onset of nausea and vomiting accompanied by profuse diarrhea with abdominal cramps. The stools resemble 'rice water' and contain mucus, epithelial cells, and large numbers of Vibrio bacteria. There is rapid loss of fluid and electrolytes, which leads to profound volume depletion that can lead to circulatory collapse, and anuria. The mortality rate without treatment is 25–50% in some epidemics.^{135,136}

Mode of transmission

Worldwide epidemics of cholera occurred in the 1800s and early 1900s. The 'classic' biotype was prevalent through

the early 1960s; the El Tor biotype, discovered in 1905, became prevalent in the late 1960s and has caused pandemic disease in Asia, the Middle East, and Africa.⁹⁴ The disease has been rare in North America since the mid-1800s, but an endemic focus may exist on the Gulf Coast of Louisiana and Texas.⁹⁴ From the endemic areas, the disease can be carried along shipping lanes, trade routes, and migration routes, and spread by individuals with mild or early illness and by water, food, flies, and person-to-person contact. The carrier state seldom exceeds 3–4 weeks, and true chronic carriers are rare. *Vibrio* species survive in water for up to three weeks.⁹⁴

Therapy

The most important part of therapy consists of water and electrolyte replacement to correct the severe volume and electrolyte depletion. Many antimicrobial agents are effective against *V. cholerae*. Oral tetracycline tends to reduce stool output in cholera and shortens the period of excretion of bacteria.⁹⁴

WATERBORNE VIRAL PATHOGENS

Waterborne viruses are present in large numbers in a variety of marine environments.^{137,138} Exposure to waterborne viruses may occur by drinking or recreational use of contaminated water, or following the consumption of improperly cooked marine or freshwater molluscs, which capture and concentrate viruses and other pathogens. Additionally, contaminated natural water or inadequately treated human or animal sewage can be put to agricultural use, exposing workers, crops and, potentially, consumers to waterborne viral pathogens. The diseases associated with waterborne viruses include acute gastroenteritis, hepatitis, conjunctivitis, acute respiratory disease, and meningitis.

Since viruses are at least an order of magnitude smaller than bacteria or protozoa and many are structurally and biochemically distinct, methods that rely on bacterial indicators, such as the coliform count, do not detect or enumerate viruses in samples of treated water accurately.¹³⁹ Newer methods, such as the use of bacteriophage indicators, quantitative PCR, and outgrowth on mammalian cell culture, are considered to be more reliable.

Waterborne viruses have properties that determine their distribution and stability in the environment, as well as the methods required to detect, enumerate, and purify them from contaminated water. First, waterborne viruses possess a capsid consisting primarily of protein subunits fitting together to form a structure with higher order symmetry. The capsid makes these viruses extremely resistant to non-ionic detergents, compared to enveloped viruses, which derive their outer layer from a biologic membrane of their host cell. Second, the genetic material of waterborne viruses, unlike bacteria or protozoa, may consist of single- or double-stranded forms of DNA or RNA. Molecular methods used to detect the presence of viruses in water samples commonly rely on PCR, which utilizes a

thermostable DNA polymerase. Because this enzyme amplifies DNA, but not RNA molecules, viruses with RNA genomes must first be converted to a DNA copy. This is often accomplished with an RNA-dependent DNA polymerase (reverse transcriptase), although a new polymerase capable of both activities is available commercially.

This section will focus on six virus families that pose health hazards to humans, and are known to be present in untreated and treated waters. The virology, clinical, and epidemiologic manifestations of the diseases and methods of detection in water are discussed below.

Adenovirus

Introduction

The Adenovirus (Ad) family includes more than 50 distinct types producing respiratory, ophthalmic, and enteric syndromes in humans. The Ad DNA genome is complex, encoding numerous polypeptides, and variation in gene content may explain the tissue tropism and biologic character distinguishing these Ad types.

Clinical symptoms

Waterborne adenoviruses of medical and public health importance lead to cases of conjunctivitis and gastroenteritis. Human adenovirus of types 3, 4, and 7 are commonly responsible for adenoviral hemorrhagic conjunctivitis (AHC), identified by the presence of small subconjunctival hemorrhages, inflammation of the corneal epithelium and upper respiratory disease. AHC appears 4–12 days (average eight days) following exposure. Infections with Ad types 8, 19, or 37 can lead to epidemic keratoconjunctivitis (EKC) 5–12 days following exposure. Other Ad types have also been linked to both AHC and EKC. Enteric Ads of types 40 and 41 are associated with cases of acute gastrointestinal disease, typically in children less than four years old and immunocompromised individuals. Symptoms typically appear in 8–10 days, and may last 1–2 weeks. Outbreaks are commonly set in daycare centers, hospitals, and nursing homes, and particularly affect immunocompromised individuals.¹⁴⁰

Transmission

Although Ad conjunctivitis is often due to direct or indirect contact with eye discharge, outbreaks have been linked to inadequately chlorinated swimming pools or inadequate disinfection of eye washing stations in work settings, and ophthalmic solutions in physician offices. Enteric Ad infections are typically transmitted via the fecal–oral route. Enteric Ads are often found in natural and treated water samples, and the presence of Ad is not correlated with bacterial indicator organisms.^{141–143}

Detection

A variety of diagnostic methods are typically used to detect and type adenovirus infections, including direct visualization by electron microscopy, serum neutralization, immunologic methods (immune fluorescence, enzyme linked immunoassay, and hemagglutination inhibition assay), virus

isolation on permissive cell lines and PCR-restriction fragment length polymorphism. The latter two methods are useful for detection of Ads in environmental samples.

Control and prevention

Outbreaks of AHC and EKC can be prevented by assuring the sterility of instruments and hands contacting the conjunctiva (with systemic sterilization or the use of disposable equipment and gloves). Maintaining the proper concentration of free chlorine in swimming pools will prevent transmission of adenovirus in swimming pools. Adenoviral vaccines are not available in the US.

Calicivirus

Introduction

The Calicivirus family consists of encapsidated RNA viruses that were once described as 'small, round structured viruses', because of their uniform size and shape when viewed by electron microscopy. Two Calicivirus subgroups are currently believed to infect humans: Sapovirus (formerly 'Sapporo-like virus') and Norovirus (formerly 'Norwalk-like virus').

Clinical symptoms

Noroviruses are a very common cause of acute non-bacterial gastroenteritis in the developed world. Symptoms, which include acute-onset nausea and vomiting, watery non-bloody diarrhea with abdominal cramps, fever, myalgias, appear 24–48 hours following exposure and last 24–60 hours.

Mode of transmission

Outbreaks often occur when large groups are exposed to a common source of infection, which could be contact with an infected individual, contaminated food, or water. Fecal–oral transmission is undoubtedly important, but other routes, such as inhalation of aerosolized virus¹⁴⁴ or ingestion of virus attached to objects or surfaces, are likely. Water plays an important role in the transmission of viruses during outbreaks, as well as sporadic cases. Although few studies have definitively demonstrated the presence of Calicivirus in natural and treated waters, exposure to water has been independently associated with infection during outbreaks,^{145–148} and virus, often having a nucleic acid sequence identical to virus shed by cases, has been isolated from water sources implicated in some outbreaks.^{145,149,150} The settings for Calicivirus outbreaks have been restaurants, hospitals, cruise ships, vacation resorts, schools, concerts, and nursing homes.^{149,151–153} Unlike many other gastroenteritis viruses, Calicivirus infects individuals of all ages, and adults are often associated with outbreaks. This suggests that virus-specific immunity is short-lived or unable to cross-neutralize viral variants.⁴⁴

Detection

The use of electron microscopy and serology to diagnose Calicivirus infections is being replaced by tests using RT-

PCR amplification of viral genomes extracted from stool or environmental samples. The nucleic acid sequence of genes amplified using these tests can be determined and compared to sequences obtained from environmental specimens to link cases and potential sources or vectors.

Prevention and control

Fastidious hygienic measures, including frequent hand washing, will prevent many cases. However, because virus may be present in aerosol and is stable in the environment, outbreak sites should be thoroughly cleaned to prevent further transmission. Shellfish, which often contains Caliciviruses, should be thoroughly cooked

Picornaviruses

Introduction

The Picornavirus family includes waterborne pathogens of medical and public health importance, including Enteroviruses (including the viruses that cause poliomyelitis), as well as hepatitis A virus. Picornaviruses are characterized by a small proteinaceous capsid enclosing a positive-sense RNA genome. The genetic organization of the picornaviral genome is similar, but nucleic acid sequences can be quite diverse.

Clinical symptoms

Important waterborne enteroviruses include coxsackieviruses and poliovirus. Multiple *Coxsackievirus* serotypes are responsible for transient cases of pharyngitis and myalgia as well as diseases with long-lasting sequelae including myocarditis, meningitis, and perhaps insulin-dependent diabetes. Rare cases of acute flaccid paralysis (AFP) are still caused by *Poliovirus*, although this virus is a target for worldwide eradication. Incubation periods for enterovirus infection range from 3–5 days for *Coxsackievirus* pharyngitis, to 3–31 days for poliovirus AFP. Enteroviruses may persist in the stool for several weeks following infection. Hepatitis A virus (HAV) causes significant food- or waterborne outbreaks throughout the world. The disease is characterized by symptoms, including jaundice, dark urine, fever, anorexia, abdominal pain, and malaise, that appear 15–50 days after exposure. Symptoms can last from 1–2 weeks to several months, and virus is shed to the stool for 1–3 weeks after exposure, often before the onset of illness. The HAV mortality rate is very low, but infection can be lethal, especially in the elderly and individuals with chronic liver disease.

Mode of transmission

Waterborne picornaviruses are commonly identified in samples of natural waters as well as waste water samples,^{154–160} and exposure to recreational water or marine molluscs has been epidemiologically linked to some outbreaks,^{161,162} especially in the case of hepatitis A.^{163,164} Fecal–oral transmission is commonly observed with HAV, and common source outbreaks are often associated with contaminated food or water, or through an infected food handler. Because of the extraordinary heat and pH stability

demonstrated by the virus, even cooked items may be a source of infection. For example, HAV infectivity is partially retained in shellfish heated to 60 degrees C for one hour.¹⁶⁵ Other transmission routes may be epidemiologically important, including direct contact (via hands or fomites), sexual contact, and blood transfusion.

Detection

Picornaviruses may be detected by isolation in permissive cell culture and suckling mice. Serologic methods (virus neutralization, IgG and IgM ELISA) may be used to diagnose polio or HAV infection in unvaccinated individuals. RT-PCR and sequence analysis of amplified genes may be used to detect virus in the environment and among cases, and is an invaluable tool for tracing outbreaks

Control and prevention

Good personal hygiene practices are necessary to prevent fecal–oral transmission, as is access to clean water in developing nations. Food- and waterborne HAV can be destroyed by thorough cooking. Shellfish should be heated to 85–90 degrees C (185–194 degrees F) for four minutes, or steamed for 90 seconds prior to eating. Inactivated and attenuated (oral) poliovirus vaccines form the basis of a worldwide campaign to eradicate this virus. An inactivated HAV vaccine is available and highly effective even after a single dose, but is not routinely recommended for children less than two years of age, or for older children and adults in low-risk populations. HAV immunoglobulin (Ig) can prevent clinical symptoms if given within two weeks of exposure.

The presence of oral poliovirus vaccine (OPV) in water samples is an important issue in nations that are using OPV to eradicate AFP because OPV is capable of reverting to virulence and, in some documented instances, causing outbreaks.^{166,167}

Hepatitis E

Introduction

Hepatitis E virus (HEV) is not assigned to a family, but these viruses, which consist of a positive-sense RNA genome enclosed within a compact, proteinaceous capsid, share genetic and morphologic characteristics with Caliciviruses and the Rubella virus family.

Clinical symptoms

Infection leads to a clinical disease similar to that caused by HAV, including a long (15–60 days) incubation period, and the presence of infectious virus in blood and stool prior to the appearance of symptoms. During outbreaks, symptoms are more common among older individuals. Mortality is generally low, except among women in their third trimester of pregnancy, where the case-fatality rate is about 20%.

Mode of transmission

The disease is endemic and outbreaks are common in developing countries in South Asia, North Africa, the Middle East, and Mexico, and especially in regions with

poor sanitation infrastructure. HEV outbreaks are primarily linked to fecally contaminated water, although other transmission routes including food or infected food handlers have been observed. Household-based secondary transmission is rare.¹⁶⁸ In the industrialized nations, infection is usually confined to individuals traveling in endemic regions. Exposure estimates based on serologic surveys may be confounded by cross-reaction,¹⁶⁹ with related virus circulating in swine and other animals. The capacity of these viruses to cause human disease is currently under investigation, but they have not been linked to large disease outbreaks. Fecally contaminated water has been identified as an important HEV transmission route in epidemiologic investigations.^{170–172} This predilection to waterborne transmission is underscored by surveys identifying HEV nucleic acid in samples of sewage, as well as natural and treated water collected throughout the world.^{159,173,174} The public health significance of sewageborne HEV-like viruses remains to be determined.

Detection

HEV infection is usually confirmed by serologic identification of circulating IgM and IgG, or the presence of viral RNA in blood or stool by RT-PCR, tests which are not routinely available in the USA.

Prevention and control

Travelers to endemic areas of the world should be educated about precautions to prevent the acquisition of food and waterborne diseases, including HEV. This is especially true for women in the third trimester of pregnancy. Proper sanitation infrastructure is needed to control outbreaks in developing nations. HEV-specific therapy and vaccination are not available.

Rotavirus

Introduction

Rotavirus, an encapsidated, multisegmented double-stranded RNA virus belonging to the Reovirus family, is a common cause of severe gastroenteritis in children throughout the world. Rotavirus isolates are serologically distinguished into six groups, three (groups A, B, and C) of which appear to cause human disease. Rotaviruses have been isolated from animals, but zoonotic transmission does not occur.

Clinical symptoms

The virus induces a typical gastroenteritis, characterized by vomiting, watery diarrhea, and fever, 1–3 days after exposure. Symptoms may last 4–6 days, during which the patient excretes virus into stool. In most cases, prolonged excretion is not observed.

Mode of transmission

Rotavirus transmission is primarily through fecally contaminated food and water or contact with contaminated

surfaces, although the presence of virus in respiratory secretions may allow air-borne transmission. Most cases of symptomatic disease are found among children less than five years old. However, a large serogroup B rotavirus outbreak on mainland China affected mostly adults,¹⁷⁵ and there is evidence that adult Rotavirus gastroenteritis, caused by genotype G2 variant of a serogroup A virus, is the cause of some outbreaks in the USA.¹⁷⁶ The presence and stability of Rotavirus in a variety of natural and treated water^{177–179} accounts for the epidemiologic importance of waterborne virus transmission.^{160,180} However, it was not detected in two recent surveys of ground water in the USA.^{181,182}

Detection

Infected individuals are usually identified by the demonstration of viral antigen in stool using an enzyme-linked immunoassay (ELISA), and may be confirmed with additional tests, including RT-PCR amplification of viral nucleic acid from stool.

Prevention and control

Since virus can survive for long periods on contaminated surfaces and in water, hygienic measures designed to prevent fecal–oral transmission may not be effective. Breastfeeding does not prevent infection, but significantly reduces the severity of diarrhea. A Rotavirus vaccine is currently not available in the USA.

Astrovirus

Introduction

Astrovirus are encapsidated, single-stranded, positive-sense RNA viruses that were first identified in 1975.¹⁸³ They have a star-like appearance when viewed by electron microscopy.

Clinical symptoms

Acute gastroenteritis caused by Astrovirus infection has a typical presentation, and is usually found in children throughout the world.^{184–186} Adult infection is rarely observed, although outbreaks have occurred among the elderly residents of nursing homes. The importance of Astrovirus infection is probably under-recognized in the USA due to the lack of diagnostic capacity.

Mode of transmission

The primary mode of transmission is probably fecal–oral, although the stability of the virus may allow it to survive on and be transmitted by inanimate objects.¹⁸⁷

Detection

The potential detection methodologies employed include EIA and RT-PCR.^{184,186,187}

Prevention and control

Like Rotavirus, hygienic measures designed to prevent fecal–oral transmission may not be effective.

Other/emerging waterborne viruses

Other viruses linked to human disease and present in natural or treated waters include Circovirus, Torovirus, Picobirnavirus, and the Aichi virus, a newly identified member of the Picornavirus family.¹⁸⁸ Additionally, Caliciviruses associated with marine mammals are believed to be the source of land-based zoonoses.¹⁸⁹ The epidemiologic strength and public health importance of these associations remain to be determined.

WATERBORNE EUKARYOTIC PATHOGENS

Eukaryotes are living cells with organelles, including nuclei that contain the genetic material. They are generally large enough to be easily seen with a light microscope, and include protozoans, helminths, and fungi. The protozoans *Cryptosporidium parvum* and *Giardia intestinalis* are notifiable disease agents, requiring the notification of state public health physicians when they are found in patients.

Single-celled protozoan parasites typically have complex life cycles with specific intermediate host requirements. Most have at least two developmental forms: the vegetative ‘trophozoite’ and the cyst that can survive under adverse environmental conditions. Humans are host to nearly 300 species of parasitic worm and over 70 species of protozoa.¹⁹⁰ Protozoa come in all sizes; those that are best understood are much larger than bacteria, some even visible without a microscope. Protozoa often live freely in water, although parasites may prefer a host organism or may even be unable to reproduce in the environment.

Acanthamoeba

Introduction

Acanthamoeba is one of the protozoan Amoebozoa parasites. It is found in most water, including fresh, brackish, sea, tap, bottled mineral, sewage, gastrointestinal washings, contact lens solution, and eyewash station water; it is also found in hot tubs, soil, dust, and air, and in heating, air-conditioning, ventilation, humidifiers, dialysis, and dental units.^{191–194} *Acanthamoeba* has been cultured from the upper airways of apparently healthy people and may be part of the normal flora. It is one of several ameboid eukaryotic lineages that undergoes slow gliding movements (others include *Hartmannella*, *Valkampfia*, and *Naegleria*).¹¹¹ *Acanthamoeba* may be free-living, parasitic, or opportunistic. In response to dry or cold environmental conditions, the motile trophozoite transforms into the cyst, protected and easily distributed throughout the environment. Cysts survive in water, soil, and dust for a year, unaffected by freezing, many chemicals, and some medications used to treat the vegetative forms.

Keratitis and pneumonitis are the principal water-related syndromes caused by *Acanthamoeba* spp.^{192,195–199}

Swimmers and diving activities in natural waters may offer an exposure route. In immunocompromised hosts, *Acanthamoeba* species also produce granulomatous amebic encephalitis, a chronic central nervous system disease.²⁰⁰ Some sources cite the lower respiratory tract as one possible route of invasion, through the inhalation of cysts from air, aerosols, or dust. Another route may be via skin infections.^{192,196,199,201}

Acanthamoeba may serve as a vector for pathogenic bacteria because it is host to *Legionella pneumophila*, *Vibrio cholerae*, *Mycobacterium avium*, and emerging pathogens, such as *Parachlamydia* and *Simkania*.^{202,203} These endosymbionts can enhance *Acanthamoeba* virulence or behave as pathogens on their own. The *Parachlamydia* strain Hall's coccus, for example, is transmitted by these amebae and was associated with fever in patients who used humidifiers in Vermont.^{204,205} *Acanthamoeba* hosts *L. pneumophila* and carries it in the cysts; *Mycobacterium avium* grows saprozoically on products secreted by *Acanthamoeba* and is found in the outer walls of the double-walled cysts.²⁰⁶ Cysts may provide a reservoir for the bacteria when environmental conditions become unfavorable.

Clinical symptoms

Wearers of contact lenses (hard, soft, or extended wear lenses) may develop keratitis, which is a sensation of a foreign body in the eye, tearing, blurred vision, photophobia, blepharospasm, and swelling of the upper eyelid. Keratitis can progress to corneal abscess; severe pain may imply a deep, long-standing infection, chronic ulceration of the corneal epithelium, and eventual loss of vision. Non-specific symptoms may be falsely diagnosed as herpes simplex keratitis, herpes zoster, fungal, and bacterial infection.²⁰⁷

Mode of transmission

Acanthamoeba has been found in the upper respiratory tract of healthy people as well as people with compromised immune systems. Most episodes of keratitis follow water exposure, such as a history of swimming in lakes and ponds while wearing contact lenses.^{196,199} *Acanthamoeba* infections are also linked to non-sterile home-made saline solutions for contact lenses.¹⁹⁹ *Acanthamoeba* enters skin or membranes through a cut or wound, or through the nostrils. Once inside the body, it can travel to the lungs and through the blood stream to other parts of the body, especially the central nervous system.

Susceptibility and resistance

Acanthamoeba is resistant to most commonly used antibacterial, antifungal, antiprotozoal, and antiviral agents. Some patients have been successfully treated using ketoconazole, miconazole, and propamidine isethionate.

Control measures

Inhalation of cysts in dust or water can be limited by using a respirator or breathing mask. Eye infection can be limited by adhering to strict contact lens hygiene and cleaning regimens and not wearing lenses in pools, hot tubs, lakes,

rivers, or oceans. *Acanthamoeba* is on the Candidate Contaminant List published by USEPA, and is undergoing consideration for regulation.

Entamoeba histolytica

Introduction

Entamoeba histolytica is one of the intestinal Amebae parasites. In the US, those at risk for amebiasis due to *E. histolytica* include travelers, immigrants, migrant workers, immunocompromised individuals, institutionalized individuals, and sexually active homosexual males.²⁰⁸

Clinical symptoms

The incubation period varies from one to four months. Four major intestinal syndromes are caused by infection: (1) asymptomatic colonization; (2) acute amebic colitis, presenting with lower abdominal pain, bloody stools, and fever; (3) fulminant colitis in children presenting with diffuse abdominal pain, profuse bloody diarrhea, and fever; and (4) ameboma, an asymptomatic lesion or a tender mass accompanied by symptomatic dysentery.²⁰⁹ Parasites can become disseminated and cause fatal disease.

Mode of transmission

E. histolytica infects people worldwide. Transmission in water is common in developing countries, where human feces is sometimes used for fertilizer.²⁰⁸

Susceptibility and resistance

Metronidazole, chloroquine, and dehydroemetine are effective in the treatment of invasive amebiasis.^{209,210}

Control measures

E. histolytica is controlled by improving hygiene, adequately disposing of fecal waste, and adequately washing fruits and vegetables.

Cryptosporidium parvum

Introduction

Cryptosporidium is a coccidian parasite that is present in large numbers in surface waters and that also lives in the intestines of animals and humans. Its outer shell helps it survive outside the body for long periods of time and makes it highly resistant to chlorine disinfection.²¹¹ *Cryptosporidium parvum* is a common cause of drinking or recreational waterborne disease outbreaks in humans in the United States.²¹¹

Clinical symptoms

Diarrhea, loose or watery stool, and stomach upset caused by *Cryptosporidium parvum* persists for about two weeks. Illness can be accompanied by fever, and the severity of symptoms may increase or subside in cycles. Asymptomatic cases have also been observed.²¹¹

Mode of transmission

Cryptosporidium is transmitted by the fecal–oral route. It is found in soil, food, water, or surfaces contaminated with feces of infected humans or animals. It is acquired by accidental swallowing of water from swimming pools, hot tubs, jacuzzis, fountains, lakes, rivers, springs, ponds, or streams contaminated with feces from infected humans or animals.

Susceptibility and resistance

Cryptosporidium is highly resistant to chlorine and requires high levels and increased contact time for inactivation. *Cryptosporidium* can be viable for days in a swimming pool with public health mandated levels of chlorine.¹³

Control measures

Physical removal of the parasite from water by filtration has become an important component of municipal water treatment systems.²¹² Filters must be capable of removing particles <1 µm to control *Cryptosporidium*.²¹² *Cryptosporidium* is killed by boiling for one minute.²¹²

Cyclospora cayetanensis

Introduction

Cyclospora cayetanensis is a Coccidia parasite previously known as a ‘cyanobacterium-like’ or ‘coccidia-like’ body (CLB). Cyclosporiasis is most common in tropical and subtropical areas. There are many life-cycle variations in the genus *Cyclospora*, so the complete life cycle of *C. cayetanensis* has not been fully described. Infected persons excrete the oocyst stage of *Cyclospora* in their feces. When excreted, oocysts are not infectious and require 5–13 days to sporulate and become infectious.^{211,213} Parasites may be found in the jejunal enterocytes.

Clinical symptoms

Cyclosporiasis onset begins with one day of malaise and low-grade fever, followed by rapid onset of diarrhea.²¹³ Infection is characterized by nausea, anorexia, abdominal cramping, watery diarrhea, constipation, and weight loss.²¹⁴ Symptoms last an average of seven weeks.^{215–217} In AIDS patients, infections tend to last up to four months.²¹⁸

Mode of transmission

Transmission of *Cyclospora* directly from an infected person to someone else is unlikely. Indirect transmission occurs when an infected person contaminates the environment and oocysts have sufficient time in water or food to become infectious.²¹¹

Susceptibility and resistance

Trimethoprim-sulfamethoxazole is an effective treatment for *Cyclospora* infection.²¹¹

Control measures

Avoiding food or water that may be contaminated with stool is the best way to prevent infection. Reinfection can occur.

Giardia intestinalis

Introduction

Giardia is a flagellate parasite that lives in the intestine of infected humans or animals. Giardiasis is the most prevalent waterborne disease in the United States.²¹⁹ The causative agent, *Giardia intestinalis*, was at one time called *Giardia lamblia*. *Giardia* is the most commonly diagnosed intestinal parasite in US public health laboratories.¹² From 1976 to 1994 it was found to be the etiologic agent most frequently associated with drinking water in the US.¹⁹⁷ The cyst is the stage found most commonly in non-diarrheal feces. Cysts are hardy, surviving several months in cold water. Animals may serve as a reservoir in the wild.

Clinical symptoms

A wide range of clinical symptoms are observed with *Giardia* infection, including diarrhea, flatulence, bloating, weight loss, abdominal cramps, nausea, malabsorption, foul smelling stools, steatorrhea, fatigue, anorexia, and chills.¹² The incubation period for giardiasis is 3–25 days.¹² Asymptomatic infections can also be observed.²¹¹ Most children under the age of five have been infected with *Giardia* at least once.⁷⁵

Mode of transmission

The organism is transmitted by a fecal–oral route from person to person. *Giardia* cysts ingested with contaminated food or water develop into trophozoites that attach to the small intestine.^{12,75} Encystation occurs as parasites transit toward the colon.

Susceptibility and resistance

Giardia is sensitive to metronidazole (Flagyl), quinacrine hydrochloride, and furazolidone. High temperatures decrease the viability of *Giardia* in the environment. *Giardia* survives a month at 21 degrees C, but cysts are killed in ten minutes at 54 degrees C.²⁷

Control measures

Improved hygiene, with adequate disposal of fecal waste and washing of fruits and vegetables is the most effective control method. Use of granular filters and coagulation are effective against *Giardia*. Commonly used water disinfectants achieve adequate *Giardia* inactivation. Boiling water for one minute kills *Giardia* cysts.⁷⁵

Isospora belli

Introduction

Isospora belli is a Coccidia parasite related to *Cryptosporidium* spp., *Cyclospora* spp., and *Toxoplasma* spp.²²⁰ Humans are the only known host.²¹³ Intestinal involvement and symptoms are usually transient, unless the patient is immunocompromised.²²⁰ *I. belli* has been associated with outbreaks of diarrhea in institutional settings, daycare centers, World War II veterans from the Pacific, immigrants, and individuals with HIV infection.

Clinical symptoms

Symptoms develop a week after *I. belli* oocyst ingestion, including diarrhea, weight loss, abdominal pain, cramping, and low-grade fever.^{210,221} The disease is usually self-limiting; however, oocyst shedding may persist for 2–3 weeks after the patient recovers.^{210,221,222} Chronic illness occurs occasionally in infants or in otherwise healthy adults.²²³ Disseminated infection may result from ingestion of large numbers of oocysts.^{220,224}

Mode of transmission

Infective *I. belli* sporulated oocysts are spread through ingestion of food and water contaminated with feces.^{213,225}

Susceptibility and resistance

Several drugs will effectively treat *I. belli*: trimethoprim-sulfamethoxazole, co-trimoxazole, pyrimethamine-sulfadiazine, primaquine phosphate-nitrofurantoin, and primaquine phosphate-chloroquine-phosphate.²¹³

Control measures

Prevention of disease can be accomplished with improved personal hygiene and sanitation to eliminate possible fecal–oral transmission from food, water, or environmental surfaces.²¹³

Microsporidia

Introduction

Intestinal Microsporidia includes over 100 genera and 1000 species. They are obligate intracellular parasites found in both vertebrates and invertebrates.²¹³ At least four genera are implicated in human disease: *Encephalitozoon*, *Enterocytozoon*, *Pleistophora*, and *Vittaforma*.^{226,227} *Enterocytozoon bienersi* is known to have tissue specificity for the human intestinal tract.^{228–230}

Clinical symptoms

Because the route of human infection has not been fully characterized, the incubation period for microsporidial disease is unknown. Most infections are found in association with HIV infection. Microsporidia can cause chronic diarrhea without blood, dehydration, weight loss greater than 10% of body weight, keratitis, conjunctivitis, hepatitis, peritonitis, myositis, central nervous system infection, renal disease, sinusitis, and disseminated disease.^{229,213–235} It has been speculated that Microsporidia may be present at low levels in human populations, becoming activated if an individual's immune system is compromised.^{228,236–240}

Mode of transmission

E. bienersi appears to be a zoonotic pathogen.²⁴¹ Common environmental sources of Microsporidia include surface water and runoff. It is possible that Microsporidia may undergo human-to-human fecal–oral, urinary–oral, ocular inoculation, sexual, or transplacental transmission.^{242–244} Respiratory transmission occurs by inhalation, aspiration of gastrointestinal contents, or hematogenous dissemination.

²²⁸ *E. bienersi* can survive in 4 degrees C water for more than one year.

Susceptibility and resistance

Topical fumagillin appears to be successful against microsporidial keratoconjunctivitis.^{245,246} *E. intestinalis* responds to albendazole therapy, but *E. bienersi* does not. No other treatment success has been achieved.^{230,239,247,248}

Control measures

Control can be facilitated with improved hygiene, adequate disposal of fecal waste, and washing of contaminated fruits and vegetables.

Naegleria

Introduction

Naegleria is one of the Amebae parasites, commonly found in soil and warm fresh water (lakes, rivers, and hot springs, unchlorinated swimming pools, and in warm water discharge pools from industrial plants).²¹³ In the United States, the disease is generally acquired while swimming and diving in freshwater lakes and ponds. Only *Naegleria fowleri* has been found to infect humans, causing primary amebic meningoencephalitis, a rapidly progressing meningoencephalitis that is almost always fatal. Significant numbers of *N. fowleri* are found in water with high concentrations of iron and manganese and in water layers containing filamentous cyanobacteria and eubacteria, which serve as food sources.

Clinical symptoms

Naegleria fowleri infection is accompanied by headache, fever, nausea and vomiting, stiff neck, encephalopathic symptoms of confusion, apathy, loss of balance and bodily control, seizures, and hallucinations. Infection often results in death within 7–10 days. The incubation period is 2–7 days. Other symptoms include abnormalities of taste and smell, seizures, cerebellar ataxia, nuchal rigidity, photophobia, palsies of the third, fourth, and sixth cranial nerves, and increased intracranial pressure and coma. Cardiac abnormalities may also develop. Subclinical infections are possible in healthy people when *N. fowleri* colonizes the nose and throat.^{191,199,249,250} Eye infections may lead to blindness.⁹¹

Mode of transmission

Naegleria fowleri enters the body through the nose and travels to the brain and spinal cord while the person is swimming underwater or diving. Infection is most common during the dry, hot summer months, when the temperature is above 27 degrees C. The preferred environment for *N. fowleri* is the soil; however, heavy rains and runoff introduce this organism into lakes, ponds, and surface waters.^{251,252} *N. fowleri* can also be associated with household washing and bathing.²⁵²

Susceptibility and resistance

Amphotericin B, an antifungal drug, is the only agent with established clinical efficacy in the treatment of *N. fowleri*,

although therapy with this drug is not always effective and has been associated with adverse effects on the kidneys and other organs.

Control measures

Avoidance is the best control measure, achieved by not swimming in warm, fresh water, such as ponds or warm water discharge pools, or unchlorinated swimming pools or polluted waters.

Schistosomiasis

Introduction

Schistosoma are flukes (worms/helminths) belonging to the class Trematode. Flukes in infected humans are found in the liver and blood. Schistosomiasis occurs among people living in tropical and subtropical zones, with water-borne transmission from freshwater snails. In the US, schistosomiasis is principally found only in immigrants from endemic areas or Americans returning from endemic areas.²⁵³ It is an occupational disease in people who are unable to avoid contact with untreated water.²⁵⁴ Adult worms can live 20–30 years in the veins of the human abdominal cavity, with hundreds of eggs each day excreted in feces or urine. Affected occupations include agriculture, fishing, washing and bathing.

Clinical symptoms

Schistosoma symptoms vary with the species of worm and the phase of infection. Initial invasion of skin may cause itching and rash, heavy infestation may cause fever, chills, lymph node enlargement, and liver and spleen enlargement. Urinary symptoms include frequency, dysuria, and hematuria. Intestinal symptoms include abdominal pain and diarrhea (which may be bloody).

Mode of transmission

Transmission of the parasites does not occur in the United States because of lack of suitable snail hosts, although dermatitis due to avian schistosomes occurs in the Great Lakes region. There the typical hosts are migratory water birds, including shorebirds, ducks, and geese.²⁵⁵

Susceptibility and resistance

Schistosoma infection can be treated with praziquantel.

Control measures

Infection with *Schistosoma* can be avoided by eradication of snails and by avoiding swimming or bathing in untreated water from endemic areas.

Chapter 55

Ethics in Occupational Medicine

Anne Krantz, Linda S Forst

The practice of medicine often occurs at the interface between clinical science and social relationships; in occupational medicine, this is almost always true. In occupational medicine, these social relationships are frequently economic and societal forces that distort the traditional relationship between physician and patient. The conflicts that arise from these forces, and their ethical implications, must be recognized and overcome by the occupational medicine physician in order to practice in this field with the highest professional standards. This chapter reviews the basis for the ethical practice of medicine, some of the ethical challenges encountered in the practice of occupational medicine, and the role of codes of ethics in this field.

ETHICS IN GENERAL MEDICAL PRACTICE

The primacy of the relationship between doctor and patient is the nucleus around which principles of ethical medical practice are formulated. Four principles central to biomedical ethics have been elucidated by Beauchamp and Childress.¹ *Non-maleficence* is the duty to not intentionally cause harm to the patient, expressed by the familiar dictum, *Primum non nocere*. *Beneficence* is the duty to act in the best interest of the patient, and to promote his or her welfare. *Respect for autonomy* is the duty to safeguard the decision-making capacity of patients, and is the basis for the principle of informed consent. Finally, there are considerations of *justice*, which relate to the fair allocation of healthcare resources.¹

The American College of Physicians gives guidance to the practicing physician in the application of these principles to the clinical context.² To serve a patient's best interest, the physician must understand the patient's complaints, goals, and expectations. The provision of care requires informed consent. The physician must respect the privacy of the patient, and afford maximum confidentiality. Disclosure of relevant medical information must be done in a way that the patient understands. The physician must be professionally competent. Finally, the practicing physician must be aware of the social, organizational, and financial conflicts of interest that might influence the provision of care, and base his or her actions only on what is appropriate medical care.²

CONFLICTS OF INTEREST IN OCCUPATIONAL MEDICINE

A conflict of interest is 'a set of conditions in which professional judgment concerning a primary interest (such as a patient's welfare or the validity of research) tends to be unduly influenced by a secondary interest (such as financial gain)'.³ In occupational medicine, financial conflicts of interest arise when the physician has a dual relationship: one with a patient (who is an employee), and at the same time, one with an employer, insurer, or other entity that employs or pays the physician for the patient's care. These entities are likely to have their own financial interest in the patient's (employee's) diagnosis, treatment, and ability to return to work. Thus, there may be undue pressure, real or perceived, on the physician to provide care or opinions that are not in the patient's best interest, or do not reflect the doctor's best professional judgment. Examples of potential conflicts of interest include the following.

- A company physician decides on the timing of returning an employee to work after an injury; the physician is explicitly or implicitly aware of the employer's concern for the costs of the employee's lost workdays.
- A physician performs an independent medical examination and renders an opinion regarding the work-relatedness of an illness; the patient was referred by a workers' compensation insurance carrier, which provides the physician with many such referrals.
- A physician in a hospital-based occupational health program plans to refer a patient with a work-related injury to the most qualified neurosurgeon; the physician is well aware that the hospital expects the occupational health program will generate referrals for its own sub-specialist physicians and ancillary services.

Conflicts of interest also pertain to the work of occupational health-related professions outside medicine, including nursing, industrial hygiene, and other sciences. For example:

- an occupational health scientist employed by the manufacturer of a persistent organic pollutant is a member of a panel which will advise the government of the extent of environmental contamination and health effects from the pollutant, and the optimal strategy for abatement; the scientist knows that the costs of abatement will be borne by the manufacturer.

Several features of financial conflicts of interest have been discussed by Thompson.³ Firstly, it is incorrect to dismiss financial conflict of interest as just one among the many competing interests which must always be weighed in the complicated practice of medicine. Physicians (occupational or otherwise) have a primary responsibility for the wellbeing of the patient, which takes precedence over financial or corporate interests. On the other hand, the mere presence of financial conflicts of interest does not mean that the physician necessarily does not act in the patient's best interest, or uses other than his or her best professional judgment. Nor is it necessarily an attack on the integrity of a physician to note that a conflict of interest exists. However, it is usually the case that many elements go into the process of medical decision making, and the influence of dual relationships may be subtle. The avoidance of conflicts of interest not only protects the professionalism of the physician, but also contributes to public confidence in the integrity of the profession.³ Thus, it is critical for physicians to recognize conflicts of interest and develop structural precautions to prevent them or minimize their influence.

An example of an important structural precaution that can minimize conflicts of interest is the freedom of an employee to choose his or her own physician for the care of a work-related injury or illness. This arrangement exists in some states. Thus, for example, if an employer knows that a worker can seek care outside, there will be less pressure on the company physician, or the contracted occupational health program, to provide substandard care, or return an injured employee to work prematurely. Another safeguard for workers would be a contractual right for a union to veto the selection of a company physician. For the physician, a practice structured so that it is not unduly dependent upon a single referral source will minimize the perceived pressure which that referral source exerts, and, in the event that the referral source has expectations that the physician believes are unethical, make it easier to decline the business. For the health scientist in the example above, a structural policy that avoids a conflict of interest would be one that prevents scientific panels having, as participants, those with a financial interest in the outcome of the question being studied.

What role does disclosure play in the management of conflicts of interest? While disclosure of a financial conflict of interest is important in the ethical care of the patient, it does not, by itself, alter the potential influence which that conflict may exert. For example, a patient may independently seek care for an illness from a primary care physician who also provides occupational health services for the patient's employer. If the patient has no other choice, perhaps due to geographic or financial limitations, of pursuing care elsewhere, then disclosure does not change the potential effect that the conflict may exert in the patient's care. Importantly, as noted by Rodwin,⁴ a physician's obligation to act in the best interests of the patient is not limited by disclosing a conflict of interest. In the case of the occupational health scientist above, the

mere disclosure of the relationship with the manufacturer does not prevent the conflict.

The current practice of occupational medicine often does occur in settings where financial conflicts of interest are unavoidable, for example, when clinical judgments are made by a company physician. In addition to the structural safeguards that may be developed for the worker/patient, the physician's individual ability to maintain an approach that uniformly puts the patient/worker's best interest above corporate interests is paramount. The best circumstance is when the company physician is allowed to practice with no interference from management, and is successful in convincing the employer that its long-term interests are best served by protecting workers from hazardous exposures. When there is conflict, however, the physician's position can be bolstered by the presence of a professional code of ethics (see below).

PATIENT CONFIDENTIALITY

Occupational medicine may be considered a subset of forensic medicine in that many, if not the majority, of work-related injury and illness claims are adjudicated within the workers' compensation system. As such, these cases are reviewed by many different groups of professionals. If the worker's compensation claim is immediately accepted by employers or insurance companies, they still may require that a copy of the medical record be sent for evaluation by a claims analyst before payment is made. If the claim is contested, attorneys may be called in and claims may go before an arbitrator at the state industrial commission; review of medical records is essential to adjudication of the case. The patient's primary provider and the designated 'company physician' may gain access to each other's records in order to deliver optimal care or to render an opinion regarding fitness for work. Case managers, human resources personnel, and owners/supervisors may all have the opportunity to scrutinize an injured worker's records, particularly in small companies where one or a few managers fill those roles. On rare occasions, enforcement agencies like the Occupational Safety and Health Administration (OSHA) or the health department may gain access to medical records.

There are both ethical and legal considerations that apply to patient confidentiality in the occupational medicine setting. In the US, the patient's right to privacy and confidentiality is implicit in the doctor-patient relationship. Injured workers, who typically have more experience with general healthcare than occupational healthcare, may expect that all provider-patient relationships are the same. The occupational physician has the obligation to inform the patient of the difference.

Even if the patient is made aware of the role of the occupational physician, 'fidelity' to the patient requires that the physician obtain consent to release medical information to a third party. To protect this right, healthcare institutions have developed medical release forms that require the patient's signature, and protocols for releasing medical information. Occupational clinics have adapted these

I have authorized _____ Medical Center to render treatment of my work-related injury/illness and to release any or all medical information, both written and verbal, regarding my work-related injury/illness (including, but not limited to, medical records, billing information, and x-rays) to my employer and its representatives, insurance carriers, and physicians for the duration of the injury.

I further give consent to _____ Medical Center for the performance of drug testing, either urine, blood or breath, in accordance with my employer's drug testing policy. I also authorize the release of such results to my employer.

This consent remains in effect until revoked in writing by me.

documents to inform the patient of the role of the provider in this case and to gain consent for release of medical information to all interested parties (Fig. 55.1). Although this protocol may interfere with the injured worker's comfort and openness with the provider, it is essential to the principle of non-maleficence.

A series of statutes and court decisions define the boundaries of patient confidentiality in occupational medicine. An implied contract between patient and physician in all clinical interactions is recognized in most of the 50 states in the US and there is much case law that upholds this understanding. Because of the changes in healthcare delivery and payment over the past several decades, the National Conference of Commissioners on Uniform State Laws approved and recommended enactment of the Universal HealthCare Information Act in 1985.⁵ The Act cites:

- 'the emergence of third party payment plans';
- 'the growing involvement of government agencies in virtually all aspects of healthcare';
- 'the exponential increase in the use of computers and automated information systems for healthcare record information as conditions that have challenged confidentiality protections';
- 'the sheer amount of personal data kept in healthcare records'; and
- 'the [increased] number of individuals who monitor those records'.

This model rule requires that a medical release be signed and dated by the patient, that it identify the nature of the information that will be disclosed, and that it identify who will receive the information. The permission lasts no more than 30 months without renewal. There are situations where patient consent is not required. Those that apply to occupational health include:

- healthcare providers who need it to render healthcare to the patient;

- for quality assurance peer review;
- for administrative or legal purposes;
- for prevention of danger to the patient or others;
- for research;
- when required by the public health system; or
- in compliance with compulsory processes.

In addition, there have been many court decisions whereby physicians hired by a party other than the patient (e.g., the employer) were exempt.⁶ When medical information regarding an employee is released to the company physician, there is an implicit obligation that this information is not re-disclosed to other parties in the company.⁶

Under workers' compensation statutes, records describing a work-related injury or illness may be disclosed to the insurer, the employer, or the state workers' compensation fund in most states. Independent medical examinations are considered the property of the payer – usually the employer.

Under the Health Insurance Portability and Accountability Act of 1996 (HIPAA),⁷ the US Department of Health and Human Services developed a standard regarding access to medical records. This law went into effect in 2002. Under the standard, providers and insurance companies must provide patients with a document describing how their health information may be used and disclosed. Patients have a right to see their records, request amendments, know of any disclosures made, and request that specific non-routine disclosures not be made. Explicit authorization is required to release the information for non-routine purposes, and then the minimal amount of information should be released. Providers and insurers must train their employees regarding HIPAA requirements, write privacy procedures, identify a 'privacy officer', and develop a procedure for accepting complaints from individuals regarding violation of their rights. Criminal and civil penalties have been established for breaching confidential-

ity. This will clearly affect the management of occupational medicine records.

Patients' trust in the occupational physician and their willingness to supply information regarding their health status make confidentiality a critical assurance in the occupational healthcare setting. While HIPAA goes a long way to defining appropriate disclosure of medical information, respect for privacy and autonomy of the employee/patient is the ethical goal of the occupational provider.

OCCUPATIONAL HEALTH RESEARCH

The protocol for protection of human subjects in medical research was established by the US Department of Health and Human Services,⁸ and based on the Belmont Report.⁹ Here, the ethical principles central to clinical practice are applied to the research setting:

- 'autonomy'— respect for individuals and informed consent;
- 'beneficence'— concern about the common good and reducing risk to the individual; and
- 'justice'— apportioning benefits and burdens of research fairly.

A key difference between clinical principles and research principles is the omission of maleficence in the latter: it is recognized that in research, harm may in fact be done, and the goal is to minimize its risk. Although federal law applies only to projects that are funded by the government, most research institutions have adopted this protocol for all research.

There are two major activities in occupational health that are regarded as research. One is use of data collected routinely for the purpose of medical or exposure monitoring and surveillance. The second is *de novo* collection of data from workers or their environment to address a scien-

tific hypothesis. The former falls in the category of review of secondary data and, if confidentiality can be maintained, does not require informed consent. The latter entails enrollment of workers and is thus guided by rules related to human subjects research.

Some would consider workers a 'vulnerable population', because job security could be jeopardized by their willingness or unwillingness to participate, and also because confidentiality may be difficult to maintain in the closed environment of the workplace. For this reason, Rothstein states that workers should be afforded 'additional protections beyond those normally provided to research participants'.¹⁰ Drawing from laws relating to research on other populations, research involving workers would be permitted only if it:

- evaluates issues related to the subjects' workplace and involves minimal risk;
- evaluates conditions that affect workers as a group; and
- is likely to improve the health of the individual enrolled worker.

There should be no connection between enrolling in the research and benefits unrelated to the research. For example, the worker should not get (or be denied) special treatment regarding payment or desirable job tasks based on his or her willingness to participate.

Emanuel proposes that workers be considered a 'community', rather than a 'vulnerable population', since they are targeted *because of* their work, rather than as a convenience sample.¹¹ In this scheme, workers are considered partners in the research; they or their representatives are then contributors to all aspects of study execution. They would be involved with protocol development, consent processes, research conduct, data access, and dissemination of results. This would allow for direct oversight by the subjects themselves, and afford a greater level of protection from research risks.

Although not common, carrying out one's duty to safeguard the health of workers and the public can have dire professional consequences. In 1994, Dr David Kern was a faculty member at a university medical school, the director of the university's occupational medicine program, and the director of an occupational and environmental health service which provided clinical services at a hospital affiliated with the university.¹² After seeing a patient at the affiliated hospital with suspected occupational lung disease, Dr Kern arranged a site visit at the patient's workplace, which manufactured finely cut nylon (flock) and flocked fabric. The site visit would serve a dual purpose: to investigate possible etiologies for the illness, and to educate students and trainees. At the start of the site visit, Dr Kern signed a confidentiality agreement regarding the limits of disclosure of information and trade secrets at the plant.

Some time later, Dr Kern saw a second patient with interstitial lung disease from the same plant. He contacted a public health agency (NIOSH) about his concern for a suspected outbreak of an occupational lung disease, and arranged a consulting agreement with the company to undertake an investigation of the suspected outbreak. During the course of the investigation, Dr Kern identified other cases, and eventually sought to present his clinical findings to the scientific

public. He was asked by the company to refrain from submitting a planned abstract of his findings for presentation at an international scientific meeting. He was then asked by the affiliated hospital (of which the company was a benefactor) to withdraw his submitted abstract. The hospital also sought to delay Dr Kern's communication with workers participating in the study about clinical recommendations based on Dr Kern's understanding of the disease. Eventually, the hospital terminated the occupational and environmental health service, despite later learning that his academic freedom had been violated. Dr Kern maintained that the confidentiality agreement had little if anything to do with the outbreak investigation, and, in any case, 'it should not be allowed to deter us from our professional responsibilities'.¹²

Dr Kern's actions were in keeping with the highest standards of public health practice: he notified a public health agency when he suspected an outbreak; he sought permission to undertake an outbreak investigation; he sought to keep all relevant parties informed of the results; and, importantly, he sought to inform other scientists of the results in a timely manner, so that other workers might be protected. Unfortunately, his story 'illustrates the conflict-prone nature of the practice of occupational medicine'.¹³

The workplace 'outbreak investigation' is an intermediate form of research, in that it is designed to address a hazard that may affect the immediate health of the workforce. Outbreak investigations are conducted expeditiously, sometimes not allowing time to adequately plan and communicate pertinent issues to the employee-subjects, or to cultivate a partnership. They generally proceed in a single workplace with a small number of employees, limiting statistical power and limiting the ability to generalize results. They may be performed or mandated by an enforcement agency such as OSHA or a public health department, bypassing institutional review procedures required of other types of research. Still, results of outbreak investigations in the workplace fall in the domain of research, and should be published, particularly when results are relevant to occupational and public health.

CODES OF ETHICS IN OCCUPATIONAL MEDICINE

Many professional organizations of physicians and other biomedical scientists have adopted codes of ethics or conduct. In general, these codes articulate core values and principles of their respective professions, establish behavioral norms expected by members of the profession, and provide moral guidance for practitioners faced with conflict or uncertainty. Ethical codes can help establish an 'ethics standard of care' for the profession and, through their development and ratification by a professional group, contribute to the 'ethics education' of the members of that group.¹⁴

Criticisms of codes of ethics include that they may simply represent an effort by professionals to police themselves, in order to avoid outside scrutiny. They are voluntary, and professional organizations have no way of enforcing them. Their content may be non-specific, so that while they outline expected values, they may not sufficiently delineate expected or proscribed behaviors necessary to achieve those values. These limitations notwithstanding, the establishment of codes of ethics for physicians and other health professionals is increasingly common and generally considered desirable.

Numerous codes of ethics for occupational medicine and related public health professions have been adopted or proposed.^{2,15-20} In the process of selecting a code of conduct for the Association of Occupational and Environmental Clinics (AOEC), Brodtkin et al. suggested seven principles most relevant to the ethical practice of occupational medicine, and therefore desirable as elements of any such code. These principles are:

- an obligation to promote a safe and healthy workplace and environment;
- an obligation to maintain professional competence;
- an obligation to advise and report;
- avoidance of conflict of interest;
- avoidance of discrimination;
- an obligation to maintain ethical standards; and
- an obligation to maintain patient confidentiality.²¹

Another code stresses the importance of transparency, with an obligation to declare conflicts of interest.¹⁹ Because the practice of occupational health is multidisciplinary, it is also relevant that all health and safety professionals have equivalent ethical standards.²²

The 1996 AOEC review found that the most robust code of those reviewed was that of the International Commission on Occupational Health. It was the most detailed, applied to the full range of occupational health practitioners, and addressed both clinical and public health dimensions.²¹ This code is reproduced below. The American College of Occupational and Environmental Medicine adopted a code in 1993,² which has been supplemented by subsequent discussions of confidentiality²³ and research on workers.¹⁰ A code of conduct that includes an explicit declaration of conflict of interest has also been proposed.¹⁹

Efforts to protect workers and the public from occupational and environmental hazards occur in a setting fraught with powerful and competing social and economic forces. Amid these forces, the occupational health professional's first priority is to the health of the worker and public. The health and safety professional must be ever mindful of the interests that conflict with that priority, and of the expectation, from patients, colleagues, and society, that one will practice according to the highest standards of ethical practice. Codes that recognize this priority remind practitioners of the ethical standards of their profession, and strengthen their ability to work effectively. These codes must remain living documents, their contents and implications being periodically reviewed and debated, to maintain a high level of attention to the ethical practice of occupational and environmental health.

Acknowledgment

The authors thank Dr Peter Orris for his insights and guidance.

Appendix

International Code of Ethics for Occupational Health Professionals

International Commission on Occupational Health

Introduction

1. The aim of occupational health practice is to protect and promote workers' health, to sustain and improve their working capacity and ability, to contribute to the establishment and maintenance of a safe and healthy working environment for all, as well as to promote the adaptation of work to the capabilities of workers, taking into account their state of health.

2. The field of occupational health is broad and covers the prevention of all impairments arising out of employment, work injuries and work-related disorders, including occupational diseases and all aspects relating to the interactions between work and health. Occupational health professionals should be involved, whenever possible, in the design and choice of health and safety equipment, appropriate methods and procedures and safe work practices and they should encourage workers' participation in this field as well as feedback from experience.

3. On the basis of the principle of equity, occupational health professionals should assist workers in obtaining and maintaining employment notwithstanding their health deficiencies or their handicap. It should be duly recognised that there are particular occupational health needs of workers as determined by factors such as gender, age, physiologic condition, social aspects, communication barriers or other factors. Such needs should be met on an individual basis with due concern to protection of health in relation to work and without leaving any possibility for discrimination.

4. For the purpose of this Code, the expression "occupational health professionals" is meant to include all those who, in a professional capacity, carry out occupational safety and health tasks, provide occupational health services or are involved in an occupational health practice. A wide range of disciplines are concerned with occupational health since it is at an interface between technology and health involving technical, medical, social and legal aspects. Occupational health professionals include occupational health physicians and nurses, factory inspectors, occupational hygienists and occupational psychologists, specialists involved in ergonomics, in rehabilitation therapy, in accident prevention and in the improvement of the working environment as well as in occupational health and safety research. The trend is to mobilise the competence of these occupational health professionals within the framework of a multidisciplinary team approach.

5. Many other professionals from a variety of disciplines such as chemistry, toxicology, engineering, radiation health, epidemiology, environmental health, applied sociology, insurance personnel and health education may also be involved, to some extent, in occupational health practice. Furthermore, public health and labour authorities, employers, workers and their representatives and first aid workers have an essential role and even a direct responsibility in the implementation of occupational health policies and programmes, although they are not occupational health specialists by profession. Finally, many other professions such as lawyers, architects, manufacturers, designers, work analysts, work organisation specialists, teachers in technical schools, universities and other institutions as well as the media personnel have an important role to play in relation to the improvement of the working environment and of working conditions.

6. The term "employers" means persons with recognised responsibility, commitment and duties towards workers in their employment by virtue of a mutually agreed relationship (a self-employed person is regarded as being both an employer and a worker). The term "workers" applies to any persons who work, whether full time, part time or temporarily for an employer; this term is used here in a broad sense covering all employees, including management staff and the self-employed (a self-employed person is regarded as having the duties of both an employer and a worker). The expression "competent authority" means a minister, government department or other public authority having the power to issue regulations, orders or other instruction having the force of law, and who is in charge of supervising and enforcing their implementation.

7. There is a wide range of duties, obligations and responsibilities as well as complex relationships among those concerned and involved in occupational safety and health matters. In general, obligations and responsibilities are defined by statutory regulations. Each employer has the responsibility for the health and safety of the workers in his or her employment. Each profession has its responsibilities which are related to the nature of its duties. It is important to define the role of occupational health professionals and their relationships with other professionals, with the competent authority and with social partners in the purview of economic, social, environmental and health policies. This calls for a clear view about the ethics of

occupational health professionals and standards in their professional conduct. When specialists of several professions are working together within a multidisciplinary approach, they should endeavour to base their action on shared sets of values and have an understanding of each other's duties, obligations, responsibilities and professional standards.

8. Some of the conditions of execution of the functions of occupational health professionals and the conditions of operation of occupational health services are often defined in statutory regulations, such as regular planning and reviewing of activities and continuous consultation with workers and management. Basic requirements for a sound occupational practice include a full professional independence, i.e. that occupational health professionals must enjoy an independence in the exercise of their functions which should enable them to make judgements and give advice for the protection of the workers' health and for their safety within the undertaking in accordance with their knowledge and conscience. Occupational health professionals should make sure that the necessary conditions are met to enable them to carry out their activities according to good practice and to the highest professional standards. This should include adequate staffing, training and retraining, support and access to an appropriate level of senior management.

9. Further basic requirements for acceptable occupational health practice, often specified by national regulations, include free access to the workplace, the possibility of taking samples and assessing the working environment, making job analyses and participating in enquiries and consulting the competent authority on the implementation of occupational safety and health standards in the undertaking. Special attention should be given to ethical dilemmas which may arise from pursuing simultaneously objectives which may be competing such as the protection of employment and the protection of health, the right to information and confidentiality, and the conflicts between individual and collective interests.

10. The occupational health practice should meet the aims of occupational health which have been defined by the ILO and WHO in 1950 and updated as follows by the ILO/WHO Joint Committee on Occupational Health in 1995:

Occupational health should aim at: the promotion and maintenance of the highest degree of physical, mental and social well-being of workers in all occupations; the prevention amongst workers of departures from health caused by their working conditions; the protection of workers in their employment from risks resulting from factors adverse to health; the placing and maintenance of the workers in an occupational environment adapted to their physiologic and psychological capabilities; and, to summarise, the adaptation of work to man and of each man to his job. The main focus in occupational health is on three different objectives: (i) the maintenance and promotion of workers' health and working capacity; (ii) the improvement of working environment and

work to become conducive to safety and health; and (iii) development of work organisations and working cultures in a direction which supports health and safety at work and in doing so also promotes a positive social climate and smooth operation and may enhance productivity of the undertakings. The concept of working culture is intended in this context to mean a reflection of the essential value systems adopted by the undertaking concerned. Such a culture is reflected in practice in the managerial systems, personnel policy, principles for participation, training policies and quality management of the undertaking.

11. It cannot be overemphasised that the central purpose of any occupational health practice is the primary prevention of occupational and work-related diseases and injuries. Such practice should take place under controlled conditions and within an organised framework – preferably involving professional occupational health services – in order to ensure that it is relevant, knowledge-based, sound from a scientific, ethical and technical point of view, and appropriate to the occupational risks in the enterprise and to the occupational health needs of the working population concerned.

12. It is increasingly understood that the purpose of a sound occupational health practice is not merely to perform assessments and to provide services but implies caring for workers' health and their working capacity with a view to protect, maintain and promote them. This approach of occupational healthcare and occupational health promotion addresses workers' health and their human and social needs in a comprehensive and coherent manner which includes preventive healthcare, health promotion, curative healthcare, first-aid rehabilitation and compensation where appropriate, as well as strategies for recovery and reintegration into the working environment. Similarly, the importance of considering the links between occupational health, environmental health, quality management, product safety and stewardship, public and community health and security is increasingly understood. This strategy is conducive to the development of occupational safety and health management systems, an emphasis on the choice of clean technologies and alliances with those who produce and those who protect in order to make development sustainable, equitable, socially useful and responsive to human needs.

BASIC PRINCIPLES

The following three paragraphs summarise the principles of ethics and values on which is based the International Code of Ethics for Occupational Health Professionals.

The purpose of occupational health is to serve the health and social well-being of the workers individually and collectively. Occupational health practice must be performed according to the highest professional standards and ethical principles. Occupational health professionals must contribute to environmental and community health.

The duties of occupational health professionals include protecting the life and the health of the worker, respecting human dignity and promoting the highest ethical principles in occupational health policies and programmes. Integrity in professional conduct, impartiality and the protection of the confidentiality of health data and of the privacy of workers are part of these duties.

Occupational health professionals are experts who must enjoy full professional independence in the execution of their functions. They must acquire and maintain the competence necessary for their duties and require conditions which allow them to carry out their tasks according to good practice and professional ethics.

DUTIES AND OBLIGATIONS OF OCCUPATIONAL HEALTH PROFESSIONALS

Aims and advisory role

1. The primary aim of occupational health practice is to safeguard and promote the health of workers, to promote a safe and healthy working environment, to protect the working capacity of workers and their access to employment. In pursuing this aim, occupational health professionals must use validated methods of risk evaluation, propose effective preventive measures and follow up their implementation. The occupational health professionals must provide competent and honest advice to the employers on fulfilling their responsibility in the field of occupational safety and health as well as to the workers on the protection and promotion of their health in relation to work. The occupational health professionals should maintain direct contact with safety and health committees, where they exist.

Knowledge and expertise

2. Occupational health professionals must continuously strive to be familiar with the work and the working environment as well as to develop their competence and to remain well informed in scientific and technical knowledge, occupational hazards and the most efficient means to eliminate or to minimise the relevant risks. As the emphasis must be on primary prevention defined in terms of policies, design, choice of clean technologies, engineering control measures and adapting work organisation and workplaces to workers, occupational health professionals must regularly and routinely, whenever possible, visit the workplaces and consult the workers and the management on the work that is performed.

Development of a policy and a programme

3. The occupational health professionals must advise the management and the workers on factors at work which may affect workers' health. The risk assessment of occupational hazards must lead to the establishment of an occupational safety and health policy and of a programme of prevention adapted to the needs of undertakings and

workplaces. The occupational health professionals must propose such a policy and programme on the basis of scientific and technical knowledge currently available as well as of their knowledge of the work organisation and environment. Occupational health professionals must ensure that they possess the required skill or secure the necessary expertise in order to provide advice on programmes of prevention which should include, as appropriate, measures for monitoring and management of occupational safety and health hazards and, in case of failure, for minimising consequences.

Emphasis on prevention and on a prompt action

4. Special consideration should be given to the rapid application of simple preventive measures which are technically sound and easily implemented. Further evaluation must check whether these measures are effective or if a more complete solution must be sought. When doubts exist about the severity of an occupational hazard, prudent precautionary action must be considered immediately and taken as appropriate. When there are uncertainties or differing opinions concerning nature of the hazards or the risks involved, occupational health professionals must be transparent in their assessment with respect to all concerned, avoid ambiguity in communicating their opinion and consult other professionals as necessary.

Follow-up of remedial actions

5. In the case of refusal or of unwillingness to take adequate steps to remove an undue risk or to remedy a situation which presents evidence of danger to health or safety, the occupational health professionals must make, as rapidly as possible, their concern clear, in writing, to the appropriate senior management executive, stressing the need for taking into account scientific knowledge and for applying relevant health protection standards, including exposure limits, and recalling the obligation of the employer to apply laws and regulations and to protect the health of workers in their employment. The workers concerned and their representatives in the enterprise should be informed and the competent authority should be contacted, whenever necessary.

Safety and health information

6. Occupational health professionals must contribute to the information for workers on occupational hazards to which they may be exposed in an objective and understandable manner which does not conceal any fact and emphasises the preventive measures. The occupational health professionals must co-operate with the employer, the workers and their representatives to ensure adequate information and training on health and safety to the management personnel and workers. Occupational health professionals must provide appropriate information to the employers, workers and their representatives about the level of scientific certainty or uncertainty of known and suspected occupational hazards at the workplace.

Commercial secrets

7. Occupational health professionals are obliged not to reveal industrial or commercial secrets of which they may become aware in the exercise of their activities. However, they must not withhold information which is necessary to protect the safety and health of workers or of the community. When needed, the occupational health professionals must consult the competent authority in charge of supervising the implementation of the relevant legislation.

Health surveillance

8. The occupational health objectives, methods and procedures of health surveillance must be clearly defined with priority given to adaptation of workplaces to workers who must receive information in this respect. The relevance and validity of these methods and procedures must be assessed. The surveillance must be carried out with the informed consent of the workers. The potentially positive and negative consequences of participation in screening and health surveillance programmes should be discussed as part of the consent process. The health surveillance must be performed by an occupational health professional approved by the competent authority.

Information to the worker

9. The results of examinations carried out within the framework of health surveillance must be explained to the worker concerned. The determination of fitness for a given job, when required, must be based on a good knowledge of the job demands and of the work-site and on the assessment of the health of the worker. The workers must be informed of the opportunity to challenge the conclusions concerning their fitness in relation to work that they feel contrary to their interest. An appeals procedure must be established in this respect.

Information to the employer

10. The results of the examinations prescribed by national laws or regulations must only be conveyed to management in terms of fitness for the envisaged work or of limitations necessary from a medical point of view in the assignment of tasks or in the exposure to occupational hazards, with the emphasis put on proposals to adapt the tasks and working conditions to the abilities of the worker. General information on work fitness or in relation to health or the potential or probable health effects of work hazards, may be provided with the informed consent of the worker concerned, in so far as this is necessary to guarantee the protection of the worker's health.

Danger to a third party

11. Where the health condition of the worker and the nature of the tasks performed are such as to be likely to endanger the safety of others, the worker must be clearly informed of the situation. In the case of a particularly hazardous situation, the management and, if so required by national regulations, the competent authority must also be informed of the measures necessary to safeguard other persons. In his advice, the occupational health

professional must try to reconcile employment of the worker concerned with the safety or health of others that may be endangered.

Biologic monitoring and investigations

12. Biologic tests and other investigations must be chosen for their validity and relevance for protection of the health of the worker concerned, with due regard to their sensitivity, their specificity and their predictive value. Occupational health professionals must not use screening tests or investigations which are not reliable or which do not have a sufficient predictive value in relation to the requirements of the work assignment. Where a choice is possible and appropriate, preference must always be given to non-invasive methods and to examinations, which do not involve any danger to the health of the worker concerned. An invasive investigation or an examination which involves a risk to the health of the worker concerned may only be advised after an evaluation of the benefits to the worker and the risks involved. Such an investigation is subject to the worker's informed consent and must be performed according to the highest professional standards. It cannot be justified for insurance purposes or in relation to insurance claims.

Health promotion

13. When engaging in health education, health promotion, health screening and public health programmes, occupational health professionals must seek the participation of both employers and workers in their design and in their implementation. They must also protect the confidentiality of personal health data of the workers, and prevent their misuse.

Protection of community and environment

14. Occupational health professionals must be aware of their role in relation to the protection of the community and of the environment. With a view to contributing to environmental health and public health, occupational health professionals must initiate and participate, as appropriate, in identifying, assessing, advertising and advising for the purpose of prevention on occupational and environmental hazards arising or which may result from operations or processes in the enterprise.

Contribution to scientific knowledge

15. Occupational health professionals must report objectively to the scientific community as well as to the public health and labour authorities on new or suspected occupational hazards. They must also report on new and relevant preventive methods. Occupational health professionals involved in research must design and carry out their activities on a sound scientific basis with full professional independence and follow the ethical principles attached to research work and to medical research, including an evaluation by an independent committee on ethics, as appropriate.

CONDITIONS OF EXECUTION OF THE FUNCTIONS OF OCCUPATIONAL HEALTH PROFESSIONALS

Competence, integrity and impartiality

16. Occupational health professionals must always act, as a matter of prime concern, in the interest of the health and safety of the workers. Occupational health professionals must base their judgements on scientific knowledge and technical competence and call upon specialised expert advice as necessary. Occupational health professionals must refrain from any judgement, advice or activity which may endanger the trust in their integrity and impartiality.

Professional independence

17. Occupational health professionals must seek and maintain full professional independence and observe the rules of confidentiality in the execution of their functions. Occupational health professionals must under no circumstances allow their judgement and statements to be influenced by any conflict of interest, in particular when advising the employer, the workers or their representatives in the undertaking on occupational hazards and situations which present evidence of danger to health or safety.

Equity, non-discrimination and communication

18. The occupational health professionals must build a relationship of trust, confidence and equity with the people to whom they provide occupational health services. All workers should be treated in an equitable manner, without any form of discrimination as regards their condition, their convictions or the reason which led to the consultation of the occupational health professionals. Occupational health professionals must establish and maintain clear channels of communication among themselves, the senior management responsible for decisions at the highest level about the conditions and the organisation of work and the working environment in the undertaking, and with the workers' representatives.

Clause on ethics in contracts of employment

19. Occupational health professionals must request that a clause on ethics be incorporated in their contract of employment. This clause on ethics should include, in particular, their right to apply professional standards, guidelines and codes of ethics. Occupational health professionals must not accept conditions of occupational health practice which do not allow for performance of their functions according to the desired professional standards and principles of ethics. Contracts of employment should contain guidance on the legal, contractual and ethical aspects and on management of conflict, access to records and confidentiality in particular. Occupational health professionals must ensure that their contract of employment or service does not contain provisions which could

limit their professional independence. In case of doubt about the terms of the contract legal advice must be sought and the competent authority must be consulted as appropriate.

Records

20. Occupational health professionals must keep good records with the appropriate degree of confidentiality for the purpose of identifying occupational health problems in the enterprise. Such records include data relating to the surveillance of the working environment, personal data such as the employment history and occupational health data such as the history of occupational exposure, results of personal monitoring of exposure to occupational hazards and fitness certificates. Workers must be given access to the data relating to the surveillance of the working environment and to their own occupational health records.

Medical confidentiality

21. Individual medical data and the results of medical investigations must be recorded in confidential medical files which must be kept secured under the responsibility of the occupational health physician or the occupational health nurse. Access to medical files, their transmission and their release are governed by national laws or regulations on medical data where they exist and relevant national codes of ethics for health professionals and medical practitioners. The information contained in these files must only be used for occupational health purposes.

Collective health data

22. When there is no possibility of individual identification, information on aggregate health data on groups of workers may be disclosed to management and workers' representatives in the undertaking or to safety and health committees, where they exist, in order to help them in their duties to protect the health and safety of exposed groups of workers. Occupational injuries and work-related diseases must be reported to the competent authority according to national laws and regulations.

Relationships with health professionals

23. Occupational health professionals must not seek personal information which is not relevant to the protection, maintenance or promotion of workers' health in relation to work or to the overall health of the workforce. Occupational health physicians may seek further medical information or data from the worker's personal physician or hospital medical staff, with the worker's informed consent, but only for the purpose of protecting, maintaining or promoting the health of the worker concerned. In so doing, the occupational health physician must inform the worker's personal physician or hospital medical staff of his or her role and of the purpose for which the medical information or data is required. With the agreement of the worker, the occupational health physician or the occupational health nurse may, if necessary, inform the worker's personal physician of relevant health data as well as of

hazards, occupational exposures and constraints at work which represent a particular risk in view of the worker's state of health.

Combating abuses

24. Occupational health professionals must co-operate with other health professionals in the protection of the confidentiality of the health and medical data concerning workers. Occupational health professionals must identify, assess and point out to those concerned procedures or practices which are, in their opinion, contrary to the principles of ethics embodied in this Code and inform the competent authority when necessary. This concerns in particular instances of misuse or abuse of occupational health data, concealing or withholding findings, violating medical confidentiality or of inadequate protection of records in particular as regards information placed on computers.

Relationships with social partners

25. Occupational health professionals must increase the awareness of employers, workers and their representa-

tives of the need for full professional independence and commitment to protect medical confidentiality in order to respect human dignity and to enhance the acceptability and effectiveness of occupational health practice.

Promoting ethics and professional audit

26. Occupational health professionals must seek the support and co-operation of employers, workers and their organisations, as well as of the competent authorities, for implementing the highest standards of ethics in occupational health practice. Occupational health professionals must institute a programme of professional audit of their activities to ensure that appropriate standards have been set, that they are being met and that deficiencies, if any, are detected and corrected and that steps are taken to ensure continuous improvement of professional performance.

Chapter 56

Occupational and Environmental Legislation, Regulation, and Litigation in the United States

Gina Solomon, Adrianna Quintero, Amanda Hawes, Ellen Widdess

INTRODUCTION

Physicians working in occupational and environmental medicine (OEM) often become involved in legal issues whether or not they seek such involvement. Understanding the legal and regulatory framework of OEM can be important in numerous clinical situations. Finding information about chemical exposure or toxicity requires knowledge of the governmental resources available. Physicians must be aware of legally mandated disease reporting requirements. Regulatory agencies can be important resources but it is important to know where their jurisdictions begin and end. Providing good information and advice to patients may require knowledge of available legal and regulatory options. Finally, patients may choose to bring legal action against a party that they presume responsible for their disease or injury, and the treating physician's medical record and testimony take on enormous importance in such a case.

The field of occupational and environmental law is relatively new. Most of the legislation in the field was passed since 1970, and most of the important litigation has taken place in the past two decades. Although the legislative framework of occupational law (other than labor relations and workers' compensation) is primarily centralized in the Occupational Safety and Health Act (OSHAct), environmental law is more diffuse. Environmental law is a confusing field with many governing laws, overlapping jurisdictions, and inconsistencies, making it difficult to understand, and resulting in some surprising gaps and omissions. The general public often assumes that the government would not allow dangerous chemicals to be used in the workplace, used in consumer products, or released into the air or water of their community. The assumption that the government has the authority to prevent hazardous chemical exposures is not legally correct, although there are some hazards that have been effectively addressed through law and regulation.

This chapter is designed to give the clinician an overview of the laws, regulatory agencies, and litigation relevant to the practice of occupational and environmental medicine. Workers compensation law is covered in Chapter 57.1. There are agencies with legal responsibility for investigating certain environmental or occupational hazards. There are also legal and regulatory resources for clinicians, including sources of information relevant to

chemical toxicity and to exposure. The clinician in turn has some legal obligations. Tort law is an area of ongoing development. Physicians have an important role in gathering information that may be helpful in a tort framework, and medical professionals should understand what is expected both of the treating physician and of the expert witness.

OCCUPATIONAL HEALTH LAWS AND REGULATORY AGENCIES

The Occupational Safety and Health Act, OSHA, and NIOSH

In 1970 President Richard Nixon signed the Occupational Safety and Health Act (OSHAct). This law was the first comprehensive attempt in the US to regulate occupational health and safety. The law created two government agencies, the Occupational Safety and Health Administration (OSHA) within the Department of Labor, and the National Institute for Occupational Safety and Health (NIOSH) within the Centers for Disease Control and Prevention (CDC) in the Department of Health and Human Services.

The OSHAct created important health and safety provisions for most workers. However, state and federal employees are exempt from protection under this law. The law creates a general duty for the employer 'to furnish to each of his employees employment and a place of employment which are free from recognized hazards that are causing or are likely to cause death or serious harm to his employees' (Section 5(a)(1)). OSHA sometimes uses this 'general duty clause' to cite employers for violations of the law even when the employer has not violated any specific workplace standard.

The OSHAct also requires OSHA to set standards governing health and safety in the work environment. The agency must 'set the standard which most adequately assures, to the extent feasible, on the basis of the best available evidence, that no employee will suffer material impairment of health or functional capacity even if such employee has regular exposure to the hazard dealt with by such standard for the period of his working life' (Section 6(b)(5)). Thus the language of the law appears to be highly

protective of the health and safety of the worker. Unfortunately, subsequent court interpretations of the legislation, and decades of actual implementation have shown serious deficiencies. Due to the cumbersome process of collecting the scientific evidence and moving forward with rulemakings, OSHA has succeeded in only adopting interim standards from industry organizations and setting a small handful of specific standards of its own.

The OSHA effort to promulgate an ergonomics standard to address musculoskeletal disorders in the workplace, for example, began in 1992. After a cumbersome 8-year process, more than 8000 written comments, and more than 700 witnesses testifying at numerous public hearings, the agency issued a standard in November of 2000. In March of 2001, the new ergonomics standard was repealed due to a change in political administration in Washington DC. In the first 16 years of its history, OSHA promulgated only 24 standards. Observers have noted that the history of OSHA standard setting has been a process 'characterized by frustration, delay and missed opportunity'.¹ The courts have placed a heavy burden of proof on OSHA to demonstrate a 'significant risk of harm' and to show that a given standard is 'reasonably necessary and appropriate to remedy a significant risk of material health impairment'.² The definition of 'significant risk' has been a longstanding cause of contention. OSHA generally considers a cancer risk of one-in-a-thousand to be a significant risk. This contrasts sharply with the Environmental Protection Agency's one-in-a-million significant risk level.

The OSHAct has given OSHA some police powers to enforce the law. The law originally gave inspectors the right to enter any workplace covered by the law without prior notification. The Supreme Court held that this right is in violation of the Fourth Amendment and OSHA inspectors are now required to obtain search warrants. Inspectors are allowed to speak privately with any employee. When violations are identified, the agency may issue citations that must be posted in the workplace, and may assess fines. The fine for a serious violation may not exceed \$1000, whereas the fine for a willful violation that results in the death of an employee or a repeated violation may be up to \$10,000 per violation. Because OSHA has been chronically short-staffed, employers can expect rarely (if ever) to see an OSHA inspector at their door. The infrequent nature of the inspections and the relatively small fines are often not a sufficient incentive to make employers address workplace health and safety problems. Because OSHA citations must be posted, employees know if their workplace was inspected and if violations were found. The presence of OSHA does not necessarily mean hazardous health and safety conditions were found at the facility, since violations of record keeping are common. Conversely an OSHA inspection that fails to identify any violations does not necessarily mean the workplace is safe – only that no OSHA standards were violated. OSHA will sometimes inspect workplaces in response to complaints from unions or groups of workers. Physicians can also contact OSHA if they have information to suggest unsafe

or unhealthy workplace conditions. OSHA frequently follows up on tips from physicians.

OSHA does require that employers keep records of some important health and safety-related items. Workplaces must maintain on 'OSHA Log' with information about workplace injuries and illnesses. An injury is recordable if it involves medical treatment, loss of consciousness, work restrictions, or job transfer. Several OSHA standards require monitoring of exposure either through industrial hygiene sampling or biologic monitoring. The employer must maintain accurate records of these employees' exposures, and keep the records for at least 30 years. Employers must also file reports of work injuries and illnesses to OSHA for statistical purposes. OSHA compiles annual statistics on work injuries and illnesses, and on results of OSHA inspections. These reports are available to the public from OSHA. Although these reporting requirements have provided useful statistics on workplace injuries, they are much less useful for work-related disease. The diseases may not be diagnosed as work related, or may occur after an individual has left the job. Thus there is likely under-reporting of work-related illness.

Individual states are legally allowed to create their own versions of OSHA, as long as the state OSHA protections are at least as stringent as the federal protections. Now more than half of the states have their own state OSHA agencies, with standards and penalties that are generally significantly more stringent than those of federal OSHA. In some states coverage has been extended to state government workers. States with their own OSHA may have somewhat different reporting requirements and standards. In addition, workplace inspections are done by state rather than federal inspectors. Physicians should know if their state has an OSHA agency, and should know whom to contact if they identify potentially unsafe workplace conditions.

NIOSH is the research and educational arm of the federal workplace health and safety program. NIOSH researches occupational illness and injuries, recommends criteria for occupational health and safety standards to OSHA, and educates the public and the medical community about occupational health and safety issues. NIOSH also conducts health hazard evaluations (HHEs) of workplaces.³ An HHE must be requested by an employer, a union representative, or by a group of workers. These investigations are most useful when a new or unusual work-related illness is suspected or when no specific OSHA standard applies. The requestor of an HHE may request confidentiality. NIOSH will triage requests and responds to some by sending teams of investigators to the workplace to conduct an in-depth investigation. If necessary, NIOSH teams can obtain a judicial warrant to perform an HHE even in the face of employer hostility. NIOSH also compiles a list of known toxic substances, known as RTECS (Registry of Toxic Effects of Chemical Substances) and writes summaries of the toxic effects of various chemicals.⁴ Information is readily available from NIOSH either via the internet or via telephone at 1-800-35-NIOSH.

In 1987, NIOSH initiated the Sentinel Event Notification System for Occupational Risks (SENSOR), a project conducted

in collaboration with the health departments of 10 states and designed to improve the reporting and surveillance of work-related health conditions. SENSOR states include California, Connecticut, Massachusetts, Michigan, Minnesota, New Jersey, New York, Oregon, Washington, and Wisconsin. States vary with regard to the health conditions tracked, but several states track traumatic injuries, occupational asthma, carpal tunnel syndrome, lead poisoning, noise-induced hearing loss, silicosis, dermatitis, injuries among teen workers, and other work-related disorders. In many of these states, physicians are legally required to report occupational diseases or injuries, and this information is critical to accurate tracking of work-related disorders by state and federal agencies.

The Mine Safety and Health Act and the Mine Safety and Health Administration (MSHA)

Passed in 1977 as a revision to the Federal Coal Mine Health and Safety Act of 1969, this statute created a federally administered compensation scheme for coal dust pneumoconiosis, known as the 'Black Lung Program'. The legislation also created the Mine Safety and Health Administration (MSHA) in the Department of Labor. MSHA is charged with addressing health and safety risks to all surface and underground miners. MSHA has set numerous health and safety standards and has established an inspection strategy that is quite different from the OSHA model. Each mine operator must provide routine sampling data for regulatory purposes to the agency. MSHA also does some inspection and sampling to confirm the submitted data. This approach guarantees that some data are available to the government on a routine and ongoing basis, irrespective of the actual frequency of government inspections. MSHA has attempted to control pneumoconiosis by establishing requirements for routine medical monitoring of miners, economic protection for workers transferred because of findings on medical monitoring, and a national surveillance program in coal mines administered by NIOSH.

Child Labor and the Fair Labor Standards Act

The Fair Labor Standards Act (FLSA) of 1938 includes several basic requirements relevant to occupational health. The FLSA requires payment of a minimum wage, overtime pay for work weeks longer than 40 hours, and restrictions on child labor. The child labor provisions include some restrictions on hours of work by youth under age 16, and a list of jobs considered too dangerous for workers under age 18 to perform. The restrictions on work hours do not apply to children working at family farms or family businesses, and the restrictions on hazardous work apply more narrowly to workers under age 16 in agricultural settings. In 1998, the Institute of Medicine released a report on child labor in the United States.⁵ The report recommended several changes in FLSA to better protect youth at work.

Suggestions included limitations on working hours for children between the ages of 16 and 18, updating of the list of hazardous jobs to reflect hazardous exposures in modern workplaces, applying the same protections to children working in agriculture that apply to children in other job settings, updating OSHA standards to make sure they protect children, and increasing enforcement of the FLSA to reduce widespread violations. To date, there has been little progress on updating and amending child labor laws and regulations. Physicians should be aware that many children do work, and may be exposed to workplace hazards. An occupational history and reporting of work-related illnesses and injuries is particularly important in this population.

Agricultural workers

Jurisdiction over the agricultural work environment is divided between OSHA, the Environmental Protection Agency (EPA), and states. OSHA oversees Field Sanitation Regulations, which require employers to provide workers with drinking water, toilets, and hand washing facilities. Agriculture is specifically exempt from many OSHA standards, such as those regulating electrical hazards, unguarded machinery, confined spaces, heat stress, carcinogens, and access to medical and exposure records. Farms with fewer than 10 employees and that do not have farm labor camps are completely exempt from OSHA oversight, meaning that only an estimated 5% of farms in the US fall under OSHA's jurisdiction at all. Several states, including Washington and California, have more stringent agricultural worker protection laws.

The EPA's Office of Pesticide Programs (OPP) oversees worker protection from pesticides, and promulgated the Worker Protection Standard (WPS); 'designed to reduce the risks of illness or injury resulting from workers' and handlers' occupational exposures to pesticides used in the production of agricultural plants on farms or in nurseries, greenhouses, and forests and also from the accidental exposure of workers and other persons to such pesticides'.⁶ Under the WPS, when an exposure occurs, employers must transport workers from the job site to a medical care facility and provide information about the pesticide to which the worker may have been exposed. EPA also sets restricted entry intervals (REIs) for pesticides, specifying how long employers must wait after a pesticide application before allowing workers to re-enter the area. OPP publishes an important resource for clinicians describing the signs and symptoms of pesticide poisoning, treatment for, and toxicology of, over 1500 pesticide products.⁷ OPP has also worked in collaboration with other agencies to develop an initiative aimed at instructing healthcare providers about pesticide toxicology.⁸

Environmental health laws and regulatory agencies

In the United States, the laws and regulations designed to protect human health from environmental hazards are

numerous and complex, including components at the federal and state level. It may be difficult for the clinician to determine who is responsible for what and where to turn for information. The Environmental Protection Agency (EPA) is the federal agency charged with administering the bulk of environmental regulations. The agency, created by President Nixon in 1970, brought together a patchwork of existing federal programs and laws concerned with environmental protection. EPA is administratively divided into 10 regions across the country. Each region addresses local and national issues. There are also numerous offices within the EPA with regulatory authority over specific classes of chemicals or environmental media. The EPA's mission includes protection of the natural environment and protection of human health. Despite the latter focus, there are few physicians, health professionals, or epidemiologists at the agency.

The EPA houses a wealth of information that may be useful to health professionals, some collected from outside parties, some developed by the EPA's Office of Research and Development. This information is available through EPA websites such as Envirofacts, a website that provides access to information about environmental issues including information on toxic chemical releases, hazardous waste, superfund, air and water releases and others.⁹ One of the more valuable sources of information is the Integrated Risk Information System (IRIS). Developed for EPA staff to address the need for information on substances for use in risk assessments and regulatory activities, IRIS is a collection of data files with information on health effects of numerous chemicals.¹⁰

Information that is not readily available on government websites can generally be obtained by filing a Freedom of Information Act (FOIA) request.¹¹ The FOIA allows anyone to request any government information (other than confidential business information, classified materials, and draft documents).¹² The requestor is charged a fee for copying the documents, and must also pay for the time staff spend searching for documents. The requestor can ask for a fee waiver if the documents will be used in the public interest and the information will be made available to the public.

Even with the information the EPA makes available, healthcare professionals are left to unravel this information for themselves and their patients. Doctors are often called upon not only to diagnose environmental illness but also to help their patients understand scientific data, sift through government records, even provoke regulatory action. Physicians should understand the legal framework, so that they may treat patients with complaints linked to environmental or occupational exposures with this regulatory structure in mind. This may be especially important when a patient presents with a condition that does, or may at some future time, warrant further action either through the filing of a complaint with the agency or by initiating legal action. While a full understanding of the laws and regulations and an assessment of any claims should be left to an attorney with knowledge of environmental law, the following summary presents an overview of the laws with which treating physicians should be familiar.

Pesticide law: FIFRA and FFDCA

Two laws deal with the impacts on human health resulting from the use of pesticides: the Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA),¹³ and the Federal Food, Drug, and Cosmetic Act (FFDCA).¹⁴ Under FIFRA, a pesticide cannot be sold or distributed in the United States until it is registered by the EPA. Registration of a pesticide means that it has been approved for sale and use. The EPA must make a determination that the pesticide, when considered with any restrictions imposed regarding its use, will perform its intended function and will not generally cause unreasonable adverse effects on the environment when used in accordance with widespread and commonly recognized practices. This determination is based on a balancing of the economic, social, and environmental costs against the benefit the pesticide provides. FIFRA also gives the EPA the authority to request any data necessary from the manufacturer to ensure that the product will not likely cause unreasonable adverse effects.

FIFRA has been amended several times to account for increasing public concern about the adverse effects of pesticides, and the advancement of scientific knowledge. In 1988, Congress amended FIFRA to require the re-registration of over 600 pesticides using the science reflected in the EPA's updated practices.¹⁵ As part of this process, EPA produces Re-registration Eligibility Decision documents (REDs) and risk assessments. Both the risk assessments and the REDs are published documents that contain valuable summaries of the health effects, ecologic and occupational risks of individual pesticides.¹⁶

The Federal Food, Drug, and Cosmetic Act (FFDCA) is the nation's major law regulating contaminants in food, including pesticides. While the Food and Drug Administration (FDA) implements most of the FFDCA, the EPA carries out its pesticide standard setting provisions. Under the FFDCA, the EPA establishes tolerances (maximum legally permissible levels) for pesticide residues in food. Any pesticide chemical residue in or on a food is considered unsafe unless a tolerance or an exemption is in effect, and the residue is in compliance with that tolerance or exemption.

The Food Quality Protection Act of 1996 (FQPA) amended both the FIFRA and the FFDCA, setting a tougher standard for pesticide use on food. This law fundamentally changed the way the EPA regulates pesticides by mandating a health-based standard aimed at protecting infants and children. Under the FQPA, the EPA is required to reassess the safety of all existing tolerances by August 2006. The EPA must now consider the public's total exposure to pesticides (through food, water and home environments) when setting tolerances for pesticide levels on food. These decisions must protect infants and children whose developing systems may be more sensitive to pesticide exposure. The law also requires the EPA to determine whether a pesticide has a common mechanism of toxicity with any other pesticides.

FQPA also requires the EPA to establish and implement the Endocrine Disruptor Screening Program to test chemicals for endocrine effects. Congress specifically addressed

the issue of endocrine disruption in the Food Quality Protection Act (FQPA) and Safe Drinking Water Act amendments of 1996. The Endocrine Disruptor Screening Program focuses on providing methods and procedures to detect and characterize endocrine activity of pesticides, commercial chemicals, and environmental contaminants. This information will be available to members of the public, and will help guide regulatory action.

Toxic chemicals: TSCA

In 1976, Congress enacted the Toxic Substances and Control Act (TSCA)¹⁷ fueled by public concern over polychlorinated biphenyls (PCBs) and their persistence in the environment. TSCA, administered by the EPA's Office of Toxic Substances, authorizes the agency to regulate the manufacture, distribution, import and processing of industrial chemicals and heavy metals and require their testing. TSCA directs the EPA to conduct a risk-benefit analysis in determining the least burdensome manner in which to reduce the risk a chemical poses while considering the benefits provided by the chemical or chemical process.

Perhaps the most valuable aspects of TSCA to physicians are the data-gathering provisions. Under TSCA, the EPA has the authority to gather exposure and health data on a broad spectrum of chemicals. Data submissions required from industry, and other databases with information on approved chemicals, provide a valuable body of information, though often not in a user-friendly form. The EPA can require manufacturers, importers and processors of chemical substances to maintain records and report such data as the EPA may reasonably require, including chemical or mixture identity, use, health and environmental effects. Under TSCA, companies can be required to record, retain and in some cases report 'allegations of significant adverse reactions' – reactions that may indicate a substantial impairment of function or long-lasting or irreversible damage to health or the environment. Information on unpublished studies pertaining to the effects of chemicals submitted by industry to the EPA is available in the Toxic Substances Control Act Test Submissions (TSCATS) database.¹⁸

TSCA's intent was to give the EPA the authority to monitor the more than 75,000 chemicals currently produced or imported into the US. Unfortunately the law has failed to fulfill its original intent, in part because courts have generally placed a heavy burden of proof on the EPA in regulating under TSCA. The EPA cannot even require testing of a chemical until the compound is shown to present an 'unreasonable risk' or may pose a substantial or significant environmental or human health hazard. The interpretation of the term 'unreasonable risk' has generally been very strict, and the EPA has acted only rarely to regulate toxic chemicals using its authority under TSCA.¹⁹

Toxic waste: Superfund and RCRA

In 1980, Congress enacted the Comprehensive Environmental Response, Compensation and Liability Act (CERCLA), commonly known as 'Superfund', to require the clean-up of

sites contaminated with toxic waste. The EPA's Office of Emergency and Remedial Response (OERR) has the authority to respond to releases or threatened releases of hazardous substances that may endanger public health or the environment. CERCLA is retroactive, allowing the EPA to hold liable those responsible for disposal of hazardous wastes before the law was enacted in 1980. CERCLA also established a trust fund to provide for clean-up when no responsible party can be identified.

CERCLA was amended in 1986 by the Superfund Amendments and Reauthorization Act (SARA).²⁰ The amendments strengthened the focus on human health risks from hazardous waste sites and encouraged greater citizen participation in making decisions on clean-up. Title III of SARA is an important source of public information, and is also known as the Emergency Planning and Community Right-to-Know Act (EPCRA). EPCRA requires the EPA to develop and maintain a toxic chemical database known as the Toxics Release Inventory (TRI).²¹ This publicly available database contains information regarding toxic chemicals that are manufactured, treated, transported, or released into the environment. Manufacturers and facilities that use hazardous chemicals are required to report information on their discharges to air, water, land, and their transport for off-site disposal. There are over 600 chemicals that are subject to reporting on the TRI. TRI information is publicly available and accessible electronically. EPCRA also requires that emergency responders, including healthcare personnel, must have immediate access to information on what chemicals are released at any manufacturing facility in the event of an emergency.

CERCLA also created the Agency for Toxic Substances and Disease Registry (ATSDR). ATSDR, an agency of the US Department of Health and Human Services, is the principal federal public health agency involved with hazardous waste sites and emergencies resulting from releases of hazardous substances into the environment. ATSDR conducts health assessments at waste sites, health consultations concerning hazardous substances, health surveillance and registries, information development and dissemination, and education and training. ATSDR evaluates communities in proximity to hazardous waste sites to identify priority sites for remediation.

ATSDR also prepares toxicologic profiles of common chemicals, and ToxFAQs, a series of summaries about hazardous substances.²² ATSDR maintains HazDat, a central database developed to provide access to information on the release of hazardous substances from Superfund sites, impacts on the general population and health information. ATSDR administers a National Exposure Registry (NER) to track the health status of individuals in communities that have been heavily exposed to specific contaminants. There are currently four active subregistries: trichloroethylene (TCE), 1,1,1-trichloroethane (TCA), benzene, and dioxin. An additional service provided by ATSDR is a referral network to occupational and environmental health clinics, including clinics with a pediatric focus (e.g., Association of Occupational and Environmental Clinics (AOEC) and Pediatric Environmental Health Specialty Units (PEHSU)).

The Resource Conservation and Recovery Act (RCRA) controls the transport, storage, and disposal of hazardous wastes onto land. RCRA was enacted in 1976 to address the management and disposal of municipal and industrial waste. RCRA is administered by the EPA's Office of Solid Waste. RCRA sets standards for the transport, labeling, and disposal of waste and includes provisions for clean-up of existing contaminated sites. The EPA and the states enforce these standards through a monitoring program using inspections, reviews, and sampling to determine a waste handler's compliance with the RCRA requirements. Under RCRA, citizens are authorized to bring direct enforcement actions against violators, known as a 'private right of action' under the law.

Air and water: the Clean Air Act, Clean Water Act, and Safe Drinking Water Act

The EPA regulates the risk posed by air pollutants to human health and the environment through the Clean Air Act (CAA), which regulates air emissions from area, stationary, and mobile sources by setting limits on how much of a pollutant can be in the air anywhere in the United States.²³ The law allows individual states to have stronger pollution controls, but prohibits weaker pollution controls than those set nationwide. The CAA established two types of national air quality standards: primary standards set limits to protect public health; and secondary standards protect public welfare, visibility and damage to animals, crops, and structures.

The CAA requires the EPA to promulgate National Ambient Air Quality Standards (NAAQS) for pollutants which the EPA has determined pose a risk to public health. These standards must be set at levels that protect the most sensitive members of the population, such as asthmatics, with a margin of safety. The EPA may require facilities emitting pollutants to conduct air quality monitoring, the results of which are made public.²⁴

Each state must devise a State Implementation Plan (SIP), a collection of the regulations a state will use to clean up the air in polluted areas, which the EPA must approve. Standards are then administered by the states. The EPA assists the states by providing scientific research, engineering designs and money to support clean air programs. The goal of the Clean Air Act was to set and achieve NAAQS for every state by 1975; however, many areas of the country failed to meet the deadlines. In 1990 the Act was again amended to address previously overlooked problems such as acid rain, ground-level ozone, stratospheric ozone depletion, and air toxics. In 1997, the EPA set more stringent health-based standards for ozone and particulate air pollution. According to the American Lung Association, in the period between 1999 and 2001, approximately 137 million people in the US were living in areas that do not meet the new NAAQS.²⁵ The 1990 CAA established a permitting program for major air pollution sources such as power plants, enabled the EPA to fine violators, and included provisions to reduce interstate air pollution. The CAA was also important in setting the stage for the federal

citizen suit. This provision, now contained in many environmental laws, allows any person to bring a civil action against any other entity, including the EPA, to enforce the law.

The Clean Water Act (CWA) is a 1977 amendment to the Federal Water Pollution Control Act of 1972.²⁶ The CWA sets the goal of making all the nation's waters fishable and swimmable, and gives the EPA the authority to set national water quality standards for contaminants in surface waters. The CWA makes it unlawful for any person to discharge any pollutant from a point source into navigable waters unless a permit is obtained.²⁷ Permits control the amount and concentration of pollutants discharged into lakes, rivers, or the ocean. The EPA is charged with the duty of monitoring which dischargers are violating their permits. Unfortunately, this basic information is not available to the public through the EPA's Office of Water website.²⁸ The US Geological Survey also provides a wealth of information on the nation's water.²⁹

The Safe Drinking Water Act (SDWA) was established to protect the quality of drinking water. Originally passed in 1974 and amended in 1986 and 1996, the SDWA does not regulate private wells serving less than 25 people. The law focuses on surface water and ground water actually or potentially designated for drinking. The Act authorizes the EPA to establish national primary drinking water standards (NPDWS) for drinking water. NPDWS set enforceable maximum contaminant levels for physical, chemical, biologic, or radiologic substances in drinking water sources. The EPA sets these standards by identifying contaminants that may adversely affect public health and that occur at a level and with a frequency that pose a threat to public health. The EPA determines an unenforceable maximum contaminant level goal (MCLG) at a level below which there is no expected health risk. Finally, the agency sets a maximum contaminant level (MCL), the maximum legally permissible level of a contaminant in treated drinking water. The MCL may be significantly higher than the MCLG, because it takes into account the maximum contaminant level goal, and the cost of achieving the level. The SDWA also contains a provision permitting citizens to file lawsuits in federal court in response to violations of drinking water standards by water suppliers or in response to the actions of the EPA.

Some of the more important features in the SDWA are its right-to-know components. The Consumer Confidence Report is the centerpiece of the right-to-know provisions in the SDWA Amendments of 1996. Water suppliers must produce annual drinking water quality reports for their customers. These reports enable the public to make informed decisions about their health and their environment by providing information about the source of local drinking water; the level of any contaminant found and the MCL for comparison; the likely source of any contaminant detected, and the potential health effects of any contaminants detected in violation of an EPA health standard. Physicians should familiarize themselves with these reports as they can be confusing, and patients may require assistance interpreting the reports. The EPA maintains drinking

water data in several databases. The Safe Drinking Water Information System (SDWIS) is the EPA's national regulatory compliance database for the drinking water program. It includes information on the nation's 170,000 public water systems. The National Contaminant Occurrence Database (NCOD) tracks contaminants in drinking water to support the EPA's decisions regarding which contaminants to regulate.³⁰

TORT LAW

With few exceptions, 'no-fault' workers' compensation is an injured worker's exclusive remedy against an employer. Nevertheless, tort litigation is increasingly common in occupational and environmental health. In some states, for example, a worker may sue an employer whose conduct is egregious and malicious, or if the conduct results in death; worker lawsuits are also sometimes directed against manufacturers and suppliers of chemical products, tools, or devices used in the workplace, or against other involved parties (e.g., a ventilation contractor). Individuals and communities in environmental exposure situations may also rely on tort law as a way of seeking compensation for their alleged injuries. A common public misperception of tort law is that juries typically award undeserving plaintiffs millions for minimal injuries. In fact, most tort cases are settled prior to trial and many that go to a jury for decision end up with a verdict for the defendant. Jury awards in tort cases are designed to compensate a person who has been wronged and who has suffered wage loss, medical expenses or other 'special damages' and who has also endured pain and suffering. When a jury finds the conduct of a defendant to be malicious, fraudulent or otherwise grossly appalling, punitive damages may be awarded to teach the wrongdoer a lesson and to try to deter similar conduct in the future. As a result, a small proportion of highly publicized lawsuits do end with large jury awards for the plaintiff.

The role of the treating physician in tort cases

When a patient brings a legal claim for compensation and asserts that a third party (the 'defendant') is legally responsible for an injury or illness, the records of treatment for that injury or illness may be subpoenaed and entered into evidence as part of the legal process. Subpoenas may also request records of a patient's prior medical history. Disputes over the relevance of old medical records may arise, along with debates about a patient's privacy and what is a legitimate scope of inquiry. Besides producing records of treatment when obliged to do so, the treating physician may be asked to testify as to the nature and extent of injury and the patient's prognosis. This process starts with a deposition, an out-of-court question and answer session, under oath, before a court reporter. Treating physicians may also be required to give testimony in court if the case proceeds to trial. Sometimes the treating physician will be asked about recognized risk factors for the patient's injury or condition,

and for an opinion on likely contributing causes in the individual case.

In cases of occupational or environmental exposure and disease, specialties in science and medicine that are germane to issues of causation generally include toxicology, epidemiology, occupational medicine, and industrial hygiene. A treating physician with knowledge and experience in such a field can be an effective witness whose opinion on causation will be given great weight. Conversely, a physician who does not customarily address issues of causation of occupational or environmental injury or disease in his/her regular medical practice may choose to defer to a physician or scientist who does specialize in such issues. Witnesses who are paid by litigants to express their opinions in the legal process are potentially vulnerable to charges of bias. At the same time, judges and jurors are sorely in need of expert assistance and interpretation in working their way through the complex medical and scientific issues raised in occupational and environmental health cases.

Admissibility of expert opinions

In 1923, a federal court held that an expert opinion should only be admitted at trial if the proponent of the opinion could demonstrate that the expert's views and opinion had been 'generally accepted' in the relevant scientific community.³¹ In the 70 years following the so-called Frye decision, both the federal courts, as well as virtually every state court in the United States, relied upon the Kelly/Frye rule for admissibility of expert opinion. The California Supreme Court clarified that courts often refer to the narrow, 'common sense' purpose of the Kelly/Frye rule: to protect the jury from techniques which, though 'new' or 'experimental', convey a 'misleading aura of certainty'. The California court has specified that 'Kelly/Frye only applies to that limited class of expert testimony which is based in whole or part, on a technique, process, or theory which is *new* to science and, even more so, the law'.³² Many would argue that expert opinions about the likely causal factors in disease are not appropriate for Kelly/Frye evaluation for the reason that the generally accepted methodology for evaluating causation is a weight-of-the evidence approach as outlined by Bradford Hill many decades ago, and is not a new or untried technique at all.

In 1993, the United States Supreme Court ruled, in *Daubert v. Merrell Dow Pharmaceuticals Inc.*, that in jurisdictions which follow federal rules of evidence, the Kelly/Frye rule for admissibility of expert scientific testimony has been pre-empted by a subsequently enacted federal rule of evidence, the Federal Rule of Evidence 702.³³ Some jurisdictions continue to use the Kelly/Frye rule, others use the test of admissibility outlined in *Daubert*.

Under *Daubert*, a trial judge deciding whether to admit expert scientific testimony at trial should specifically determine whether the expert's testimony: (1) reflects 'scientific knowledge' and (2) will assist the judge and jury in understanding or determining a material fact at issue. These determinations, in turn, require a specific assessment as to

whether the reasoning or methodology underlying the testimony is 'scientifically valid' and whether that reasoning or methodology can properly be applied to the facts at issue.

The Court explained that many factors will bear on these assessments, including whether the scientific hypothesis can be (and has been) tested, whether it has been subjected to peer review and publication, its error rate, and whether the theory or technique has attracted widespread acceptance within a relevant scientific community. The Court indicated that the judge's analysis should be flexible, and no one factor should be considered determinative. The Court further emphasized that, *for purposes of determining admissibility of testimony, the focus must be on the principles and methodology underlying an expert's testimony, rather than on the expert's conclusions.*

In theory, this approach appears comparable to the Kelly/Frye rule still used in many state court jurisdictions. In practice, Daubert has given judges greater latitude in deciding whether to admit or bar experts from testimony in tort litigation. Despite the apparently reasonable standards laid out by the Supreme Court in Daubert, lower courts have taken divergent approaches to implementing the decision. Some federal courts have indicated that scientific opinions are admissible when they are based on methods reasonably or traditionally relied on by other experts in the same field, and the fact that such an opinion does not conclusively establish a cause-effect relationship will not render the opinion inadmissible under Daubert.³⁴

In a key federal district court case, however, the judge barred the plaintiff's witnesses from testimony, reasoning that they did not engage in activities in a relevant field of expertise. The question at hand related to the potential teratogenic effects of a medication, and the plaintiff witnesses were experts in clinical medicine, pharmacology, and toxicology. The judge ruled that the only relevant and admissible field of expertise would be teratology.³⁵ Other courts have barred experts from presenting testimony based on case reports or case studies, or even based on animal studies, saying that these cannot reasonably be relied upon to support causation.³⁶ One court excluded expert testimony on the association between ethylene dioxide and brain tumors because the expert was relying on animal studies rather than human epidemiologic studies, even though the substance is classified as a carcinogen by regulatory agencies.³⁷

Scientific uncertainty and the standard of proof

In tort cases, judges and juries are expected to decide whether, in light of the available evidence and data, it is more likely than not, to a reasonable degree of scientific and medical certainty, that a given exposure was a substantial contributing factor in the production of a specific disease or condition. It is not unusual for the state of evidence to be incomplete or subjected to the degree of scientific rigor that physicians are taught to expect of

scientific data. In law, the relevant question is whether the exposure, activity or conduct in question was a substantial contributing cause to the outcome. It need not be the sole cause. The degree of confidence that it was a contributing cause is sometimes expressed in probabilities – that it is more likely than not that it was a contributing cause (a 51% probability) or the 'preponderance of the evidence' indicates that it is a contributing cause. This is a different concept than 'beyond a reasonable doubt', the standard in criminal cases. The standard in tort cases is also different from the concept that an association can be considered to be causal only if it satisfies a test of statistical significance. In the courtroom, questions of causation generally draw on the disciplines of epidemiology, toxicology, industrial hygiene, occupational medicine, and clinical medicine, as interpreted and explained to the judge or jury by appropriately trained, qualified and experienced practitioners from these disciplines.

Physicians and scientists routinely use guidelines based on those proposed by Bradford Hill for assessing causation when they express opinions about causation in legal proceedings.³⁸ Because the Bradford Hill guidelines are well recognized and widely used in the scientific and medical community, their use as a methodologic approach for assessing causation is generally accepted in the courtroom. Consistency, specificity and strength of the association, the existence of an animal model, biologic plausibility of the putative association, temporality, and reasoning by analogy are all relevant considerations. None is a *sine qua non*. Further, diagnostic conclusions should be based on a consideration of differential diagnostic possibilities.

Challenges in tort litigation

Despite the lowered standard of proof compared to the 'beyond a reasonable doubt' standard in criminal cases, it can still be quite challenging to prove causation in a toxic tort context. In many cases of potential association between an occupational or environmental exposure and disease, there is likely to be less scientific research to draw on for determining causation than in situations such as those involving pharmaceutical drugs, where medical records of dosage and pre-market testing data are generally available. Many occupational and environmental diseases have long latency periods, making it a challenge to associate current illnesses with exposure that may (or may not) have occurred many years in the past. The requirement of the federal Hazard Communication Standard of 1986, that employers maintain exposure records for a 30-year minimum, is a helpful start in uncovering the nature and extent of potentially contributory exposures on the job. Biologic monitoring and medical surveillance data can be of particular use in documenting past exposures. At the same time, it is well recognized that people live complicated lives with numerous potential exposures in their homes, communities and workplaces. The identification of a substantial contributing cause can become very confusing when there are numerous potential causal factors. Studies on the health outcomes of persons engaged in similar work as the litigant and/or with

similar exposures can shed useful light on causal factors, especially when the studies report consistent patterns, can detect dose–response trends, and are consistent with what is generally understood about the biology of the disease in question.

Establishing a causal connection in an individual case can be challenging for a variety of reasons. First, the sciences of toxicology and epidemiology have inherent limitations that narrow the interpretations one may draw from the available data; thus different evaluators may draw very different conclusions from the same overall body of literature. Animal data can provide a framework for evaluating the potential of a chemical to cause or contribute to effects in humans, but extrapolation from animal data to human risk requires consideration of inter-species differences, dosage, route of exposure, and whether mechanistic studies indicate likely relevance of the animal finding in humans. Completely controlled human studies are often out of the question due to ethical concerns about intentionally dosing humans with a toxic chemical to monitor its effects. In the real world, workers exposed to toxic materials are much more likely to be exposed to a mix of chemical compounds than to a single chemical, as would be the case in an animal toxicology experiment.

Epidemiologic studies may also be of limited application standing alone because of small or unrepresentative population sizes, inability to control for all confounding variables, difficulties in measuring historic exposure, and risks of recall bias. Judges have often been unfriendly to conclusions based on in-vitro studies, toxicology studies, and case reports, often demanding several positive, statistically significant epidemiologic studies prior to allowing evidence to come before a jury.³⁹ In this regard, under a ‘weight-of-the-evidence’ approach, a series of studies which consistently report positive associations between a given exposure and a disease endpoint may provide a compelling case for causation, even if none standing alone ‘proves’ the association. This observation is well to keep in mind given the struggle that some courts have had with epidemiologic data – sometimes according it much more and sometimes much less weight than the epidemiologic community itself would.

Several courts have narrowed the admissibility of epidemiologic studies since *Daubert*. Courts have ruled, for example, that it is unreasonable for experts to rely on studies with a relative risk less than 2.0 to support causation,⁴⁰ or that experts cannot present or rely on data from epidemiologic studies if the studies are not statistically significant with a *P* value less than 0.05, or with a confidence interval that includes one. These rulings appear to many to unduly narrow the scope of admissible evidence in tort cases, to accord less weight to epidemiologic data than scientists do, and to exclude studies that could be scientifically relevant to the understanding of causation.

The sciences of epidemiology and toxicology, as well as the structure of the laws and the rules by which regulatory agencies operate, make it possible to deal with some issues such as risk assessment and the consideration of precautionary principles on a population level. These same

scientific tools and disciplines may also be useful and relevant in the situation that a clinician is most likely to be addressing – an individual instance of disease in a given patient. In this individual context, a concerned clinician has an opportunity to become involved in a constructive way, usually in conjunction with the input of specialists in such disciplines as occupational medicine, toxicology, industrial hygiene, and epidemiology.

Clinicians can contribute to a better societal understanding of the role of occupational and environmental exposures in the development of disease and thus assist in preventing future instances. These same efforts help individuals to document the prevalence of disease among similarly exposed persons. For example, the treating physician should make a patient’s work history and exposure information a routine and readily abstractable part of the chart, along with standard social history and life style information. Patients often assume that their treating physicians know if a job or environmental exposure is a risk factor for disease and will not necessarily volunteer information if the treater does not show interest in eliciting it. The treating physician should also participate in coordinated efforts to report and track exposures and disease. The observations of astute clinicians have played a significant role in the discovery of many exposure/disease connections.

Regulators, legislators, judges, and juries with no scientific background must often weigh scientific information to make necessary legal decisions – some involving individuals who are already sick, some affecting populations at risk for future disease. Often these decision makers must call on physicians or other scientists to help interpret the science and guide appropriate health-protective decisions. The clinician should be aware of the resources available through government agencies, and should be able to direct a patient to these resources as appropriate.

Chapter 57

Legal and Regulatory Issues in the Workplace

57.1 Government Agencies/Statutes/Legislation

Mark A Rothstein

PHYSICIAN–PATIENT RELATIONSHIP IN THE OCCUPATIONAL SETTING When does the relationship exist?

Traditionally, the physician–patient relationship has been based on the contract created when an individual selects a physician and the physician agrees to perform certain medical services. The contract model does not seem appropriate, however, when the physician is selected and paid by a third party rather than the individual recipient of the medical services. This third-party relationship, which applies in many employer-required medical examinations, is not unique to the occupational setting. Insurance, Social Security, workers' compensation, and other third-party medical examinations involve similar relationships.

Historically, the law has provided that there is no physician–patient relationship between an individual and a third-party physician, including in the occupational setting.¹ There is some evidence, however, that this view is changing, and the current state of the law is unclear. Courts that adhere to the dichotomy between employer-provided and traditional, patient-obtained medical care look to whether the physician is treating or merely examining the individual or for whose benefit the physician is performing the service. When the physician is merely examining the individual to determine employability or performing services for the benefit of the employer, no physician–patient relationship has generally been found. If the physician renders treatment² or is providing services for the benefit of the employee,³ then a physician–patient relationship may be found.

These distinctions between employer-provided and patient-obtained medical care are probably too simplistic and artificial when applied to contemporary practice. Today, physicians employed by corporations examine *and* treat; their services may benefit *both* employer and employee. Similarly, patient-chosen physicians may increasingly assume roles in recommending and promoting changes in the workplace environment. However, independent medical examinations to determine the presence or extent of disability continue to stand outside the realm of the doctor–patient relationship.

Legal consequences of relationship or absence of relationship

If a physician–patient relationship is established, a physician is required to use 'that degree of care, skill and proficiency which is commonly exercised by the. . . careful and prudent physician engaged in similar practice under the same or similar circumstances'.⁴ The standard of care required of a specialist is higher. It is the degree of care, skill, and proficiency commonly exercised by a specialist in good standing.

In the context of an occupational medical examination, the physician–patient relationship would establish a number of duties on the part of the physician. These include the duty:

- to inform the patient of his or her conditions and of all medical facts of which the patient reasonably should know;
- to notify the patient of the results of tests and of the physician's diagnosis, including issues of work-relatedness and impairment;
- to inform the patient of the need for treatment;
- to refer the patient to a specialist;
- to give the patient proper instructions for self-care;
- to advise the patient of the conditions that could aggravate the illness; and
- to preserve the confidentiality of the patient's medical information.

When there is no physician–patient relationship, most, if not all, of these duties are inapplicable. Some courts hold that the physician has no duty except to avoid injuring the individual during the course of the examination. Other courts hold that the physician owes the individual some degree of reasonable care or, if the physician undertakes to give some medical advice during the course of the examination, to exercise the same degree of care as one who renders services gratuitously.

Liability issues

Employer-salaried and, to a lesser extent, employer-retained independent contractor physicians are generally immune from employee lawsuits for two reasons. First, the existence of a legal duty to act with reasonable care usually depends on a physician–patient relationship. Second, co-employees (including a co-employee physician) may not

be legally responsible for harms sustained by the employee because of workers’ compensation laws, which limit liability of an employer and all co-employees to that which can be recovered under workers’ compensation.⁵ Nevertheless, there are exceptions.

As in more traditional medical malpractice cases, an injury caused during the course of an employer-mandated medical examination could establish liability on the part of the examining physician as well as that of the employer.⁶ Not surprisingly, these situations are rare. A more common allegation is that in conducting a medical examination, the physician failed to diagnose a serious illness and the delay in treatment aggravated the individual’s condition or reduced the likelihood of successful treatment. Even though an employer may be under no duty to conduct an examination, once the duty is assumed, any negligence in performing the examination may be actionable. For example, in *Green v. Walker*,⁷ the defendant physician contracted with an employer to perform an annual physical examination of an off-shore cook. The physician then allegedly negligently failed to diagnose the early stages of lung cancer, and the employee subsequently died. In a medical malpractice action brought by the man’s widow, the United States District Court for the Eastern District of Louisiana granted summary judgment to the defendant on the ground that there was no physician–patient relationship. The United States Court of Appeals for the Fifth Circuit reversed this ruling. According to the court, even in the absence of a traditional physician–patient relationship, a physician owes a duty of reasonable care to an employee undergoing an employer-mandated medical examination.

Another theory on which plaintiffs have sued is that a negligent medical assessment resulted in an improper job placement.⁸ Actions against employer-salaried physicians and employers for improper job placement normally are found to be barred by workers’ compensation, but actions against independent contractor physicians are more likely to be successful.

Besides providing medical examinations, some company physicians become involved, to varying degrees, in the actual treatment of employees, from first aid to ongoing care. A number of lawsuits have alleged malpractice in treatment. Again, although most personal injury actions have been barred by workers’ compensation,⁹ in some cases of alleged negligent treatment, the courts have held that the plaintiffs have stated a legally cognizable claim.¹⁰

MEDICAL EVALUATION UNDER THE AMERICANS WITH DISABILITIES ACT

Coverage

The Americans with Disabilities Act (ADA) of 1990¹¹ is the first comprehensive federal law to prohibit discrimination in employment against an estimated 43 million Americans

with physical or mental disabilities. The ADA covers most private employers and state and local government employers. Federal employers are covered under comparable provisions of the Rehabilitation Act.¹² The ADA does not pre-empt state discrimination laws (such as a state law that covers small employers). The enforcement procedures and remedies are the same as exist under Title VII of the Civil Rights Act of 1964, which prohibits discrimination based on race, color, religion, sex, or national origin, and is enforced by the Equal Employment Opportunity Commission (EEOC).

Medical examinations

The ADA limits the way companies and physicians may assess the health status of applicants and employees (Table 57.1.1). Section 102(d)(2) of the ADA prohibits pre-employment examinations and questionnaires. An employer may not ‘conduct a medical examination or make inquiries of a job applicant as to whether such applicant is an individual with a disability or as to the nature or severity of such disability’. The only permissible inquiries are about the ability of the applicant to perform job related functions. For example, an employer could ask if an applicant had a driver’s license or could climb telephone poles, if these tasks were part of the job, but could not ask about specific medical conditions.

After a conditional offer of employment, an employer may require an ‘employment entrance examination’ (pre-placement examination) pursuant to Section 102(d)(3). These examinations, however, must be given to all conditional offerees, regardless of disability. Certainly, the examinations need not be identical for each individual and may vary based on the job requirements; the age, sex, and medical history of the individual; and other factors.

Pre-placement examinations need not be job related, although only job-related medical criteria may be used to screen out qualified individuals with disabilities.¹³ Thus, many physicians limit pre-placement examinations to assessing medical conditions that bear directly on the individual’s ability to perform the job. Among other things, this means that physicians:

- tailor each examination to the specific demands of the job;
- only use medical screening procedures with a high positive predictive value (thus precluding, for example, the use of low-back X-ray studies for screening out asymptomatic individuals); and

Timing	Legality
Pre-employment examinations	Impermissible
Pre-placement examinations (after conditional offer of employment)	Permissible
Current employee examinations	Permissible if job related or voluntary

Table 57.1.1 Medical examinations under the ADA

- use less comprehensive examinations for less physically demanding jobs.

The limited scope of pre-placement examinations under the ADA suggests two necessary responses by examining physicians. First, individuals undergoing an examination should be informed of the limited nature of the medical assessment and advised that it is not designed to substitute for a comprehensive examination by their personal physician. Although legal, broad release forms authorizing access to all private medical records of an individual result in employers obtaining more medical information than may be lawfully used. Thus, physicians and employers should consider more limited releases.

Records, disclosures, and accommodations

Section 102(d)(3) of the ADA regulates medical records. '[I]nformation obtained regarding the medical conditions or history of the applicant [must be] collected and maintained on separate forms and in separate medical files and [must be] treated as a confidential medical record. . . .' For most companies with on-site medical facilities, this is standard procedure already. Most problems arise at facilities without on-site medical departments that use contract physicians to perform pre-placement examinations. These contract physicians frequently do not want to maintain huge files of non-patients who were examined only once. Although EEOC regulations to implement the ADA do not address this issue, it would appear that an employer would be in compliance if contractor-generated medical records were stored at the worksite separate from other files, and with controlled access.

The ADA also limits the disclosures that physicians can make to non-medical personnel. Section 102(d)(3) provides that 'supervisors and managers may be informed regarding necessary restrictions on the work or duties of the employee and necessary accommodations'. They may not be given any other medical information, such as specific diagnoses. This provision is consistent with principles of confidentiality addressed in Chapter 55, and mandated under the Health Insurance Portability and Accountability Act (HIPAA), 1996, which went into effect in 2002. Releases authorizing wider disclosure of medical information raise substantial legal concerns. Significantly, because Section 104(d) provides that a drug test is not a 'medical examination', disclosing the results of a pre-placement drug test to management would be legally permissible (although arguably in contravention of appropriate ethical principles).

Section 103(d) of the ADA, dealing with infectious and communicable diseases, permits the exclusion of individuals from food-handling jobs if they have an infectious or communicable disease (such as hepatitis A) that the Secretary of Health and Human Services determines may be transmitted through food handling. Although the ADA does not contain any express provisions concerning HIV, it is clear that HIV testing, isolation, or other discrimination against people who are seropositive for HIV or who have

AIDS is unlawful under the ADA, if the individuals with or without reasonable accommodation are otherwise qualified and capable of performing job-related duties.

The ADA provisions applicable to periodic medical examinations of employees are more explicit than those applicable to pre-placement examinations. Pursuant to Sections 102(b)(6) and 102(d)(4), all medical examinations and inquiries must be 'job-related and consistent with business necessity'. Employers may offer medical examinations of a non-job-related nature, such as comprehensive medical examinations and wellness programs, but employee participation must be voluntary.

The responsibility of occupational physicians may encompass determining what 'reasonable accommodation' will permit an otherwise qualified individual with disabilities to perform the job. According to Section 101(9) of the ADA, reasonable accommodation may include making facilities accessible; job restructuring; part-time or modified work schedules; reassignment to a vacant position; modification of equipment; appropriate adjustment of examinations, training materials, or policies; and the provision of qualified readers or interpreters. Reasonable accommodation is not required, however, if it would impose an 'undue hardship' on the employer based on the nature and cost of the accommodation, the size and financial resources of the facility or company, and the nature of the workforce.

One of the many reasons an individual with disabilities may be considered medically unqualified for a particular job is the employer's concern that the individual may pose a safety or health threat to the individual, coworkers, customers, or the public. Section 103(b) provides that 'the term "qualification standards" may include a requirement that an individual shall not pose a direct threat to the health or safety of other individuals in the workplace.'¹⁴ Although this language is narrow and does not include harm to the individual employee with a disability, the interpretive regulation of the EEOC is broader. It defines 'direct threat' to include the affected individual, requires these determinations to be made on the basis of reasonable medical judgment, and lists four factors to consider. These factors are the duration of the risk, the nature and severity of the potential harm, the likelihood that the potential harm will occur, and the imminence of the potential harm. The legislative history and the EEOC regulations make it clear that a 'direct threat' claim of an employer is difficult to prove. Patronizing assumptions, generalized fears, and speculative or remote risks are insufficient.

In *Chevron USA Inc v Echazabal*,¹⁵ an individual who had worked for independent contractors at a Chevron Oil refinery was denied a position with Chevron because he had a history of hepatitis C. Although he had worked at the facility for 20 years without any health problems, Chevron said that chemicals at the refinery could damage his liver. The Supreme Court held it was lawful for the employer to consider the individual's risk to 'self' as well as 'others'. Another case finding a direct threat involved an individual with uncontrolled epilepsy who worked with hazardous machinery.¹⁶

OCCUPATIONAL SAFETY AND HEALTH ADMINISTRATION (OSHA)-REQUIRED AND OTHER MANDATORY PRACTICES

Mandatory examinations

Generally speaking, there is no legal duty for an employer to perform pre-placement or other medical examinations. There are, however, some governmentally mandated employee medical examinations. These medical examinations are conducted for two main purposes:

- to protect the health and safety of the employee; and
- to protect the health and safety of the public.

Perhaps the best example of a medical examination designed to protect the health of employees is an OSHA-mandated examination. These examinations, however, only pertain to employees with exposure to about two dozen specific toxic substances¹⁷ (see Chapter 59). In general, physicians must furnish employers with a statement of suitability for employment in the regulated area; the employer must offer employees periodic (usually annual) examinations; and, in some instances, employers also must provide examinations at termination of employment. The failure to offer these required medical examinations may lead to the issuance of OSHA citations and the assessment of penalties.

Three of the most common questions regarding OSHA-mandated medical examinations are:

1. Is the medical examination mandatory?
2. Who selects the physician?
3. Who pays for the examination?

First, Section 6(b)(7) of the Occupational Safety and Health Act provides that medical examinations shall 'be made available' to exposed employees. OSHA has interpreted this language to mean that the employer must offer the examination; however, the employee may refuse to take the examination. Nevertheless, OSHA does not protect a refusal to participate. Unless the issue is covered by the terms of a collective bargaining agreement, an employer may make cooperation with medical examinations a valid condition of employment.

Second, the Act does not specifically indicate whether the employer or employee has the right to select a physician to perform medical examinations. Early on, OSHA determined that the employer should have the option of choosing the physician and should have access to the results of the examination. This policy has been followed in all of the health standards.

Third, Section 6(b)(7) of the Act makes it clear that medical examinations shall be made available 'by the employer or at his cost'. OSHA's health standards have included language indicating that all costs for medical examinations must be borne by the employer. The employer also may be required to compensate employees for time spent taking the examination (outside normal working hours) and for extra transportation expenses.

Although physicians should be familiar with OSHA's medical examination provisions (see Chapter 59), these regulations may be of limited value for the following four reasons.

1. The provisions only apply to specific occupational exposures and, therefore, are of limited scope.
2. The provisions list required procedures but often give little guidance as to the significance of specific clinical or laboratory findings.
3. The provisions do not indicate what procedures or tests may or may not be performed.
4. With a few exceptions, there is no mention about what personnel actions are required, permitted, or prohibited on the basis of test or examination results.

Another law requiring medical examinations to protect employee health is the Mine Safety and Health Act.¹⁸ Section 203(a) of the Act requires that all miners working in a coal mine be given a chest X-ray study within 6 months after commencement of employment, a second X-ray study 3 years later, and a third X-ray study 2 years after that if the second X-ray study showed evidence of pneumoconiosis.

There are a number of federal laws mandating employee medical screening to protect the health and safety of the public. Two of the most important of these laws prescribe medical certification for over-the-road truckers and airline pilots. The Department of Transportation's (DOT) Bureau of Motor Carrier Safety has issued detailed regulations for the physical examination of drivers operating motor vehicles in interstate commerce.¹⁹ Successful completion of the examination is a prerequisite for driver certification. Physicians are provided with a form and instructions about specific conditions to evaluate. Similar regulations have been promulgated by the Federal Aviation Administration (FAA) for airline flight crews.²⁰ Unlike the motor carrier examinations, which may be performed by any licensed physician, aviation medical examinations may be performed only by physicians designated by the FAA under the auspices of the Federal Air Surgeon.

The DOT and FAA examinations contemplate a role for the physician different from that in other examinations. Because of concern for public safety, detailed procedures and standards have been adopted that remove a great deal of the discretion from the physician. If the standards are excessively stringent and serve to disqualify individuals who would normally be considered fit, it may be viewed as an acceptable price to pay for protecting the public.

A number of state laws also require pre-placement medical examinations to protect public health and safety. Among the occupations for which a medical examination may be mandated are teachers, school bus drivers, police, firefighters, divers, transportation, and maritime workers. Laws in many states also mandate the reporting of various occupational diseases.²¹

Access to exposure and medical records

The primary purpose of OSHA's rule on access to exposure and medical records is 'to enable workers to play a

meaningful role in their own health management'.²² The regulation applies to all covered general industry, maritime, and construction employers. It is, however, limited to employers having employees exposed to toxic substances or harmful physical agents. Unlike other OSHA record-keeping requirements, the access regulation does *not* require that certain documents be prepared but only that existing records be maintained and made available to employees and other parties designated in the regulation.

Any current or former employee being assigned or transferred to work where there will be exposure to toxic substances or harmful physical agents has a right of access to four kinds of exposure records:

- environmental monitoring records;
- biologic monitoring results;
- material safety data sheets; and
- any other record disclosing the identity of a toxic substance or harmful physical agent.

Any worker who has a right of access to exposure records may designate a representative to exercise access rights. Recognized or certified collective bargaining agents (i.e., labor unions) are automatically considered 'designated representatives' and have a right of access to employee exposure records without individual employee consent. OSHA also has a right of access to exposure records.

Access to employee medical records is more restricted (Table 57.1.2). Employees have a right of access to their entire medical files regardless of how the information was generated or is maintained. Excluded from the definition of 'employee medical record' are certain physical specimens, certain records concerning health insurance claims, and certain records concerning voluntary employee medical assistance programs. A limited discretion is also given physicians to deny access in cases in which there is a specific diagnosis of a terminal illness or psychiatric condition. Collective bargaining agents must obtain specific written consent before gaining access to employee medical records. OSHA has a right of access to employee medical records, but those records in a personally identifiable form are subject to detailed procedures and protections. The Occupational Safety and Health Review Commission has held that OSHA has a right of access to employee medical records as part of its enforcement process and in discovery before a Commission hearing.²³ The Commission also has held that a release referring only

to medical records does not require the disclosure of employee exposure records.²⁴

With a few exceptions, employers must preserve exposure records for at least 30 years and must preserve medical records for the duration of employment plus 30 years. With the exception of X-ray studies, employers may keep the records in any form, such as microfilm, microfiche, or computer disk. On receipt of a request, access must be provided in a reasonable time, place, and manner within 15 days. In responding to an initial request, an employer may provide a copy without cost, provide copying facilities at no cost, or may loan the record for a reasonable time. Administrative costs may be charged for subsequent copying requests.

Although identities of substances, exposure levels, and health status data may not be withheld, the employer may delete any other trade secret data that disclose manufacturing processes or disclose the percentage of a chemical substance in a mixture, so long as the employee or designated representative is notified of the deletion. Access to other trade secrets may be on written agreement not to misuse this information.

The access regulation also includes an exemption from record retention requirements for medical and exposure records for short-term employees (the short-term employee may be handed the records), permission for employers to store medical records on microfilm, protections for employer trade secrets, and a requirement that unions must have need before they may see an employee's exposure records without the employee's consent, thereby allowing employers to deny blanket requests.

Hazard communication

OSHA's original Hazard Communication Standard²⁵ covered an estimated 14 million employees in 300,000 manufacturing establishments. Among other things, it required chemical manufacturers and importers to assess the hazards of chemicals they produce or import, and all employers engaged in manufacturing to provide information to their employees concerning hazardous chemicals by means of hazard communication programs including labels, material safety data sheets, training, and access to written records. One of the purposes of the standard was to pre-empt state right-to-know laws.

The standard originally applied only to chemical manufacturers and importers (SIC Codes 20 to 39), applied only to 600 substances, and excluded hazardous wastes, foods, drugs, and pesticides. By contrast, many state right-to-know laws cover more classes of employers and many more substances.

An amendment to the Hazard Communication Standard expanded coverage beyond the manufacturing sector to cover all workers. The revised standard contains three new provisions:

- a requirement that at multi-employer worksites, employers exchange their material safety data sheets, either individually or through a central location;
- an exemption from labeling requirements for consumer products used in the same manner and quantities as intended for consumer use; and

WORKERS' COMPENSATION

General provisions

The workers' compensation system consists of a series of state and federal laws designed to provide income replacement, medical expenses, and rehabilitation services to individuals disabled by work-related injury or illness. Each state has its own workers' compensation law, and federal laws provide additional coverage for federal civilian employees, longshoring and harbor workers, seamen, railroad workers, and coal miners.

Workers' compensation is essentially a form of employer-provided life and disability insurance for work-related injury, illness, and death. With only a few exceptions, such as domestic household employees, all private sector employees are covered. For commercially purchased or state-administered plans, premiums are paid by the employer into an insurance fund, which pays worker claims. For self-funded employers, claims are paid directly by the employer. Work-related injuries are compensable without regard to who was at fault. Common law defenses, such as contributory negligence, assumption of the risk by the employee, and claiming the injury was caused by a co-employee, are inapplicable.

Workers' compensation law generally precludes an employee from suing or otherwise being reimbursed for injury or harm by the employer. Only third parties, such as suppliers of hazardous materials or equipment, can be sued (see Chapter 56). Further, the compensation laws do not preclude other types of defenses by an employer, such as that work did not cause the injury or illness. As in other legal actions, the burden remains on the employee who has been hurt or become ill to prove that an injury or illness is compensable.

Although each state law sets its own eligibility requirements, benefit levels, and claims procedures, most state laws are similar. An employee is usually required to notify the employer of an injury or illness, and to file a timely claim with the state agency that administers the workers' compensation system. All states have waiting periods before a claimant is eligible for benefits. In virtually all jurisdictions, contested workers' compensation cases are adjudicated by an administrative agency. This procedure is less formal than a court proceeding, and generally faster and less expensive. Denial of claims frequently results in lengthy appeal processes, especially in occupational disease cases. Further, the administrative determination is invariably subject to judicial review.

Eligibility for benefits

The claimant has the burden of demonstrating eligibility for workers' compensation, and this usually requires medical documentation of the claimant's injury or illness. In many states, the administrator of the workers'

compensation system has the authority to order the claimant to undergo a medical examination by an examiner selected and paid by the state agency. Refusal to submit to a medical examination will bar the recovery of benefits, but claimants usually need not submit to potentially dangerous or painful procedures.

Virtually all workers' compensation laws use a four-way classification of disabilities:

- temporary partial;
- temporary total;
- permanent partial; and
- permanent total.

Temporary claims are relatively easy to determine. Temporary partial disability is applicable when it is determined that the claimant is unable to perform at his or her regular job but is able to engage in some other gainful employment. Temporary compensation is based on wage loss and includes medical and hospital expenses. Temporary total disability exists when the claimant is unable to work at all for a limited period of time. All states have waiting periods (from 3 to 7 days) before a claimant is eligible for wage replacement benefits. There are usually no waiting periods, however, for medical benefits.

From a medical standpoint, it may be difficult to determine when the period of temporary total disability has ended or, if a degree of impairment remains, when the temporary total disability becomes a permanent partial disability. The dates most frequently used for deciding that a temporary total disability has become a permanent partial disability are the date the claimant has reached maximum medical improvement (i.e., no further improvement in medical status is anticipated), the date the impairment has become stationary, or the date the claimant is able to return to work.

Awards for permanent partial disability may be scheduled or unscheduled. Scheduled benefits are legislatively set and involve total or partial loss of use of specific body members, in cases in which wage loss is presumed. These scheduled benefits may be given in addition to benefits received for temporary total disability; in such cases the claimant is entitled to a scheduled payment, regardless of the economic consequences of the impairment. In other words, the basis of the award is medical impairment rather than wage loss.

For unscheduled permanent partial disability cases, the wage loss principle is generally used. Degree of disability is calculated by comparing the individual's earnings before the injury or illness with his or her earning capacity after the injury or illness. This later estimate, of course, depends on the medical determination of impairment as well as other non-medical factors relative to the claimant's employment opportunities.

Many workers' compensation laws and regulations are vague about the method to be used by examining physicians in calculating the claimant's level of impairment (see Chapter 8). Some states use the American Medical Association's Guide to the Evaluation of Physical Impairment (currently in the fifth edition); other states have their own systems. Commonly, the physician will

initially determine the degree of impairment caused by an injury or illness to a specific organ system or body part, and subsequently calculate the degree of impairment to the body as a whole.

Medical opinions

The examining or treating physician has two major responsibilities to the patient in workers' compensation matters. First, and most crucial, is determination of whether an illness or injury is, in fact, work related, the sine qua non of eligibility for this benefit as compared with others. For sudden injuries and acute diseases, this connection may be obvious; for chronic or delayed effects of work, determination of causation may be more challenging. The standard used in most compensation systems is 'more probably than not', or more than 50% likely to be work related. Although strategies for arriving at this opinion are beyond the scope of this chapter, the physician must recognize that the clinical continuum becomes a categorical 'all or nothing' as far as eligibility for this benefit is concerned.

The second obligation of the physician is determination of disability status. Part of this determination is entailed in the assessment of physical impairment, discussed in Chapter 8. However, the physician also must translate this clinical information into a decision about whether and what work the patient can do, because this factor is vital to the compensation system's decision about the assignment of benefits. This task requires knowledge not only of the illness or injury and the patient, but also of the job tasks, exposure, and physical demand requirements.

In workers' compensation cases, it is not unusual for there to be conflicting medical evidence concerning the work-relatedness or level of the claimant's disability. There is some disagreement among the states on how conflicting medical evidence should be resolved. The industrial commission or workers' compensation board is charged with determining which conflicting medical testimony is to be accepted. Deference usually is given to the opinions of the treating physician. The theory behind giving greater weight to the testimony of treating physicians is that a treating physician is likely more experienced than an examining physician with the specific health status of an individual patient. Although it could be argued that the testimony of some treating physicians may be affected by advocacy for their regular patients, the countering argument is that some third-party examining physicians may have biases, including financial interests, related to the third parties who have retained their services.

DRUG TESTING

Overview

Perhaps the most ubiquitous procedure performed in company medical departments is drug testing. Although pre-placement drug testing is most common, some companies also test 'for cause', post-rehabilitation, periodically, or randomly. Some companies limit testing to

employees in safety-sensitive positions; others test all applicants or employees.

Pursuant to an Executive Order issued by President Reagan in 1986,²⁶ about half of all federal government employees are subject to drug testing. Some comparable state laws also mandate the testing of state employees. In the private sector, certain employees in safety-sensitive jobs, such as transportation and nuclear workers, are subject to federally mandated drug testing. The Drug Free Workplace Act,²⁷ applicable to recipients of federal grants, requires grantees to have a written substance abuse policy but does not require drug testing. Therefore, most private sector drug testing has been voluntarily adopted by employers.

Drug testing is a forensic procedure rather than a medical test. Nevertheless, physicians are often assigned a major role in the process. For example, under the Department of Health and Human Services' guidelines for federal drug-testing programs, a 'Medical Review Officer' (termed 'MRO') is responsible for interviewing tested individuals about prescription drug use and reviewing and interpreting drug test results.²⁸

Legal issues

The legality, morality, and efficacy of drug testing remain subjects of great controversy. Whether drug testing is legal depends on many factors, including the following: whether the employment is in the public or private sector, whether the drug testing is government mandated, whether the employees are represented by a union, whether there is an applicable state drug-testing law, and whether the testing involves employees in safety-sensitive jobs (Table 57.1.3). In general, private sector employers are given great leeway in drug testing.

About half the states have enacted their own laws to regulate drug testing. The laws vary widely, and deal with issues such as whether probable cause is needed to test, which job classifications may be subject to testing, the permissible time for testing, sample collection methods, confidentiality, analytic methodology, and laboratory certification.²⁹

Because of the large number of potential legal issues involving drug testing, legal counsel should be consulted about these matters. Nevertheless, some general advice will help avoid problems. First, occupational health personnel must be particularly careful about maintaining the confidentiality of drug test results. Second, all drug-screening tests should be confirmed using gas chromatography, mass spectrometry, or comparable technology. Third, observed

1. Private or public sector?
2. Government mandated?
3. State drug-testing law?
4. Collective bargaining agreement?
5. Confirmatory testing used?
6. Pre-employment, pre-placement, periodic, for cause, or random?
7. Safety-sensitive position?

Table 57.1.3 Factors determining the legality of drug testing

urination is likely to be challenged as an invasion of privacy. Fourth, random testing is the most likely form of testing to be invalidated by the courts, and it is often considered unlawful except in cases of clear-cut public safety considerations.

57.2 Environmental Justice

Rachel Rubin, Linda Rae Murray

INTRODUCTION

Environmental and occupational hazards and the resultant illnesses, diseases and injuries caused by exposure to these hazards frequently go unrecognized. Modern industrial production generates pollutants that may contaminate surroundings and quality of life, and sometimes threaten human health.

The Environmental Justice movement is a global phenomenon, and reflects a challenge to the present distribution of rewards and burdens of our industrial world. In the US, the Environmental Justice movement reflects the confluence of several major social movements. In general terms, this movement reflects the blending of the civil rights movement, the broad movement for social and economic justice, and concerns for the environment. Some critics have attempted to interpret the Environmental Justice movement more narrowly as a debate about siting of toxic landfills and disproportionate burden of environmental hazards. In particular, the Environmental Protection Agency (EPA) defines Environmental Justice as ‘the fair treatment and meaningful involvement of all people regardless of race, color, national origin, or income with respect to the development, implementation, and enforcement of environmental laws, regulations, and policies’.¹ This definition neglects the relationship between environmental protection through promulgating and enforcing laws equitably, and ensuring environmental health and wellbeing. The struggle for environmental health inherently coexists with other social needs, including fair wages, safe jobs, access to quality healthcare, good schools and recreation facilities, adequate housing, and communities free of violence, drugs and poverty.²

The Environmental Justice movement at its core is concerned with challenging the status quo and with the equitable distributions of society’s burdens and resources.

HISTORICAL OVERVIEW

The environmental movement in the US traces its history from early conservation and preservationist movements of the late 1800s and early 1900s. In 1969, the National Environmental Policy Act was passed and signed by President Nixon. This policy act was the most comprehensive legislation concerning environmental health in US history. During the 1970s, this movement reached the mainstream of American political discussion and concentrated on the passage of legislation addressing the environment. The 1969 Act created a council on environmental quality that published an annual report on the state of the environment. Its 1971 report acknowledged that environmental quality is affected by race and class status of communities.³ The Clean Air Act of 1970 was a major revision to the 1963 Act and set much more demanding standards for control of air pollution. Similarly, the Federal Water Pollution Control Act, more commonly known as

the Clean Water Act, was passed in 1971. The establishment of the EPA in 1970 moved beyond established federal agencies that had not effectively addressed environmental issues, independent of other socioeconomic interests.^{4,5}

There is a broader context in which the history of mainstream environmental movements can be understood. Schlosberg argues that it is more useful to see the first wave of the American environmental movement as a synthesis of early preservationist/conservationist concerns and the urban public health issues of the Progressive era in the early 20th century. This approach allows some understanding of race, class, and gender issues. This history includes the work of individuals such as Alice Hamilton in criticizing the impact of occupational hazards on the health of workers and the communities in which they lived. Social activism, publicizing the effects of industrialization and the dangers of the urban environment (e.g., poor housing, overcrowding, sewage, and water quality), and the settlement movements can then be understood in a broader context of contributing to today’s environmental justice movement. In addition to foreign immigrant communities affected by urban industrial environments, the early decades of the last century saw the beginning of the historic internal migration of African-Americans from the rural south to urban industrial centers. This period saw a widening of the disparities in morbidity and mortality for African-Americans compared to the white population. The dominant theory of the day proposed that these disparities were due to racial differences; this theory was directly challenged by ‘environmentalism’ which maintained that differences of housing, working conditions, diet, availability of medical care, and other environmental factors, not genetics, explained the disparity between the health status of the races. In black communities across the nation, community-based organizations joined with African-American public health and medical professionals to attack and eliminate these health disparities. These early movements foreshadowed today’s modern Environmental Justice movement.⁶⁻⁹

During the 1960s and 1970s, a number of ‘environmental’ issues were again taken up by community groups. Struggles against lead poisoning and poor housing conditions, while ignored by mainstream environmental groups, were important issues for organizations representing people of color. Occupational health and safety struggles among workers of color have informed the Environmental Justice movement. In the 1970s, interaction between labor unions, environmental groups, and minority organizations focused on issues of the urban environment; by the mid-1970s a number of efforts were formalized. A number of unions played an important role in educating their rank-and-file workers about health and safety issues; the United Auto Workers (UAW) and the Oil, Chemical, and Atomic Workers (OCAW) are notable examples. The UAW held a conference on the urban environment that included church groups, unions, and organizations devoted to social and economic justice. The Urban League began a project directed at addressing

environmental concerns of the inner city. In 1977, the Urban Environmental Conference (UEC) began holding nationwide conferences attempting to build coalitions between occupational health and safety activists, communities of color, and environmentalists. In 1979, the National Urban League, the UEC, and the Sierra Club held a national conference, 'City Care: A Conference on the Urban Environment', attended by 700 participants. A few years later, the UEC held a national conference, 'Taking Back Our Health – An Institute on Surviving the Toxic Threat to Minority Communities'. This conference emphasized the connections between minority occupational health and safety labor activists and their communities. However, these early efforts had little impact on the mainstream environmental movement.¹⁰

In 1982, over 500 African-Americans were arrested attempting to stop construction of a polychlorinated biphenyl (PCB) landfill near Afton in Warren County, North Carolina. Many writers consider this protest to be a formative event of the modern Environmental Justice movement. Civil rights and environmental activists came together to plan and stage numerous demonstrations in Warren County. Among the arrested were Dr Benjamin Chavez Junior, then executive director of the United Church of Christ Commission for Racial Justice, Dr Joseph Lowery of the Southern Christian Leadership Conference, and Congressman Walter Faunteroy.^{10,11}

Following the protests in Warren County, Congressman Faunteroy requested a congressional study of hazardous waste sites and race. In 1983, the General Accounting Office (GAO) reported that three out of four hazardous waste sites in EPA's Region 4 (eight southern states) were located near communities composed mainly of minorities.¹² In 1985, the Council of Energy Resource Tribes commissioned by the EPA conducted a survey revealing as many as 1200 hazardous waste sites on or near 25 Indian reservations.¹³

In 1987, the Commission for Racial Justice of the United Church of Christ (UCC) published its seminal report, 'Toxic Wastes and Race in the United States'. This report showed that race was the most significant factor, more so than income, in determining the placement of hazardous waste facilities in communities. Three out of every five African-Americans or Hispanics live in a community with unregulated commercial hazardous waste facilities.¹⁴ Despite some methodologic problems with the UCC study, it placed the question of disproportionate exposure to environmental hazards in the public arena. The Reverend Benjamin Chavez coined the term 'environmental racism' while presenting the UCC report, and the debate took an even more controversial tone.

Since the late 1980s, hundreds of community organizations not tied to national mainstream environmental groups have protested local environmental issues. Many of these local struggles have been well documented. They include work around 'Cancer Alley' in the Mississippi delta, Chicanas in east LA who protested against the building of a toxic waste incinerator, residents of public housing projects in south-east Chicago, and many others.^{13,15-17}

In 1990, as an outgrowth of its own struggles against corporate polluters, the Southwest Organizing Project (SWOP) brought together African-Americans, Asian-Americans, Latino-Americans, and Native Americans from the southwestern states to organize issues around environmental health from the perspective of peoples of color. Activists and SWOP wrote an open letter to major mainstream environmental organizations criticizing their failure to address minority issues and particularly for their discriminatory hiring practices of environmental organization staff.^{10,18}

During the Fall of 1991, more than 650 people attended the First National People of Color Environmental Leadership Summit from almost all states of the union, many American-Indian nations, Puerto Rico, Canada, Latin America, and the Marshall Islands. Attendees adopted a document entitled 'Principles of Environmental Justice', which provided a framework for the Environmental Justice movement. The 17-point document addresses the need for public policy free from discrimination or bias, a right to participate as equal partners in decision making, for producers to be strictly responsible for detoxification and containment of their products, the right of all workers to a safe and healthy work environment, and the need for urban and rural ecologic policies to clean up and rebuild communities. The principles also address more general social issues, including the fundamental right to self-determination of all peoples, and fair access for all to resources. While these principles make explicit the connections between the right to a clean toxin-free workplace, home, and community, they extend to more general sociopolitical issues, as well as quite controversial issues such as ceasing production of 'all toxins, hazardous wastes, and radioactive materials'.¹⁹

GOVERNMENTAL RESPONSE TO ENVIRONMENTAL JUSTICE

In 1990, the EPA established the Environmental Equity Workgroup to evaluate the available evidence of environmental injustices. The Group confirmed the widespread existence of major environmental inequities, and recommended the formation of the Office of Environmental Justice. The Office has been responsible for addressing issues of environmental justice into all EPA policies and activities. Many have criticized the EPA's formulation of environmental equity as a narrowing of the principles of environmental justice.²⁰ However, the establishment of the Office of Environmental Justice and EPA administrator Carol Browner's declaration of environmental justice as one of its seven main priorities in 1993 was a major step forward in acknowledging and addressing environmental injustices.

In 1994, President Bill Clinton signed Executive Order 12898 entitled 'Federal Actions to Address Environmental Justice in Minority Populations and Low-Income Populations'. This Order called for all federal agencies to make environmental justice part of their mission, where applicable.

Agencies were charged with ‘identifying and addressing any or all disproportionately high and adverse human health or environmental effects in its policies, programs and activities’. The Order established the Interagency Working Group on Environmental Justice, which provides guidance to federal agencies in identifying environmental injustices in their policies, programs, and activities, and acts as a clearing-house for federal agencies to develop environmental justice strategies, help coordinate environmental justice-related data collection, research activities between agencies, examine existing data, and hold public meetings for fact-finding and addressing community concerns. In addition, the Order calls for each federal agency to develop an environmental justice strategy. Federal environmental health research, where practical and appropriate, should include diverse segments of the population, especially those at high risk from environmental hazards, such as minority and low-income populations.²¹

Since the issuance of Executive Order 12898, the various federal agencies (i.e., Health and Human Services, Housing and Urban Development, Defense, Labor, EPA, Commerce, Transportation, Energy, amongst others) have developed environmental justice strategies with varying degrees of implementation. Various rollbacks in environmental protections have been attempted, but grassroots activism and various committed government officials have continued to struggle for environmental justice and sound environmental policies.

EVIDENCE FOR DISPROPORTIONATE EXPOSURE AND HEALTH EFFECTS RELATED TO DEMOGRAPHIC AND SOCIOECONOMIC FACTORS

There is evidence to suggest that low-income and minority communities and workers may be exposed disproportionately to environmental hazards. Numerous hazardous waste sites, legal and illegal, have been placed in communities of color and low-income neighborhoods. These sites can leak contaminants into water and soil of the surrounding community. Factory emissions can contaminate the air of surrounding communities. Multiple exposure routes with complex mixtures of toxicants may produce synergistic effects on human health that are difficult to quantify.

Research has centered around three types of problems: health-based problems; land-use and space-based problems; and structural/economic problems.²² With regard to health-based problems of environmental justice, a series of classic case studies in occupational health document differential exposure of workers of color, and the often resultant disparities in occupational disease and injuries. Perhaps the most devastating industrial disaster in US history occurred at Gauley Bridge, West Virginia. This project of dry tunneling through a mountain of silica rock resulted in the deaths of hundreds of workers from acute silicosis and the development of chronic lung disease in

thousands of others.²³ These workers were disproportionately African-American. (See excerpt from the paper by Ashley Lucas and Ariadne Paxton²⁴ overleaf.)

Asian immigrants are exposed to dangerous solvents in the dry-cleaning industry, where they work in disproportionate numbers. The classic studies of steelworkers showed that the higher rates of lung cancer among African-American steelworkers resulted not from genetic differences, but from occupational segregation to work duties on the tops of the coke ovens. Investigators have described many examples that demonstrate segregated patterns of employment. Even after correction for length of employment and educational status, workers of color are often disproportionately exposed to greater occupational hazards compared with their counterparts.^{25–34} In addition to occupational exposures and diseases are numerous health impacts on communities, such as childhood lead poisoning. The age and quality of housing and geographic proximity to lead-based industries and highways are among the factors that help to explain the higher blood lead levels among African-American and Mexican-American children.^{35–37} The increasing disparity in asthma in African-American and Latino children in urban areas compared to whites is also well documented, with concern for environmental risk factors.^{38–40}

RESEARCH ADDRESSING ENVIRONMENTAL JUSTICE

A number of researchers have reviewed the evidence for disproportionate exposure to environmental hazards by race, ethnicity, and class. The overall picture is contradictory, and plagued with numerous methodologic challenges. A number of studies have used zip code and smaller geographic areas to look at the location of industrial sources of pollution and toxic waste sites. The early UCC study used 1980 census data to assess toxic waste sites and correlations with community demographics.¹⁴ The study showed that race and, secondarily, income were particularly important predictors of geographic proximity to hazardous waste facilities. However, the 26 million people of color living near closed and abandoned waste sites in the UCC study were not significantly greater than the percentage of whites living near these sites. A number of investigators have chosen to define environmental injustice using an ecologic approach. In this approach, a differential siting of CERCLA toxic waste sites according to race is emphasized. This rather simplistic model ignores the rich literature and research on race-related effects, and reduces this complicated issue to a single ecologic variable, namely the location of certain types of toxic waste dumps.

Many investigators looking at the demographic characteristics of populations residing around toxic waste sites appropriately emphasize that income is an important variable. Some of these investigators also argue that race is not a factor – rather, income level is the major variable – and dismiss the interactions between race and income. There are also methodologic problems with the unit of analysis used in these studies. Geographic areas such as counties and zip

The Hawk's Nest Incident*The Gauley Bridge Disaster***Preparation for Disaster**

In 1927, construction of a hydroelectric plant on the New River in Gauley Bridge, West Virginia, began under the Union Carbide and Carbon Corporation. Union Carbide then formed the New Kanawha Power Company and the Rinehart and Dennis Company of Charlottesville, Virginia, was contracted to begin construction. Workers came from all over the Southeast. The majority of these new employees were African-American. One procedure used to build the tunnel was called 'mucking'. This was the process by which the broken rock was removed from the tunnel. The removal of the broken rock aided the dispersal of dust that might have been contaminated with silica dust. This dust might have infected several hundred men. The rock was then carried out of the tunnel via 'dinkeys' (or small locomotives).

Working in the Tunnel

The work schedule was a 6-day workweek with two 10-hour shifts per day. The workforce was composed unevenly of African-Americans and Caucasians, with more African-Americans employed by Union Carbide to work in the tunnels than white workers. As a result, more African-Americans died from silicosis. The company provided its workers with housing. The housing was scarcely better than living in a shack, but the white workers were charged less rent for their accommodations than their African-American counterparts. There were not even close to enough beds for all the workers and their families. The cost of living in the villages, much like the rent, was determined by race. Working in the tunnel consisted of two 3-hour shifts. Holes were drilled in the rock for several feet and then dynamite was inserted in the holes to blast out the remainder of the rock. The clearing out of debris involved a lot of contact with dust that contained silica. In addition to the dusty conditions, the use of gasoline-powered equipment also polluted the already contaminated air. It has been reported that mainly black workers were forced to clean out the tunnel after the blast and that was by far the most dangerous part of the job. Length of employment rarely lasted over a year as a result of the dangerous working conditions. The records of medical services rendered to the workmen have never been fully recovered. Physicians of the time were not very familiar with silicosis as a disease. It resembled tuberculosis and was often misdiagnosed as such. It also appears that Union Carbide never took any steps to assess the risk of the

workers being exposed to silica dust. There are accounts from workers saying that they emerged daily from the tunnels coated in dust from head to toe, and members of the community said that the workers were often so dust covered that they left footprints as they walked away from the tunnels back to their houses. The officials of Union Carbide and Rinehart and Dennis said that if there was any dust coverage on the workers, it was minimal.

Recognition of Disaster

In 1932, several lawsuits began to be filed on behalf of some of the afflicted workers. By the mid-1930s, the courts had ruled in favor of compensating the plaintiffs. The allocation of money was based on race and marital status, just as wages and housing had been earlier. A single black man would receive \$400, while a married white man received \$1000. The families of deceased workers received an extra \$600. In 1935, the West Virginia House of Delegates passed a new state workers' compensation law which would compensate workers who were infected with silicosis. Despite this giant step forward in compensating workers for illness contracted on the job, there were many loopholes. These loopholes cleared the employer of responsibility for the disease and made eligibility for this law almost impossible for workers. The hearings that existed at this time did not do enough to relieve or compensate the victims and their families, despite the new legislation.

How Many Died?

An actual number of how many people died as a result of silicosis in Gauley Bridge has never been determined; however, the estimate has been set at around 700 deaths and several thousand diagnosed with lung disease. The victims, for the most part, remain anonymous. There were no headstones for the graves that have been found. The one consistent factor is that proportionally more blacks than whites died in this great disaster. Black deaths were also under-reported, thus skewing the number of deaths even further.

Epilogue

The prospects for local men to work in the mines after working at Hawk's Nest were slim to none when the operators discovered that these men had been exposed to silica dust, which could be killing them. After the afflicted were compensated, Rinehart and Dennis never again competed for a major project. Union Carbide claimed no responsibility for silicosis. Up until at least 1940, silicosis remained absent from the list of diseases that could be claimed under the workman's compensation laws. There is no longer any indication of where the camps once stood on the construction site.

codes may be too large to provide a meaningful assessment of exposure and demographics. The studies do not address the issue of whether people of color settled in these polluted areas because they were not welcome in more desirable neighborhoods or communities, or whether impoverished and disenfranchised communities were systematically chosen for toxic waste disposal facilities.^{14,41-47}

A number of studies have examined ambient concentrations of air pollutants in various community locations. The evidence is contradictory, with some investigators finding differences based on race, or income, or both. These studies have also been limited by exposure assessment, as the movement of air pollutants is dependent on meteorologic conditions, which may be poorly characterized.^{22,48,49}

Societal racism and class distinction are seen by many in the Environmental Justice movement as the most proximal causes for the disproportionate burden of environmental

exposures. These ideologic philosophies are delineated by the resultant lack of political and economic power in poor communities and communities of color. The fact that poor people, and especially workers of color, labor in jobs that are often more hazardous and live in communities more likely to be located near hazardous industries or waste sites contributes to their increased exposure to environmental toxins. Patterns of discrimination in areas of housing and education, for example, can result in large numbers of minority populations being exposed to environmental toxins.^{28,50} Race- and ethnicity-specific data should be collected to characterize more completely the extent of this problem. Caution should be exercised, however, when categorizing populations into specific racial or ethnic groupings. Racial and ethnic groupings are not biologic or genetic categories, nor do they correlate systematically with socioeconomic status, occupational categories, or other relevant variables.

In addition to challenges in exposure characterization and frequent exposure to a complex mixture of toxicants, a major problem with many current epidemiologic studies related to environmental injustices is that most populations studied are relatively small in size. A statistically significant and robust association between an exposure and a disease cannot be observed when the population studied is too small to document an effect. In addition, few studies have attempted to determine the role socioeconomic or race factors play in the development of potential disease clusters in workplaces or communities. Socioeconomic factors are treated as confounders as opposed to variables of interest to investigate with respect to disease development.⁴⁴ The 1999 Institute of Medicine Report entitled 'Toward Environmental Justice' supports three principles for public research to address environmental justice issues, namely:

- improvement of scientific methodologies;
- involvement of affected populations; and
- communication of findings to all stakeholders.⁴⁴

This will require greater resources and improvements in research methodologies, including development of participatory research approaches.

PUBLIC HEALTH MODEL

The Environmental Justice movement emphasizes that environmental health be addressed in terms of public health principles and policy.

Interventions are thus inherently connected to other civil rights and social justice issues. Community empowerment has the potential for the greatest impact. Governmental actions, such as the Executive Order issued by Clinton, that facilitate consideration of environmental justice issues when designing programs can profoundly change the actions of environmental agencies. These broader conceptual approaches challenge the thinking of governmental agencies and the mainstream environmental movement. Whether or not such broad approaches increase our understanding of environmental health, or cloud it with irrelevant issues, is at the heart of the debate around environmental justice.

Currently, Executive Order 12898 is the basis for federal policies regarding environmental justice. The Order directed all federal agencies to develop environmental justice policies and strategies specific to their areas of responsibility. In particular, the US EPA strategies focus on five major areas:

- public participation and accountability, partnerships, outreach and communication with stakeholders, including minority populations and/or low-income populations;
- health and environmental research, including minority and/or low-income populations;
- data collection, analysis and stakeholder access to public information;
- Native American and indigenous environmental protection; and
- enforcement, compliance, assurance, and regulatory reviews.¹

All of these areas need attention and development to appropriately address and prevent environmental injustices. Public participation must be collaborative. Government,

community, and industry partnerships are essential for effective hazard and illness identification through data collection, as well as research, risk communication, and remediation and prevention efforts. Placing the burden of providing definitive evidence linking adverse health outcomes to specific environmental exposures on community residents is not appropriate. Effective intervention will require an understanding that these communities, generally minority and poor, do not necessarily have the resources or expertise to gather the needed data and information.⁴⁴ Risk communication approaches should be grounded in a clear understanding of the cultural contexts involved. It is imperative to train and utilize community residents, as a matter of policy, to aid in development and implementation of educational programs. The National Environmental Justice Advisory Council in 1996 proposed a 'public participation checklist for government agencies'⁵¹ to facilitate this approach, including identification of stakeholders and providing opportunities to offer input into decisions that may impact their health, property values, and lifestyles. Such an approach is based on participatory research, involving 'the affected communities in the planning, implementation, evaluation and dissemination of results'.^{44,52} Soliciting community input before beginning the project, using community residents to gather data where appropriate, and continual feedback on the progress of the research will likely minimize distrust and maximize needed community cooperation and participation.⁵³

ROLE OF THE HEALTHCARE WORKER

Physicians, nurses, and other healthcare workers, particularly occupational and environmental medicine specialists, have a critical role addressing environmental injustices. When patients present to their primary care providers with concerns regarding workplace or community environmental exposures, most medical practitioners do not have the appropriate knowledge to fully address the concerns. Rarely is a public health approach taken to determine whether an entire community is at risk.

Primary care practitioners need to be aware of occupational and environmental resources in their community. Many local health departments, university hospitals or schools of public health have environmental health experts who know of occupational and environmental medicine clinicians in the area.

Unfortunately, poor and rural communities, which include many communities of color, may not have access to quality primary healthcare, much less to trained specialists. One useful resource is the Association of Occupational and Environmental Clinics (AOEC), which is a network of clinics in the US and Canada that specialize in the evaluation of occupational and environmental diseases and injuries.⁵⁴ There are over 60 full-service occupational and environmental clinics, 12 pediatric environmental health specialty units, and 250 individual members in the network.

Finally, it is important to recognize that the physician's role goes beyond the individual doctor-patient relationship and should enter the arena of public involvement with communities in need. Any public health intervention needs to be developed as a partnership between community members, the primary healthcare providers for the community, and the occupational and environmental research and educational experts.

CONCLUSION

In summary, the Environmental Justice movement views race and social class as two fundamental issues impeding environmental equity. Ongoing disparities devalue the lives of those from lower socioeconomic strata and peoples of color, resulting in disproportionate exposure to environmental toxins, and concomitant health risks.

The lack of political and economic power among people of color and the poor frequently means that environmental health concerns in these communities receive inadequate attention or are ignored completely. It also means that the range of options open to these communities is much narrower. For example, one frequent argument for siting a toxic waste facility or an incinerator in impoverished communities is that such enterprises will result in badly needed jobs. This inappropriate emphasis on economic issues must be viewed skeptically in the overall context of public health and social justice.

The Environmental Justice movement has not been characterized by a large national infrastructure, but is rather organized as a network of local and regional organizations.⁹ Dana Alston's summation speech at the First National People of Color Environmental Leadership Summit emphasizes the social, spiritual, and political nature of this movement:

'The environment affords us the platform to address the critical issues of our time: questions of militarism and defense policy; religious freedom; cultural survival; energy and sustainable development; the future of our cities; transportation; housing; land and sovereignty rights; self-determination; and employment. We can go on and on. For us, the issues of the environment do not stand alone by themselves. They are not narrowly defined. Our vision of the environment is woven into an overall framework of social, racial and economic justice. It is deeply rooted in our cultures and our spirituality. It is based on a long tradition of understanding and respect for the natural world. The environment, for us, is where we live, where we work and where we play.'¹⁹

The Environmental Justice movement has been criticized for focusing on things not accomplished, and links to causation not proven, and an overly broad approach to the issues of occupational and environmental health. However, in its relatively short history it has challenged the approach to 'environmentalism' as a merely regulatory function. The movement has caused the US EPA and other government agencies to rethink their approach to community participation. It has broadened the concept of

environmental issues to include social and economic justice, and has embraced a public health model for its approach to issues.⁹

Chapter 58

Integrating Clinical Care with Prevention of Occupational Illness and Injury

Robin Herbert, Jaime Szeinuk

INTRODUCTION

Occupational medicine is a unique clinical specialty that links the direct clinical care of individuals with occupational illnesses or injuries to workplace preventive efforts.¹ Thus, the occupational medicine physician has an opportunity not only to impact the identified patient, but also to prevent disease or injury in similarly exposed coworkers.¹

As in other medical specialties, prevention efforts in occupational medicine can be categorized as primary, secondary, or tertiary.² The goal of primary prevention is to prevent injuries or the onset of disease, either by preventing exposure to workplace hazards or by preventing health effects due to exposure. Secondary prevention seeks to identify and treat asymptomatic individuals in whom preclinical disease has developed, before the condition becomes clinically apparent. Tertiary prevention seeks to prevent disability, disease progression, or death due to clinically apparent illness or injury.³

Occupational and environmental medicine practitioners can contribute to the prevention of occupational diseases and injuries in a number of ways. Examples of primary interventions that healthcare providers can initiate in individual clinical encounters include immunizations against occupational infectious diseases and provision of patient education about the effects of exposures sustained in the workplace and about ways to minimize those exposures. Examples of provider-based secondary prevention include blood lead monitoring and screening for asbestos-related malignancies. Examples of tertiary prevention initiatives that can be conducted in the clinical setting include treatment of occupational cancers or occupational asthma. In the workplace, primary preventive efforts include the substitution of less toxic chemicals and processes and ventilation systems to reduce exposure. Examples of secondary disease preventive efforts include workplace-based screening for occupational disease. Examples of workplace-based tertiary modifications include job modifications to prevent reinjury and facilitate return to work.

This chapter will describe approaches in the clinical setting to the primary, secondary, and tertiary prevention of occupational disease and injury, and will also provide an overview of Occupational Safety and Health Administration (OSHA)-mandated examinations for targeted populations, which provide the opportunity for secondary disease prevention.

PRIMARY PREVENTION OF OCCUPATIONAL ILLNESS AND INJURY

Primary prevention of occupational illness and injury is largely based on minimizing exposure to workplace hazards. While the healthcare provider may have limited ability to effect reductions of hazardous workplace exposures, there are a number of ways in which he or she can work towards primary prevention of occupational disease and injury in the clinical setting. These are described below.

1. Identification of occupational hazards by taking an occupational history, with follow-up to employers regarding hazard abatement

By taking a careful occupational history, the healthcare provider can identify possible occupational hazards and can play an important role in prevention by communicating with employers about reduction of hazardous exposures that are identified in the occupational history. Ultimately, the employer has responsibility for, and control over, whether or not appropriate preventive measures are employed in the workplace. However, the healthcare provider can function as an advocate for workplace safety in a way that individual workers cannot. For example, a study of predictors of employer-based risk reduction efforts for workers with upper extremity work-related diseases found that a physician recommending specific workplace exposure modifications increased the likelihood of their implementation.⁴ However, despite the potential effectiveness of healthcare provider communication with employers regarding workplace interventions, the healthcare provider should never communicate with an employer or other party without explicit permission from the patient, as such activities can result in severe consequences for some workers, particularly those in vulnerable populations.

2. Use of the sentinel health event approach

When an occupational disease or injury is identified in an individual patient, it should be treated as an index case, or

sentinel health event, whenever feasible. As defined by Rutstein et al., an occupational sentinel health event 'is a disease, disability or ultimately death which is occupationally related and which occurrence may 1) provide the impetus for epidemiologic or industrial hygiene studies; or 2) serve as a warning signal that materials substitution, engineering continuation, personal protection or medical care may be required'.⁵ This approach thus relies upon public health-based follow-up of index cases of occupational injury or illness with the goal of decreasing exposure, as well as preventing disease or injury in similarly exposed coworkers. In the sentinel health event approach, following identification of an index case, similarly exposed coworkers should be screened for disease and/or exposure (e.g., blood lead levels). Reduction of the inciting exposure should be initiated. Healthcare providers can play an important role in recognition and follow-up of sentinel health events. Follow-up can potentially result in both primary prevention (hazard identification followed by exposure reduction) and secondary disease prevention (screening of similarly exposed workers). However, again, the healthcare provider should never communicate with employers or unions without explicit permission from the patient.

3. Patient/worker education about minimizing hazardous workplace exposures, and about modifying non-occupational risk factors that may potentiate the effects of occupational exposures

Healthcare providers can contribute to the primary prevention of occupational injury and illness by providing patient/worker education about the health effects of exposures sustained by the patient, and about ways in which the worker might minimize exposures to workplace hazards. For example, because motor vehicle fatalities are the leading cause of fatal occupational injuries in the US, healthcare providers should inquire about and encourage seatbelt use in patients whose jobs involve driving.^{3,6} Similarly, healthcare providers should ask lead-exposed patients about availability and use of handwashing facilities, and patients should be instructed not to eat in work areas where there is the potential for contamination of food with lead.⁷ Reviewing proper use of respirators is another example of a strategy for primary prevention.

Additionally, the healthcare provider should counsel the patient about individual, modifiable behaviors which may increase the risk of occupational diseases. For example, cigarette smoking, in addition to being an independent risk factor for a larger number of diseases, acts in synergy with asbestos to increase the risk of lung cancer. Therefore, primary preventive efforts in an asbestos-exposed worker who also smokes cigarettes would include both providing education and communicating with the employer about minimizing exposure to asbestos and adhering to OSHA standards, but also working on smoking cessation with the individual patient.

4. Use of the US Preventive Services Task Force recommendations on periodic health examinations

Healthcare providers can contribute to primary prevention of some occupational diseases by utilizing appropriate components of the *Guide to Clinical Preventive Services*, a report of the US Preventive Services Task Force.³ The guide recommends specific components of periodic health examinations for various high-risk populations, including certain working groups. For example, the guide recommends that healthcare workers receive hepatitis A and B vaccine, influenza vaccine, and regular purified protein derivatives.³

SECONDARY PREVENTION OF OCCUPATIONAL ILLNESS

The goal of secondary disease prevention is to detect disease at a stage when cure or control is possible. Secondary prevention relies primarily on screening. The general principles of screening are that:

- a test or series of tests will identify asymptomatic persons at risk for a specific disease;
- persons with a positive result on a screening can be further evaluated to determine whether they have the disease;
- ideally, once the disease is established, early intervention can change the course of disease, resulting in decreased morbidity and mortality.^{3,8}

In the clinical setting, secondary prevention of occupational illness can occur in the milieu of mandated screening examinations (e.g., OSHA, Department of Transportation [DOT]) or as part of routine clinical care provision.

SCREENING FOR OCCUPATIONAL DISEASE UNDER THE OSHA STANDARDS

In the US, OSHA has promulgated a series of federal regulations, the OSHA Standards, which deal with various aspects of biologic monitoring and medical surveillance for some hazardous workplace exposures.⁹ OSHA requires employers to provide mandated periodic screening examinations for workers with certain exposures (e.g., asbestos) or job titles (e.g., hazardous waste workers). The occupational medicine professional should be familiar with the requirements of periodic screening examinations under the OSHA law. Regulations can be obtained by logging into the OSHA website at www.osha-slc.gov/OshStd_toc/OSHA_Std_toc.html. Because many of the OSHA standards were written 10 to 20 years ago, provisions of the law need to be supplemented by review of newer scientific criteria about the potential health effects of the exposures for which the workers are being evaluated, and appropriate screening modalities for the health effects of interest. The occupational medicine provider should review the known toxicity of exposures for which he or she is conducting examinations,

and be familiar with both the use of biomarkers of exposure to the substance(s) under consideration, as well as the best screening methods for health conditions associated with the exposure(s). Finally, when planning or conducting a medical screening program, the occupational medicine practitioner should be certain to refer all laboratory and ancillary tests to well-known, respected and certified laboratories and diagnostic facilities, as there can be significant variation in techniques and laboratory procedures that sometimes may render false or equivocal results.

OSHA has strict regulations regarding patient confidentiality and record keeping for OSHA-mandated examinations. The healthcare provider must be aware of the regulations when planning to conduct an OSHA-mandated screening program (see Chapter 57.1). OSHA usually only permits the healthcare provider to inform the employer of issues related to the specific hazard for which the worker is being screened, in order to protect patient confidentiality. The provider is generally obligated to maintain medical records and test results for long periods of time, which vary according to the exposure.

Table 58.1 summarizes both the requirements of the OSHA Standards on medical screening for workers with specific exposures, and other OSHA regulations regarding medical screening of workers in specific trades, such as hazardous waste workers. For each exposure, the table presents the toxicant in consideration together with the number of the OSHA Rule that covers this specific substance. Next is a review of target occupation and industries where exposure to this substance is most commonly encountered. A list of the target organs that have been found to have susceptibility to organ damage by the specific substance, and the carcinogenic potential of the substance, follow. Finally, a summary of the recommendations under the OSHA Standard and a succinct review of a series of tests recommended for periodic monitoring of workers exposed to these specific toxicants is provided. For Standards in which the OSHA recommendations for medical surveillance are sparse or vague, the table has been supplemented with additional recommendations about appropriate surveillance techniques for particular exposures.

One of the purposes of the medical examinations under the OSHA Standards is to establish a baseline for future health monitoring of workers exposed to occupational toxins. Baseline evaluation is important in providing a basis for subsequent assessment and changes in the health of the individual and in evaluating her or his risk factors to exposure to toxins. Baseline examinations can also provide the opportunity to provide education to the patient/worker about the potential deleterious health effects of the agents to which he or she may be exposed, and to assess the presence or absence of co-morbid conditions that may affect risk of developing an occupational disease. Thus, when performing the required periodic medical and laboratory examinations, the occupational medicine professional should take time to compare current with previous results in order to detect early, subclinical changes in test results. Although these may not yet be 'clinically significant', such changes and trends may be the first sign of early tissue

damage that, when detected in a timely manner, should lead to avoidance or control of exposure to prevent development of clinically apparent disease.

In addition to the routinely recommended tests and evaluations for workers with particular exposures, it is important for the occupational medicine professional to be aware that some workers may have greater susceptibility to the effects of some substances, or may have other medical conditions that make it difficult to use particular protective equipment. Consequently, it is recommended that in certain cases the healthcare provider should be prepared to evaluate situations not directly related to the specific toxicant in question, to the extent that they may affect occupational safety and health. For example, workers with skin diseases may be unable to tolerate wearing protective clothing or particular gloves. Some workers with chronic respiratory diseases may not tolerate wearing negative pressure (air-purifying) respirators. Additional tests and procedures may be required to help the healthcare provider determine which workers are medically unable to be exposed to certain toxicants or to wear specific work protection equipment. Supplemental testing may include, for example, evaluation of cardiovascular function, baseline and repeated chest X-ray, pulmonary function test (spirometry), periodic monitoring of blood-forming organs (i.e., complete blood count), liver and kidney function tests, or early markers of kidney damage such as low-molecular-weight proteins in the urine (e.g., beta-2 microglobulin). However, medical surveillance should not be used for employment purposes such as hiring and firing.¹⁰ Furthermore, the healthcare provider should be aware of the Americans with Disabilities Act (ADA) provisions of federal law (see Chapter 57.1).

Screening at-risk workers who are not covered by OSHA-mandated examinations

There are many workers who sustain exposures known to be associated with increased risk of occupational cancers and other occupational illnesses whose employers are not required to provide OSHA-mandated screening examinations, but who might benefit from periodic screening examinations. They include, for example, workers exposed to known carcinogens such as chromium, radiation, nickel, and coal tar pitch, and workers in industries that have been associated with significant health hazards and/or cancer risk, such as the rubber industry, furniture workers (wood dust), and steel foundries.

In general, screening for either occupational exposure resulting in detectable internal dose (utilizing biomarkers) or for asymptomatic occupational disease should be considered in the following settings in addition to those mandated by OSHA:

- when a sentinel health event is identified, as described earlier in this chapter;
- when an occupational history reveals that a patient's work involves exposure to a given agent such as lead, for which a screening device is available;

Exposure ⁹ OSHA Rule #	Workers at risk/uses	Target organs ^{1,2}	Medical screening and surveillance
2-Acetylaminofluorene (13-carcinogens) 1910.1014	Chemical research, experimental carcinogen	Liver, bladder, kidney, pancreas, skin	<i>Trigger:</i> Working in a regulated area <i>Examinations:</i> 1; 2*; 5 <i>Exam components:</i> PE focusing on increased risk for cancer such as reduced immunologic competence, treatment with steroids or cytotoxics, pregnancy and cigarette smoking; work and medical history; genetic and environmental factors <i>Tests:</i> Urinalysis, urine cytology and cystoscopy * Annually
Acrylonitrile 1910.1045	Manufacture of acrylic fibers for the apparel, carpeting, and home furnishing industries; in plastic pipes and pipetting; in automotive parts, appliances, and building components; in the petrochemical industry; to make acrylamide; prior to World War II, used in the production of oil-resistant rubbers	Eyes, skin, cardiovascular system, liver, kidney, CNS Cancer: brain, lung, bowel	<i>Trigger:</i> Exposure at or above the AL (2 ppm) <i>Examinations:</i> 1; 2; 3; 4; 5 <i>Exam components:</i> PE with special attention to CNS dysfunction symptoms such as headaches, dizziness or weakness, respiratory system, GI system, thyroid and skin; work and medical history. Persons unusually susceptible to effects of anoxia or those with anemia would be expected to be at increased risk <i>Tests:</i> CXR, FOB (for workers >40); blood cyanide, blood plasma, urinalysis; urinary level of acrylonitrile and urinary excretion of thiocyanate over a TWA; additional tests as needed <i>See 2-acetylaminofluorene</i> <i>Tests:</i> Urinalysis, urine cytology and cystoscopy
Alpha-Naphthylamine (13-carcinogens) 1910.1004	Dyes, prints	Bladder, skin	<i>See 2-acetylaminofluorene</i> <i>Tests:</i> Urinalysis, urine cytology and cystoscopy
4-Aminodiphenyl (13-carcinogens) 1910.1011	Rubber, byproduct of aniline dye manufacturing, used in cancer research	Bladder, skin Cancer: bladder	
Arsenic 1910.1018	For hardening lead in battery grids, bearings, and cable sheets; in the manufacture of calcium, copper, and lead arsenate pesticides (arsenic trioxide and pentoxide); as pigment and refining agent in glass and as preservative in tanning and taxidermy; copper acetoarsenite and chromated copper arsenate (CCA) as a wood preservative; also used as herbicide and desiccant for cotton harvesting; in veterinary pharmaceuticals and feed additives; arsine gas in the microelectronics industry	Liver, kidney, skin, lungs, lymphatic system, nose, nervous system, reproductive system Cancer: lung, skin, liver (angiosarcoma)	<i>Trigger:</i> (1) Exposure at or above the AL (5 mg/m ³) for at least 30 days/year; (2) Exposure for 10 or more years above the AL, though worker may no longer be exposed above the level; (3) Assignment to areas in which exposure will probably exceed action level <i>Examinations:</i> 1; 2*; 3; 4; 5 <i>Exam components:</i> PE; nasal and skin; work and medical history, including smoking history, respiratory symptoms <i>Tests:</i> CXR; CBC; reticulocyte count; LFT; PFT; urinalysis; total urine arsenic levels (measurement of dimethylarsinic acid and monomethylarsonic acid eliminates confusion with dietary sources); additional tests as needed * Annually for employees 45 years of age or younger with less than 10 years of exposure, and every 6 months for all other employees
Asbestos 1910.1001 (General Industry) 1926.1101 (Construction)	Asbestos is present in over 3000 manufactured products, which include: building, construction, cement work, insulation, fireproofing, textiles, pipes and ducts for water, air, and chemicals, automobile brake pads and linings (friction products), in construction work involving demolition or salvage, alteration, repair, maintenance, renovation or installation of products; in removal or encapsulation of old asbestos-containing materials	Respiratory system, GI system, eyes Cancer: lung, pleura and peritoneum, colon, ?kidney	<i>Trigger:</i> (1) Exposure at or above the PEL (0.1 fiber per cm ³ of air) for a combined period of 30 or more days/year; (2) Requirement to wear respiratory protective equipment because of asbestos jobs <i>Examinations:</i> 1; 2*; 4; 5 <i>Exam components:</i> PE; work and medical history with emphasis directed to symptoms of the respiratory system, cardiovascular system, and digestive tract; completion of the standard respiratory disease questionnaire at the initial exam, and of the follow-up questionnaire yearly <i>Tests:</i> CXR (B-reading); PFT (FVC, FEV₁); FOB, colonoscopy, low-dose spiral CT scan of the chest; additional tests as needed. * Within 10 days following the 13th day of exposure and at least annually thereafter
Benzene 1910.1028	For extraction in chemical analyses and as a specialty solvent; in the production of ethyl benzene for the production of styrene; in gasoline	Blood, bone marrow, CNS, eyes, respiratory system, skin, liver, kidney Cancer: leukemia	<i>Trigger:</i> (1) Exposure at or above the AL (0.5 ppm) for at least 30 days/year; (2) Exposure at or above the PEL (1 ppm) for at least 10 days/year; (3) Assignment to areas in which exposure will probably exceed action level

Table 58.1 Requirements of the OSHA Standards on medical screening for workers with specific exposures, and other OSHA regulations regarding medical screening of workers in specific trades

Exposure ⁹ OSHA Rule #	Workers at risk/uses	Target organs ¹²	Medical screening and surveillance
Benzidine (13-carcinogens) 1910.1010 Beta-Naphthylamine (13-carcinogens) 1910.1009 Beta-Propiolactone (13-carcinogens) 1910.1013 Bis-chloromethyl ether (13-carcinogens) 1910.1008 Blood-borne pathogens 1910.1030	Dyes, detection of blood, reagent for metals Dyes Disinfectant, organic synthesis Ion-exchange resins, bactericide, pesticide, dispersing agent, water repellent, solvent for polymerization, flameproofing agents This term refers to pathogenic micro- organisms that are present in human blood and can cause disease in humans. These pathogens include, but are not limited to, hepatitis B virus (HBV) and human immunodeficiency virus (HIV). Healthcare workers with direct patient contact, but also workers at laboratory facilities, and housekeeping and laundry workers in healthcare facilities, are at risk	Bladder, skin, kidney, liver, blood Cancer: bladder Bladder, skin Cancer: bladder Kidney, skin, lungs, eye Eye, skin, respiratory system Cancer: lung Liver, immune system	<i>Examinations:</i> 1; 2; 3; 5 <i>Exam components:</i> PE; work and medical history, including smoking history, hematologic symptoms, and family history of blood dyscrasia <i>Tests:</i> CBC (including red blood cell indices, reticulocyte count); LFT; PFT for workers required to use respirators; urinalysis; additional tests as needed. MRP <i>See 2-Acetylaminofluorene</i> <i>Tests:</i> PFT; urinalysis; occult blood in urine (recommended each month); urine cytology (recommended every 6 months); cystoscopy <i>See 2-Acetylaminofluorene</i> <i>Tests:</i> Urinalysis; urine cytology; cystoscopy <i>See 2-Acetylaminofluorene</i> <i>Tests:</i> PFT <i>See 2-Acetylaminofluorene</i> <i>Tests:</i> PFT <i>Trigger:</i> Reasonably anticipated skin, eye, mucous membrane, or parenteral contact with blood or other potentially infectious materials* <i>Examinations:</i> 1†; 3‡ <i>Exam components:</i> Evaluations and procedures including hepatitis B vaccination series and post-exposure evaluation and follow-up, including prophylaxis, provided in a timely fashion, at no cost to the employee and under the supervision of a licensed physician * Other potentially infectious materials include: 1) human body fluids: semen, vaginal secretions, cerebrospinal fluid, synovial fluid, pleural fluid, pericardial fluid, peritoneal fluid, amniotic fluid, saliva in dental procedures, any body fluid that is visibly contaminated with blood, and all body fluids in situations where it is difficult or impossible to differentiate between body fluids; 2) unfixed tissue or organ (other than intact skin) from a human (living or dead); and 3) HIV- containing cell or tissue cultures, organ cultures, and HIV- or HBV-containing culture medium or other solutions; and blood, organs, or other tissues from experimental animals infected with HIV or HBV † Hepatitis B vaccination within 10 working days of initial assignment, unless already immune or vaccine contraindicated ‡ Post-exposure monitoring: following a report of an exposure incident, the employer shall make immediately available to the exposed employee a confidential medical evaluation and follow-up, including at least the following elements. 1. Documentation of the route(s) of exposure, and the circumstances under which the exposure incident occurred. 2. Identification and documentation of the source individual, unless the employer can establish that identification is unfeasible or prohibited by state or local law. 3. The source individual's blood shall be tested as soon as feasible and after consent is obtained in order to determine HBV and HIV infectivity. If consent is not obtained, the employer shall establish that legally required consent cannot be obtained. When the source individual's consent is not required by law, the source individual's blood, if available, shall be tested and the results documented. When the source individual is already known to be infected with HBV or HIV, testing for the source individual's known HBV or HIV status need not be repeated. 4. Results of the source individual's testing shall be made available to the exposed employee, and the employee shall be informed of applicable laws and regulations concerning disclosure of the identity and infectious status of the source individual. 5. Collection and testing of blood for HBV and HIV serologic status if consented by the employee. 6. Post-exposure prophylaxis, when medically indicated, as recommended by the US Public Health Service, counseling, and evaluation of reported illness.

Table 58.1 (Cont'd) Requirements of the OSHA Standards on medical screening for workers with specific exposures, and other OSHA regulations regarding medical screening of workers in specific trades

Exposure ⁹ OSHA Rule #	Workers at risk/uses	Target organs ^{1,2}	Medical screening and surveillance
1,3 Butadiene 1910.1051	Manufacture of acrylic fibers for apparel, carpeting, home furnishing, plastic pipes and pipefitting, automotive parts, appliances, and building components; exposure occurs in the petrochemical industry	Eyes, respiratory system, CNS, reproductive system Cancer: hematopoietic cancer	<i>Trigger:</i> (1) Exposure at or above the AL (0.5 ppm) on 30 or more days; (2) Exposure at or above the PEL (1 ppm TWA) on 10 or more days a year <i>Examinations:</i> 1; 2; 3*; 4; 5 <i>Exam components:</i> PE emphasis directed on the hematopoietic and reticuloendothelial systems and skin; work and medical history; environmental history; standardized medical questionnaire <i>Tests:</i> CBC with differential and platelet count every year * Include CBC within 48 hours of exposure and monthly for 3 months; and PE if employee reports irritation of eyes, nose, throat, lungs, or skin, blurred vision, coughing, drowsiness, nausea, or headache
Cadmium 1910.1027 1926.1127	Smelting and refining of zinc, lead, and copper; recovery and refining of cadmium products; manufacture of batteries, paints, and plastics; welding and brazing, and electroplating operations	Respiratory system, prostate, blood Cancer: lungs and prostate	<i>Trigger:</i> (1) Exposure at or above the AL (2.5 mg/m ³) for at least 30 days/year; (2) Exposure for 10 or more years above the AL though they may no longer be exposed above the level; (3) Assignment to areas in which exposure to cadmium will be encountered <i>Examinations:</i> 1; 2*; 3; 4; 5 <i>Exam components:</i> PE; prostate palpation in men >40 years of age; work and medical history, including smoking history, respiratory symptoms <i>Tests:</i> Biologic monitoring including: cadmium in blood, cadmium in urine and beta-2-microglobulin in urine, serum creatinine; CBC; BUN; CXR; PFT (FVC, FEV₁); urinalysis for proteinuria; pulmonary diffusion capacity; prostate-specific antigen; additional tests as needed. MRP * Semi-annually † Biologic monitoring should be conducted quarterly <i>Trigger:</i> Working in a regulated area for at least 30 days per year <i>Examinations:</i> 1; 2*; 4; 5 <i>Exam components:</i> PE including weight and skin examination; work and medical history, including smoking history and respiratory symptoms <i>Tests:</i> CXR; PFT (FVC, FEV₁); urinalysis for sugar, albumin, hematuria; urine cytology examination; additional tests as needed * Semi-annual for employees 45 years of age or older or with 5 or more years of employment, and annual examinations for all other employees
Coke oven emissions (COE) 1910.1029(j)	COE are the benzene-soluble fraction of total particulate matter present during the destructive distillation or carbonization of coal for the production of coke. Work-titles included under this Standard are: lidman, tar chaser, larry-car operator, luterman, machine operator and benchmark on the coke side, quenching car operator, pusher machine operator, screening station operator, wharfman, oven patcher, oven repairman, spellman, and maintenance personnel	Skin, respiratory system, urinary tract Cancer: skin, lungs, kidney, and bladder	
Compressed air spaces 1926.803	Tunnel operators, caisson operator, deep-sea divers, air personnel at high altitudes	Central and peripheral nervous system, joints, bones	<i>Trigger:</i> Working in a regulated area <i>Examinations:</i> 1; 2; 3 <i>Exam components:</i> Medical examination directed to assure that employee is in good physical condition for working in compressed air spaces. * Special attention given to: weight, vascular system, coagulation mechanisms, respiratory system, osseous system * The physician must be familiar with and experienced in the physical requirements and the medical aspects of compressed air work and treatment of decompression illness. S/he shall be available at all times while work is in progress. S/he shall be physically qualified and be willing to enter a pressurized environment

Table 58.1 (Cont'd) Requirements of the OSHA Standards on medical screening for workers with specific exposures, and other OSHA regulations regarding medical screening of workers in specific trades

Exposure ⁹ OSHA Rule #	Workers at risk/uses	Target organs ¹²	Medical screening and surveillance
Cotton dust 1910.1043	Yarn manufacturing, slashing and weaving, waste house textile operations. Workers are NOT exposed in woven or knitted materials, harvesting or ginning of cotton	Respiratory system, cardiovascular system, byssinosis	Trigger: Exposure at or above the following AL: yarn manufacture and cotton washing – 100 µg/m ³ ; textile operations – 250 µg/m ³ ; slashing and weaving – 375 µg/m ³ Examinations: 1; 2*; 5 Exam components: Work and medical history; standardized questionnaire; Schilling grading system Tests: PFT (FVC, FEV₁, FEV₁/FVC)[†] MRP * Annually for workers exposed above the AL. Every 2 years for workers exposed at or below the AL. Every 6 months for workers whose initial FEV ₁ is above 80% but decreases by 5% or 200 ml on the first day of work, or for those employees whose initial FEV ₁ is below 80%. Exam should include all the elements of the initial examination and comparison with previous test results [†] Before worker enters the workplace on the first day of the working week preceded by at least 35 hours of no exposure to cotton dust (PFT must be repeated during the shift not less than 4 hours and no more than 10 hours after beginning the work shift, and in any case no more than 1 hour after cessation of exposure)
1,2-Dibromo-3-chloropropane (DBCP) 1910.1044	Nematocide used on citrus fruits, grapes, peaches, pineapples, soybeans, and tomatoes. Its use has been banned in the US since 1979	Eyes, skin, respiratory system, CNS, liver, kidney, spleen, reproductive system, digestive system Cancer: in animals; nasal cavity, tongue, pharynx, lungs, stomach, adrenal and mammary glands Bladder, liver, lung, skin, GI	Trigger: Working in a regulated area Examinations: 1; 2; 3; 5 Exam components: PE including examination of the genitourinary tract, testicle size and body habitus; reproductive history Tests: Serum specimen for RIA determinations of FSH, LH and total estrogen (females), and sperm count in males See 2-Acetylaminofluorene Tests: PFT
3,3'-Dichlorobenzidine and its salts (13-carcinogens) 1910.1007	Dyes (azo dyes), pigments	Skin, respiratory system, liver, kidney, bladder	See 2-Acetylaminofluorene
4-Dimethylaminoazobenzene (13-carcinogens) 1910.1015	pH indicator, test for identification of peroxidized fats, for determination of free chlorhydric acid in gastric juice	Eyes, skin, respiratory system, liver, CNS, blood, kidney, and reproductive system Cancer: peritoneal cancer, leukemia	Trigger: Exposure at or above the AL (0.5 ppm) for at least 30 days/year without regard to respirator use Examinations: 1; 2; 3; 4; 5 Exam components: PE with emphasis directed on symptoms related to the pulmonary, hematologic, neurologic, and reproductive systems and to the eyes and skin; work and medical history Tests: CBC to include at least a white cell count (including differential cell count), red cell count, hematocrit, and hemoglobin; additional tests as needed*
Ethylene oxide (EO) 1910.1047 1926.1147	In the manufacture of ethylene glycol (antifreeze and an intermediate for polyester fibers, films, and bottles), non-ionic surface-active agents (used for home laundry detergents and dishwashing liquids), glycol ethers (used for surface coatings), and ethanolamines (for soaps, detergents, and textile chemicals). Used as a pesticide fumigant and as sterilant in hospitals, medical products manufacture, libraries, museums, beekeeping, spice and seasoning fumigation, animal and plant quarantine, transportation vehicle fumigation, and dairy packaging	Eye, skin, respiratory system, liver, kidney	* If requested by the worker, pregnancy testing or laboratory evaluation of fertility will be provided, as deemed appropriate by the physician
Ethyleneimine (13-carcinogens) 1910.1012	Textile finishing agent, insect sterilant, antineoplastic, manufacture of resinous products		See 2-Acetylaminofluorene Tests: CXR; PFT

Table 58.1 (Cont'd) Requirements of the OSHA Standards on medical screening for workers with specific exposures, and other OSHA regulations regarding medical screening of workers in specific trades

Exposure ⁹ OSHA Rule #	Workers at risk/uses	Target organs ¹²	Medical screening and surveillance
Formaldehyde 1910.1048	In the manufacture of urea-formaldehyde foam and resins used as adhesives in particle board, fiberboard and plywood. Used as tissue fixative and embalming agent and as preservative in cosmetics, glues and shampoos	Eyes, respiratory system, skin Cancer: nasal cavity, nasopharynx	<i>Trigger:</i> Exposure at or above the AL (0.75 ppm) <i>Examinations:</i> 1; 2; 3; 5 <i>Exam components:</i> PE with special emphasis directed to symptoms and signs related to the pulmonary system and to the eyes and skin; work and medical history <i>Tests:</i> PFT (FVC, FEV₁, FEF) ; blood and urine; additional tests as needed MRP <i>Trigger:</i> Working in a regulated area <i>Examinations:</i> 1*; 2; 3; 4; 5 <i>Exam components:</i> PE including vision and audiometric tests, determination of fitness to work wearing protective equipment and baseline monitoring for specific exposures; work and medical history; relevant lifestyle habits <i>Tests:</i> LFT; kidney function; urinalysis; CBC; CXR. Baseline and periodic tests for specific toxicants should be tailored to exposure, such as: serum PCB testing, lead and zinc protoporphyrin (ZPP), cadmium, arsenic and organophosphate pesticides. PFT and electrocardiogram if necessary to assess worker's capacity to perform while wearing protective equipment
Hazardous waste 1910.120 1926.65	More common potential exposures: aromatic hydrocarbons, asbestos, dioxin, halogenated aliphatic hydrocarbons, heavy metals, herbicides, organochlorine insecticides, organophosphate and carbamate insecticides, polychlorinated biphenyls, other toxic chemicals, safety hazards, radiation, heat or cold stress, explosions and fires	Lungs, kidneys, central nervous system, blood, skin, eyes, stress, cancer. Additional target organs as per exposures	* Freezing pre-employment serum specimen for later testing is suggested <i>Trigger:</i> (1) Exposure at or above the AL (50 µg/m ³) at any time calls for biologic monitoring of blood lead levels (BLL) and ZPP levels; (2) Exposure above 30 µg/m ³ TWA for more than 30 days/year; (3) Employees whose BLL exceeds 40 µg/dl <i>Examinations:</i> 1*; 2†; 3‡; 5 <i>Exam components:</i> PE with emphasis on neurologic, GI, and cardiovascular systems, teeth, gums, and renal system; work and medical history <i>Tests:</i> BLL** ; ZPP†† ; hemoglobin ; hematocrit ; BUN ; serum creatinine ; red cell indices ; examination of the peripheral blood smear to evaluate red blood cell morphology ; routine urinalysis with microscopic examination ; X-ray fluorescence of the bone; additional tests as needed MRP##
Lead 1910.1025 1926.62	Manufacture of storage batteries; as an alloy in pipes, cable sheathing, solder; in paints and plastics as pigments and stabilizers; as glazes for ceramics; in construction for attenuation of sound and vibration and for the shielding of radioactivity; in ammunition, bronze and brass, cosmetics and jewelry; organic lead (tetramethyl lead) used as antiknock agent in gasoline	Eyes, GI tract, CNS, kidney, blood, gingival tissue	* All workers assigned to work in an area in which air-borne lead concentrations reach or exceed the 30 µg/m ³ TWA for more than 30 days/year † Annually for workers exposed above 30 µg/m ³ for more than 30 days/year, or whose BLL conducted at any time during the preceding 12 months resulted in level of 40 µg/dl or higher ‡ Medical examination must be provided as soon as possible after notification by the worker that s/he has developed signs or symptoms commonly associated with lead intoxication, that s/he desires medical advice regarding lead exposure and the ability to procreate a healthy child, or that s/he has demonstrated difficulty in breathing during a respirator fitting test or during respirator use. Examination is also to be made available to each worker removed from exposure to lead due to risk of sustaining material impairment to health, or otherwise limited or specially protected pursuant to medical recommendations ** Workers exposed above 30 µg/m ³ for more than 30 days/year or whose BLL is above 40 µg/dl but exposed for no more than 30 days/year, should have BLL determined at least every 2 months for the first 6 months of exposure and every 6 months thereafter. Frequency is increased to every 2 months for workers whose last BLL was 40 µg/dl or above. For workers who are removed from exposure to lead due to an elevated blood lead, a new BLL must be measured monthly †† Recommended on each occasion a BLL measurement is made ## When the BLL reaches 50 µg/dl, confirmed by a follow-up BLL performed within 2 weeks after the employer receives the results of the first BLL. Return of the employee to his or her job status depends on a worker's BLL declining to 40 µg/dl. In addition to the above BLL criterion, temporary worker removal may also take place as a result of medical determinations and recommendations

Table 58.1 (Cont'd) Requirements of the OSHA Standards on medical screening for workers with specific exposures, and other OSHA regulations regarding medical screening of workers in specific trades

Exposure ⁹ OSHA Rule #	Workers at risk/uses	Target organs ¹²	Medical screening and surveillance
Methylene chloride (MC) 1910.1052	Paint stripping, polyurethane foam manufacturing, and cleaning and degreasing	Eyes, skin, cardiovascular system, liver, CNS Cancer: in animals; lung, liver, salivary and mammary glands	<i>Trigger:</i> (1) Exposure at or above the AL (12.5 ppm) on 30 or more days per year, or above the 8-hour TWA PEL (25 ppm) or the STEL (125 ppm) on 10 or more days per year; (2) Exposure above the PEL or STEL for any time period where an employee has been identified as being at risk from cardiac disease or from some other serious MC-related health condition <i>Examinations:</i> 1; 2*; 3; 4; 5 <i>Exam components:</i> PE with emphasis on lungs, cardiovascular, liver, nervous, skin, hematologic; work and medical history <i>Tests:</i> Carboxyhemoglobin (before- and after-shift); resting ECG; hematocrit; LFT; cholesterol levels; additional tests as needed MRP * For employees 45 years of age or older, within 12 months, and for employees younger than 45 years of age, within 36 months of the initial surveillance <i>See Bis-chloromethyl ether</i>
Methyl chloromethyl ether (13-carcinogens) 1910.1006	<i>See Bis-chloromethyl ether</i>	Eye, skin, respiratory system	
Methylene-dianiline (MDA) 1910.1050 1926.60	Production of rigid polyurethane foams, as a curing agent and as epoxy resin hardener	Eyes, liver, cardiovascular system, spleen Cancer: bladder	<i>Trigger:</i> (1) Exposure at or above the AL (5 ppb) for 30 or more days per year; (2) Dermal exposure to MDA for 15 or more days per year; (3) Exposure in an emergency situation and for employees who show signs or symptoms of MDA exposure <i>Examinations:</i> 1; 2; 3; 5 <i>Exam components:</i> PE with emphasis directed on skin and liver; work and medical history with emphasis on past work exposure to MDA or any other toxic substance, history of drugs, alcohol, tobacco, or medication routinely taken, and history of dermatitis, chemical skin sensitization, or previous hepatic disease <i>Tests:</i> LFT; urinalysis repeated annually MRP <i>See 2-Acetylaminofluorene</i> <i>Tests:</i> Urinalysis; urine cytology; cystoscopy
4-Nitrobiphenyl (13-carcinogens) 1910.1003 1915.1003 1926.1103	Rubber industry	Bladder, blood	
N-nitroso-dimethyl amine (13-carcinogens) 1910.1016 Noise 1910.95 1926.52	Used as antioxidant for lubricants, softener of copolymers; formerly used in rocket fluids; present in cigarette smoke Construction, manufacturing, military, mining, production, and transportation industries	Liver, kidney, lungs Ears	<i>See 2-Acetylaminofluorene</i> <i>Tests:</i> LFT; PFT <i>Trigger:</i> Exposure to sound levels in excess of those shown in the following table, when measured on the acoustic scale of a standard sound level meter at slow response: PERMISSIBLE NOISE EXPOSURES* Duration per day, hours Sound level dBA, slow response 8 90 6 92 4 95 3 97 2 100 1 1/2 102 1 105 1/2 110 1/4 or less 115 <i>Examinations:</i> 1; 2; 4

Exposure ⁹ OSHA Rule #	Workers at risk/uses	Target organs ^{1,2}	Medical screening and surveillance
Noise <i>continued</i>			<p><i>Exam components:</i> Hearing conservation program whenever employee noise exposures equal or exceed an 8-hour TWA sound level of 85 decibels measured on the A scale (slow response). Program consists of obtaining valid audiograms as follows: a baseline study, within 6 months of an employee's first exposure at or above the AL, annual new audiograms for each eligible employee, which should be compared with the baseline audiogram, and an audiogram at termination of employment. If the annual audiogram shows that an employee has suffered a standard threshold shift, the employer may obtain a retest within 30 days and consider the results of the retest as the annual audiogram, and the audiologist, otolaryngologist, or physician in charge of the program shall determine whether there is a need for further evaluation.</p> <p>* When the daily noise exposure is composed of two or more periods of noise exposure of different levels, their combined effect should be considered, rather than the individual effect of each. If the sum of the following fractions: $C(1)/T(1) + C(2)/T(2) + C(n)/T(n)$ exceeds unity, then the mixed exposure should be considered to exceed the limit value. Cn indicates the total time of exposure at a specified noise level, and Tn indicates the total time of exposure permitted at that level. Exposure to impulsive or impact noise should not exceed 140 dB peak sound pressure level</p> <p><i>Trigger:</i> Use of respiratory protective equipment</p> <p><i>Examinations:</i> 1; 2; 5</p> <p><i>Exam components:</i> Work and medical history; standard medical questionnaire; follow-up evaluation (interview) required if answering 'yes' to questions 1–8 or 10–15 of the standard questionnaire; if evaluation finds a significant clinical problem, clinical examination and special tests as recommended by healthcare professional; re-evaluations determined by individual's health status, medical recommendation, changes in working conditions or observations from the respiratory protection program or at the time of annual fit-testing; additional tests as needed</p> <p><i>Trigger:</i> Exposure in excess of the AL (0.5 ppm)</p> <p><i>Examinations:</i> 1; 2*; 5</p> <p><i>Exam components:</i> PE focusing on enlargement of the liver, spleen, or kidneys, or dysfunction in these organs, skin, connective tissue, and pulmonary abnormalities; work and medical history including alcohol intake, past history of hepatitis, past exposure to potential hepatotoxic agents including drugs and chemicals, past history of blood transfusions, and past history of hospitalizations</p> <p><i>Tests:</i> Serum determination of total bilirubin, alkaline phosphatase, aminotransferases and gamma-glutamyl transpeptidase, urinary coproporphyrins, ultrasonography of the liver</p> <p>* Examinations should be performed at least every 6 months for each employee who has been employed in vinyl chloride manufacturing for 10 years or longer, and annually for all other employees</p>
Respirator use ¹³ 1910.134	Used to prevent inhalation of harmful substances and to provide a source of respirable air when breathing in oxygen-deficient atmospheres	Respiratory system, skin, senses, musculoskeletal system, cardiovascular, psychologic effects	
Vinyl chloride 1910.1017	Production of polyvinyl chloride resins for plastic piping and conduit, floor coverings, home furnishing, electrical applications, records, toys, packaging, and transportation industry (auto tops, upholstery, and mats). Standard does NOT apply to handling or use of fabricated products made of polyvinyl chloride	Liver, CNS, blood, respiratory system, lymphatic system, skin Cancer: hepatic angiosarcoma	

Examinations are provided as 1=pre-placement examination; 2=periodic examination; 3=emergency/exposure examination and tests; 4=termination examination; 5=evaluation of ability to wear a respirator.

OSHA-mandated medical tests and procedures are in **bold**.
AL, action level; BUN, blood urea nitrogen; CBC, complete blood count; CNS, central nervous system; CXR, chest X-ray; EKG, electrocardiogram; FOB, fecal occult blood; FVC, forced vital capacity; FEV, forced expiratory flow; FEV₁, forced expiratory volume in 1 second; GI, gastrointestinal; LFT, liver function tests; MRP, medical removal plan; PE, physical examination; PFT, spirometry; R/A, radioimmunoassay; TWA, time-weighted average; ? = possible association.

Table 58.1 (Cont'd) Requirements of the OSHA Standards on medical screening for workers with specific exposures, and other OSHA regulations regarding medical screening of workers in specific trades

- when the patient has had significant exposure to an agent or agents known to be associated with a disease for which screening tools exist and there is evidence that early detection may improve outcomes; or
- when the US Preventive Services Task Force recommends screening, e.g., the Task Force recommendation that patients with potential tuberculosis contact receive regular PPD skin testing; PPD testing should be performed in settings with recognized high potential for exposure to tuberculosis, such as prisons.

Screening programs for occupational diseases should be based on the standard principles of screening previously described. Unfortunately, there is limited information available for the occupational healthcare provider on the efficacy of screening for disease in occupationally exposed populations. The American College of Occupational and Environmental Medicine (ACOEM) has developed protocols for the detection of various occupational conditions, based on target organ, disease type, and exposure; the National Institute for Occupational Safety and Health (NIOSH) website also provides guidance.¹¹

An important and often overlooked barrier to secondary prevention of occupational diseases is access to follow-up diagnostic testing and treatment. In some states, the worker's compensation system may unfortunately pose barriers to prompt care. Additionally, healthcare providers need to recognize that the treatment of any occupational diseases that are identified should include attempting to decrease occupational exposure to the causal agent. Ideally, this should be accomplished both for the identified patient and for similarly exposed coworkers.

TERTIARY PREVENTION OF OCCUPATIONAL ILLNESS AND INJURY

Tertiary prevention of illness and injury is focused on minimizing morbidity, disability, and mortality due to occupational diseases and injuries. Examples of tertiary occupational disease prevention include surgery for the treatment of lung cancer in an asbestos-exposed worker or carpal tunnel release in a worker with work-related carpal tunnel syndrome. In addition to medical treatment, tertiary preventive services include disability prevention. Disability prevention may be facilitated by:

- providing appropriate therapeutic medical care;
- coordinating with the employer regarding return-to-work issues such as modified duty, in which work tasks or schedules may be changed to allow return to work; and
- in those situations in which the worker cannot return to the previous job, facilitating vocational rehabilitation. An example of a situation in which return to work at the previous job might not be feasible would be in a worker with isocyanate-induced asthma – in that situation, the affected worker should be referred to appropriate vocational rehabilitation programs.

Managing return to work for patients with occupational health problems requires intensive coordination between

the healthcare provider, the employer, and, where it exists, the union. As is true with requests to modify exposure for primary disease prevention, healthcare providers should explicitly request the patient's permission prior to communicating with the union or the employer about return to work. An example of how the healthcare provider can assist in return to work efforts is provided by that of a reporter who has undergone carpal tunnel surgery for work-related carpal tunnel syndrome and is now ready to return to work. Often, after receiving surgery, the patient will receive hand therapy to minimize his or her chance of reinjury. In the interim, the healthcare provider can work with the employer to initiate ergonomic changes designed to prevent both exacerbation of the carpal tunnel syndrome and development of new musculoskeletal disorders. Appropriate changes might include improvements in the computer workstation by provision of an adjustable keyboard, an adjustable chair, and voice-recognition software, and introduction of a modified schedule, in which the patient progressively increases repetitive work activities and is provided with alternative tasks to minimize hand-intensive work.

CONCLUSION

In conclusion, primary, secondary, and tertiary prevention of occupational health problems should be an integral part of the practice of occupational medicine. Successful prevention endeavors often require time-intensive efforts by healthcare providers coupled with management cooperation. Finally, healthcare providers should familiarize themselves with exposures that trigger OSHA-mandated screening examinations.

Chapter 59

Communication and Assessment of Risk

Bernard D Goldstein, Audrey R Gotsch

INTRODUCTION

The success of a physician's practice must always be judged in terms of the outcome of health and wellbeing of the patients. This reflects not only the correctness of the physician's diagnosis and actions but also the physician's ability to communicate recommendations to the patient. Communication is thus a central skill in the practice of medicine and risk communication is, in a sense, a subset of patient communication. Since before the time of Hippocrates, communicating risk to patients has been an important tool used by physicians. In recent years, however, the concept of risk communication has been extended to the health and wellbeing of the community.¹⁻³

Modern medicine has two competing trends in terms of the need for physicians to communicate effectively. The move toward superspecialization places many physicians in positions where there is little or no opportunity to explain anything to a patient, e.g., pathologists and radiologists. Conversely, the increased desire of patients to be involved in medical decisions that affect them in this era of holistic medicine places more demands on the communication skills of those physicians who do have patient contact. This is further complicated by the increasing complexity of modern medicine and by the rapid movement from a passive to an active information era. Coverage by mass media may lead to the patient learning about the significance of a study outcome published in the latest issue of the *New England Journal of Medicine* before the physician's own copy of the journal arrives in the mail. The blossoming of the internet as a communications medium is providing patients with new information sources, many of which are not subject to even a modest amount of peer review.

The risk communication focus in this chapter will be on those aspects of risk communication that are pertinent to physicians involved in occupational and environmental medicine on a full- or part-time basis. We describe some of the basic behavioral theories that provide the foundation for sound risk communication, and generalize from single patient issues familiar to the general physician to special problems involved in the workplace, to the often more difficult problems encountered in environmental medicine when communicating with groups of individuals, communities, or representatives of different interested parties, regulatory agencies, and the media.

Risk communication will be addressed broadly in this chapter to include the one-on-one activities of physicians dealing with individuals, and the issues faced by the public such as the risk assessments of chemical and physical

agents. It is the latter application of the risk communication concept that has gained widespread use among governmental agencies and various interest groups who are exploring means to improve their ability to communicate about risks.

Concern about health risks of chemical and physical agents in the environment has led physicians to become more involved in responding to the public about controversial issues related to the levels of risk to human health. If appropriate societal balance is to be maintained between the risks and benefits posed by environmental agents, it is crucial that physicians increase their understanding and communication skills regarding these issues. The next section provides an overview of the risk assessment paradigm at a level that is useful for a physician to understand and to translate to the public. The ensuing section addresses the basic concepts that provide the foundation for effective communication. These are followed by a consideration of a number of issues pertinent to the communication of risks.

RISK ASSESSMENT PARADIGM

The risk assessment paradigm consists of four major steps: hazard identification; dose-response evaluation; exposure assessment; and risk characterization. It is derived from standard engineering approaches, such as those that attempt to determine the likelihood that a bridge will fall based upon knowledge of the strengths of the structural components, the weight that will be carried and external forces such as wind speed. It is also derived from the three 'laws' of toxicology: the dose makes the poison, the specificity of the biologic hazards posed by chemical and physical agents, and the unity of the animal kingdom, including humans.

The first law of toxicology, the dose makes the poison, is attributed to Paracelsus. It is central to all toxicology and is equivalent to the dose-response evaluation step of risk assessment. Basically, everything causes risk, even water – it is all a matter of dose. The second law of toxicology, recently attributed to Pare, is that the inherent structure of a chemical and the biologic niche in which it reacts confer a very high level of specificity to the type of effects, i.e., the hazard, caused by a chemical. As examples, radioactive iodine preferentially causes thyroid cancer because of the specific iodine uptake mechanisms of the thyroid gland, and carbon monoxide interferes with oxygen delivery because of its propensity to bind to the oxygen-combining site of hemoglobin. Note that risk is conferred only by the

combination of hazard and exposure – no matter how intrinsically hazardous a chemical is, there is no risk unless there is some exposure to it leading to the internal dose at the organ of concern.

The third law of toxicology, that humans are animals, is the basis for using laboratory animals for the extrapolation of hazard identification and dose–response information to humans. There are certainly differences between humans and laboratory animals, but these are relatively minor compared to the broad degree of similarity in structure and function of organelles, cells, tissues and organs. Understanding the relevant differences permits extrapolation from animals to humans. Where ethically possible, human data are of value because they avoid the pitfalls inherent in extrapolation. But human data usually have been obtained from relatively high-level exposure situations, often in the workplace. Accordingly, extrapolation from such data to lower levels and to the general population also is necessary.

Exposure assessment, the third step of risk assessment, is the measurement of internal dose, often indirectly. Physicians are most comfortable with the situation of drugs in which dose is usually obvious because it is prescribed. In the workplace it is often industrial hygienists who evaluate the extent of exposure of individual workers, sometimes through the use of area-wide measurements or, ideally, of personal monitors. Exposure assessment for members of the general population, for example to the effluent of a factory, often requires simplifying assumptions which are best made by taking into account worst case situations for the most sensitive members of the general population.

Translation of external dose to internal dose to the target tissue often depends upon the availability of biologic markers. In the two examples above, one can use radioactive scanning of the thyroid gland to determine radioactive iodine uptake, and carboxy hemoglobin levels to provide an accurate marker of the extent of carbon monoxide exposure over the past 4–6 hours, as well as a predictor of its adverse effects. But there are very few such internal indicators. In many cases, increased susceptibility to chemical exposures will represent changes in the internal pathways that lead to the formation or detoxification of toxic intermediates at a target tissue. In other words, genetic polymorphisms that alter human susceptibility to chemicals often act to alter the extent to which external exposure is converted to internal dose to target tissue.

Risk characterization, the last step of a risk assessment, is the interface between the risk assessor and the risk manager.⁴ Too often risk is characterized in terms of an abstruse and poorly understood mathematical formulation. The aim of risk characterization should be to serve as the basis for the communication of risk information. The risk should be characterized in such a way that it is readily translatable into who is at risk, for what diseases, and under what circumstances.² The parameter should include the duration of time for adverse outcomes to develop, which is often better understood than the usual numerical statement of chances per million.⁵ The key

uncertainties underlying the risk assessment should be included as part of the characterization, but a mathematical formulation of the extent of uncertainty is usually unnecessary and can further obscure the goal of the risk assessment.⁶

RISK COMMUNICATION AND MAJOR HEALTH EDUCATION CONCEPTS

A basis for effective risk communication exists in the body of theoretical concepts and research knowledge underpinning the practice of health education. Of the major health education concepts, perhaps the most important for risk communication is the health belief model, which explains behavioral change on the basis of patients' belief in their own susceptibility to a disease or condition, its severity, the effectiveness of techniques for its prevention or treatment, and their own capacity for making use of those techniques. This section summarizes the health belief model as well as other major health education concepts, such as empowerment, locus of control, social learning theory, social support, and diffusion of innovations.

The health belief model

The health belief model developed in the 1950s from stimulus–response and cognitive theories of behavior.⁷ The model was conceptualized by Hochbaum⁸ and his colleagues in the US Public Health Service who examined the motivating factors for individuals to participate in free tuberculosis screening programs sponsored by the US Public Health Service. Their work identified three critical motivational factors: people's perception of themselves as personally susceptible to tuberculosis, even in the absence of symptoms; their belief in the effectiveness of chest radiographs as a detection technique; and their belief that early detection and treatment would benefit them. The single most important variable in moving individuals to take action was the belief in their own susceptibility to tuberculosis.

Since this initial study, the health belief model has been refined through further research and is now applied to the full spectrum of behaviors that affect health. Training in the application of the model can greatly enhance physicians' ability to perform risk communication in environmental and occupational medicine settings.

Components of the health belief model

The health belief model, as it is now generally formulated, holds that individuals will take action to prevent damage to their health, to screen for disease, or to control disease, if they: (1) regard themselves as personally susceptible to a given condition; (2) believe the condition to have serious consequences; (3) believe that the action will either reduce their susceptibility or reduce the severity of the condition; and (4) believe that the anticipated barriers to (or costs of) taking action are outweighed by the benefits.⁷ The combi-

nation of perceived susceptibility and perceived severity is often referred to as 'perceived threat'. In most formulations of the model, educational level and other demographic factors are taken into account as influencing perceptions of susceptibility, severity, benefits, and barriers.

A refinement of the health belief model has involved the introduction of Bandura's concept of self-efficacy.⁹ This concept relates to the individual's belief that he or she can effectively perform a given action believed to be protective of health; self-efficacy amplifies the model's reliance on the perception of benefits. For example, if workers are to use protective equipment during exposure to an occupational hazard, they must believe not only that the equipment will protect them but also that they are capable of using the equipment consistently and effectively. Studies point to the significance of self-efficacy as a critical factor in behavior change.^{10,11}

Implications of the health belief model for risk communication

The health belief model underscores the importance of risk communication and provides an important framework for physicians to use in conducting it. The model points to the fact that risk communication must be a part of a comprehensive strategy for communicating about health beliefs if it is to be effective in producing behavior change.¹² For example, providing information about an occupational hazard may not cause workers to modify their actions if it is not also accompanied by information that stresses the workers' self-efficacy.

The evidence is strong that attention to the variables outlined in the model can lead to sustained changes in behavior, whether one is dealing with an individual patient, a group of patients, or a community. Such changes can be accomplished if communication is designed to underline the susceptibility of an individual or group to a particular risk, the severity of the risk, the effectiveness of a course of action in protecting health, the capacity of the individual or group to perform the action, and the relative weight of the benefits of the action as opposed to its costs.

Interventions can be more effectively planned if data are available on the health beliefs of the target population. For example, if workers in a particular industry accept their susceptibility to occupational asthma and understand that appropriate clean-up and ventilation procedures can help prevent it,¹³ but do not regard asthma as a severe enough condition to warrant the inconvenience of utilizing the procedures, an intervention could be designed that would emphasize the severity of the disease (while at the same time giving appropriate weight to the other variables identified in the model). In another population, however, it might be more important to emphasize susceptibility or in another setting self-efficacy, depending on the baseline health beliefs of the target group.

Empowerment and locus of control

Closely related to the idea of self-efficacy are the concepts of empowerment and locus of control. The latter has to do

with an individual's conception of the ability to control threats to health. If control is perceived as external, such as controllable only by an employer or by civil authorities, the individual is unlikely to have any motivation for behavior change that could protect his or her health.^{14,15} Motivation for action is far more likely when patients believe themselves to have some control over risks to health. The locus of control may be at the individual level (in quitting smoking or in taking appropriate safety precautions on the job) or it may be at the level of the community, for example, in persuading industries to properly discharge their hazardous wastes.

Empowerment is a process through which individuals or communities take control over risks and over their environment, acting to protect their health.^{16,17} It is often viewed as a process whereby problem-solving ability is increased. In the patient-provider relationship, the provider who empowers patients enables them to take an active role in protecting their health, rather than encouraging them to take the passive role of sick people who wait to be cured. As Lewis explains, the provider's role is not so much to 'intervene' as to enable patients to 'modify their interpersonal environment in ways that foster positive health behavior. In the process, personal levels of power and control, including self-efficacy, are enhanced'.¹⁸

Empowerment plays an important role in approaches to improving health through community organization, where the physician can also have a critical enabling role. Communication about risk at the community level means empowering both the community as a whole and individuals within it. Community action to restore areas of contamination, frequently cited as brownfields, is an example of community empowerment. Involvement with community efforts, with its resulting increase in social support, has been shown to increase the individual's sense of control and to produce significant physical and emotional health benefits.^{10,19} As communities become empowered they are better able to engage in collective problem solving and to reduce risks. Research indicates that community empowerment may be statistically reflected in declines of alcoholism, suicide, and divorce rates.^{20,21}

Social learning theory

Social learning theory explains health behavior change in terms of dynamic inter-relationships among behavior, personal factors, and environmental influences; the interaction of these three components is called reciprocal determinism. The theory identifies a variety of personal factors as critical, including the individual's ability to symbolize the meanings of behavior, to foresee the outcomes of behavior, to learn by observing others, to regulate behavior, and to reflect on and analyze experience.^{10,22} Environmental factors extend to all external influences on a person's behavior, including both physical and social dimensions. Some proponents of social learning theory use a behaviorist framework, in that they consider health behavior in terms of positive and negative reinforcements. This branch of the theory places strong

emphasis on the individual's locus of control – those with an internal locus of control being more likely to initiate change themselves, those with an external locus of control more likely to be influenced by others.²³

The other important branch of social learning theory, developed in the early 1960s, emphasizes cognitive constructs, among them 'observational learning', which holds that behavior can be learned by observing the behavior of others and the rewards others receive, without the rewards having to be received directly by the observer.²⁴ Among other constructs that the theory identifies as critical in determining behavior, one of the most important is 'behavioral capability', which distinguishes two components of behavior – knowledge and skill. To make a behavior change a person needs to know not only what the behavior is, but also how to perform it. This concept points to the importance in risk communication not only of addressing the behaviors that can reduce risk, but also of providing training and practice in the skills involved in performing the relevant behaviors.

Social learning theory provides a foundation for risk communication by identifying both behaviorist and cognitive constructs in individual behavior; and by placing these within the framework that recognizes that behavior does not occur within a vacuum; that it is a continuous interaction between a person's behavior and the environment where the behavior takes place (reciprocal determinism). It provides an especially valuable theoretical foundation for the design of multilevel, multicomponent interventions, in which individual behavior change and change within the environment are addressed simultaneously.

Diffusion theory

Diffusion theory examines the process by which innovations – ideas, practices, and services – are communicated among members of a social system. It sees innovations as developing from a realm of expertise, known as the resource system, and ultimately being adopted by a given population, known as the user system. The theory identifies the central factors of successful diffusion efforts and points to potential system failure points. Among the attributes of innovations that are likely to meet with successful diffusion and adoption are cost-efficiency, simplicity, flexibility, a low degree of risk, and compatibility with the target population's economic, sociocultural, and philosophical value systems. Innovations are also more likely to be adopted if they show a relative advantage over existing methods and if they are reversible – allowing the individual or group adopting the innovation to return to earlier methods if need be.^{25,26}

Classic diffusion theory saw the adoption process as a relatively straightforward movement from the source that provides the needed knowledge or expertise required to make the change to the agency or individual making the change. Modern formulations of the theory describe a reciprocal, multistep process that may extend well beyond adoption itself (taking into account the need to maintain changes in behavior). Rogers²⁶ identifies a six-step diffusion

process: (1) recognition of a problem or need; (2) basic and applied research; (3) development, in which an innovation is given a form intended to meet the needs of a particular population; (4) production, marketing, and distribution; (5) diffusion and adoption; and (6) consequences.

The constant interaction of the behavior, the individual and the environment involved in adoption of innovations is emphasized by a refinement of diffusion theory known as the linkage approach.^{27,28} This approach identifies a linkage system involved in developing innovation and diffusion strategies; the linkage system includes members of both the resource system and the user system, whose collaboration is facilitated by 'change agents' (themselves often members of the other systems). The linkage approach draws on social marketing research to describe the collaboration between user and resource systems in developing and adopting innovations. The role of the resource system is seen as one of helping the user system determine its needs, expectations, and limitations. In this context, the theory emphasizes the collection of quantitative and qualitative data about a target population, segmentation of a population into subgroups, and tailoring of innovations to suit the needs and sociocultural characteristics of a particular group or subgroup.²⁵

Risk communication can benefit from the use of diffusion theory to analyze how innovations in research knowledge can be effectively transmitted to practitioners and ultimately to the general population. Diffusion theory also offers a means for determining the most effective techniques for developing real-world applications of risk communication approaches that have been developed in demonstration settings.^{3,25,26}

WHO IS INVOLVED IN RISK COMMUNICATION?

The risk communicator

The most important determinant for success in communicating risk is the perceived credibility of the individual engaged in the communication process.²⁹ While many other aspects of risk communication include technical skills that can be learned by the physician, credibility is not a skill that can be learned; it is a standing that needs to be earned.³⁰ Obviously, part of the physician's credibility will depend, at least initially, on his or her employment affiliation. For example, the physician employed by a company will have a different level of credibility if there is a difference of opinion concerning the extent of employee risk than a physician representing workers who is not employed by the same industry. Company physicians can and do build credibility with employees through activities on a one-to-one basis as part of their routine practice of occupational medicine, and this can be extremely helpful when the physician assumes the role of a risk communicator.

Corporations also differ among themselves in their inherent credibility on health issues. It is hard to imagine that a company that fights to obtain 'give-backs' on health

insurance at the collective bargaining table will be very convincing when it attempts to communicate a concern about reducing risk for a worker or community. Perhaps the least credible industry will be one that is seen as inherently inimical to public health. For example, it is unlikely that anyone in the workforce or general community would believe any communication concerning the risk of a chemical hazard that emanated from a cigarette company, or an otherwise neutral industry that happened to be owned by a major tobacco corporation.

Similar to general clinical medicine, the basis for risk communication is a history that includes questions that will identify potential risks. Such a medical history allows the physician to understand the full range of risks facing the patient and facilitates the use of communication techniques appropriate for the individual's level of understanding and concern.³¹ A careful history that identifies work, home, or recreational activities that could lead to chemical exposures is crucial (see Chapter 3). The work practice and its possible adverse consequences should be sufficiently understood so that alternative activities leading to protection can be stressed. As is clear from studies of cigarette smokers, the physician can be highly effective in reinforcing messages that may be present in the workplace or available through product labels. Conversely, the absence of such reinforcement, when the risk is or should be known to the physician, may be perceived by the patient as a form of acquiescence in the unsafe activity.

Physicians also need to consider that concern about risks expressed by an individual can actually mask other issues. For example, stress due to job dissatisfaction, problems with an employer, or even unstable home situations may result in non-specific symptoms which are attributed to a chemical or physical agent in the workplace. In community issues, concern about property values or changes in the ambience of a community may also be expressed as health issues.

Physicians have a responsibility not to abuse their position of trust in a community by allowing such ancillary factors as property values or community ambience to interfere with their judgments about health risk. A particularly egregious example of abusing this position occurred when a surgeon, active in local medical society affairs, predicted in a letter to the Mayor and the local media that dire health consequences from air pollution would be caused by the siting of a natural gas co-generation plant in the local industrial park. The community contained many senior citizens who were thus led by concern for their health to strongly oppose the development of the plant. This opposition occurred even though the community was experiencing frequent brownouts during the hottest days of the year which could have led to heat stress due to the lack of functioning air conditioning equipment, as well as to potential problems with medical assistance equipment which also required electricity. The physician later admitted to his colleagues that he had overstated the health problem because of his concern with the change in the character of his previously rural community.

Recipients of the risk message

Workers

Communicating the level of risk that may be present for a worker in a specific industry presents many of the same challenges that exist for communicating to an individual patient. Workers, as well as patients, are more likely to heed advice belatedly about preventive measures when they are suffering from a problem caused by their failure to take preventive action. A physician is derelict in responsibility if he or she simply conducts first aid after a workplace accident and allows the workers to return to the same setting where the injury occurred. Any injury in the workplace must lead to a full inquiry as to its cause. To the extent that the worker's actions, whether negligent or not, played any role, it is crucial that the physician actively communicate to the individual worker, to coworkers and to management the cause of the injury in order to avert a future problem, and to encourage the worker to seek appropriate training.³²

Every physician encounter with a worker should be viewed as an opportunity for the prevention of occupational disease. The best way to reinforce safe work practice and to inform workers of potential hazards is for the physician to thoroughly understand the job tasks that are conducted within the workplace. Physicians with responsibility for a group of workers are obligated to familiarize themselves with the range of tasks that are performed in their setting. One of the best ways to evaluate the workplace is simply to ask workers what they believe to be the most dangerous part of their job, and to follow up on site by observing them on the job. This not only educates the physician, but it also establishes a link that will foster effective risk communication between the physician and the worker.

The obligation to understand the workplace also extends to the primary care practitioner who sees patients in his or her office independent of any formal relationship with the employer. All patients should be questioned regarding their workplace responsibilities. Again, questioning that goes beyond the patient's job title and approaches an understanding of the potential workplace hazards is itself a risk communication tool. Demonstration of concern by a physician is a highly effective way of letting a worker know that workplace hazards do exist, and reinforces health and safety messages that are provided at the workplace. How effective the physician may be in obtaining information from the patient will be determined by the physician's communication skills.

Peer group support can be a major determinant in how workers respond to job threats. Changing risky work behaviors frequently requires an understanding of the group dynamics that may lead a population of workers to fail to act in a safe manner. Sometimes long-standing traditions of work practice or 'macho' attitudes, particularly among young males, may interfere with safety at the workplace. In addition, certain preventive actions may be cumbersome or uncomfortable, such as wearing protective

clothing, and therefore may not always be accepted by workers. Effective risk communication in such situations is facilitated by understanding the peer structure and using an approach that maximizes the likelihood that peer pressure will lead to the reinforcement of safe work practices. Change is possible; if 'macho' hockey players can be convinced to wear protective headgear, so can construction workers.

Physicians also have the opportunity to communicate the risks of personal health behaviors to workers that are not due to workplace hazards. Health promotion activities aimed at high blood pressure, obesity, high cholesterol levels and other risk factors have proven to be effective in decreasing adverse health consequences among workers and may be cost-effective for employers who develop these programs.

General public

While physicians are accustomed to discussing issues in terms of health, it must be emphasized that the residents in communities respond to environmental risks for many other reasons, stated and unstated. One potentially strong force in environmental issues is a sense of outrage of what *they* are doing to *me*. Whether or not health is the primary or actual concern, health will almost always be a stated issue.^{30,33,34}

So, to whom does the public listen? Note that we have not asked the question 'Where do members of the public get their information?'. There have been a number of attempts to study the latter question, but there is an important distinction between where one obtains information and whether the information is believed. Despite the fact that at least in the US, the public rates doctors and universities as highly credible sources,³⁵ they are rarely accessed as a source for information. Perhaps the most important point is that the American public is highly skeptical about their usual sources of information regarding environmental matters; surveys have rated industry, government, and the press as very poor sources, with environmental groups rated only slightly better if at all.

An effective strategy is to include family members, also part of the general public, in discussions with employees about health roles and may facilitate discussion of dose-response. For example, a worker may be exposed to a chemical at levels that he or she can smell at the workplace with no concern about its health effects, but will be genuinely frightened by the exposure of family members to much smaller amounts if it becomes part of a community problem. Similarly, the worker's spouse, based on warnings about relatively small amounts in the general environment, realizes that there is reason to be concerned when a worker is exposed to higher levels.³⁶

In every society risks to children are of particular concern, as has been demonstrated by the public alarm about alar in apples. Asbestos in schools has presented a particularly difficult problem in risk communication. Asbestos is dreaded as a carcinogen for very good reasons; however, depending upon its location and physical state, there may be less risk leaving the asbestos in place, or seal-

ing it, than there is in dislodging the asbestos and removing it. The process of removing asbestos may be risky to the workers and tends to put asbestos into the air where it can be inhaled by children. Unfortunately, consultants hired by schools to give advice on asbestos removal may themselves be in the business of removing asbestos. We need to be at least as cautiously skeptical about so-called 'environmental experts' as we are with advice from medical consultants.

Decision makers

Physicians with expertise in environmental and occupational health are often asked by societal decision makers for advice on risk assessment and communication. In some ways community physicians and healthcare providers may be better able than academic scientists to empathize with the problems of decisionmakers. The latter are often facing time pressures caused by court, legislative, or political factors and, like physicians, may not have the luxury of obtaining all the needed data before a decision needs to be made.

Like a physician faced with a puzzling diagnostic problem, it is important to the decision maker to be able to cull significant information from a mass of data, to logically place a particular issue into a coherent framework, and to synthesize seemingly disparate information. When issues involve human health, the lay decision maker can be greatly assisted by a lucid explanation of the health risks and their implications by an even-handed physician.

Often the question is not so much whether an effect will occur, but how important it is to human health. For example, using sensitive modern techniques, researchers can accurately determine the level of an air pollutant capable of causing as little as 3% constriction of airways. Industry may tell a lay decision maker to ignore such minimal bronchoconstriction, as it is well within the range of physiologic changes that occur when one goes from a warm room to a cold outdoor environment. On the other hand, clinicians are well aware of the morbidity due to asthma-induced bronchoconstriction; while small on a population basis, pollutants may have a marked effect in susceptible individuals.

Many occupational medicine physicians work for corporations and will become involved in interactions between the corporation and the community, particularly when issues affecting public health are raised. To function effectively in this situation the physician must understand the numerous cultural issues that profoundly affect the interface between a corporation and a community. Many of these represent the difference in the populations involved. Not uncommonly, industries with significant workplace hazards or emissions are located in economically disadvantaged communities whose predominant populations are often African-American or Hispanic, while the key corporate decision-makers tend to be members of the relatively wealthy white population, who live in distant communities. The term 'environmental justice' is used to characterize the recognition that minority and disadvantaged

	Industry culture	Community culture
Secrecy	Good	Bad
Organizational clarity	Good	Rare
Redundancy	Bad	Good
Accountability	Good	Rare to non-existent
Initiative on community issues	Dangerous	Rewarded
Metric of success	Extrinsic: easily measurable as dollars	Intrinsic: difficult to measure

Table 59.1 Current issues inherent to risk communication by industrial organizations

communities bear a disproportionate burden of polluting and hazardous industries. The issues posed by environmental injustice are increasingly important and are not solvable without careful and respectful attention to the voice and involvement of the community (see Chapter 57.2).

It must be emphasized, however, that even without the issues considered under the sphere of environmental justice, there remain substantial differences between the culture of industries and the culture of communities (Table 59.1). Secrecy in the form of trade secrets is central to the continued competitive success of industries, while within a community secrecy is met with suspicion. The corporate world strives for organizational clarity, while communities tend to derive strength from a plethora of overlapping organizations that combine or go their own way depending upon the specific issue they are addressing. To a corporation redundancy is wasteful, while to a community it may be the only way to get the message across; success in the corporate world may be relatively easily measured in terms of dollars, while for a community member success is much more of an intrinsic metric that is not so readily gauged.

None of these cultural differences between corporations and communities is absolute but the physician must be aware of them when in the position of representing an industry to the community. In fact, there are really only two laws of interaction with the community for government or for industry. The first is if you have already irrevocably made a decision, do not approach the community as if there is a true dialogue in mind, as they will certainly see through the falseness of such an approach; and, second, there are no laws, each situation is different and each community is different. There are, however, reasonably obvious rules of engagement which include openness, transparency, honesty and respect.^{33,34,37}

The press

Physicians have not been trained to communicate with the press, and are often astounded that what they say or do is transmitted so poorly by the press to the public.

The first task is to understand the press.³⁸ Five characteristics seem particularly pertinent.

1. Similar to physicians, members of the press consider themselves to be professionals performing a very important public service.

2. Members of the press are often highly suspicious cynics and iconoclasts; a desire to bring down idols and the successful may be part of their personal make-up and a key to success in their field.
3. In America the press is less subject to checks and balances than any major institution.
4. They may have minimal scientific or medical background.
5. Different professional subgroups of the press, e.g., daily newspaper reporters, magazine writers, or TV newscasters, have different needs in order to accomplish their jobs.

It is important to understand how members of the press handle a situation in which they may have very little background and may know little about the underlying technical concerns of specific issues. However, what an ethical journalist has been trained to do is to provide a balanced presentation of an issue. This leads to obtaining one quote from an industry representative and one quote from an environmental representative on a health issue or, more commonly, asking industry and environmental or labor groups for names of health experts for them to interview. This seemingly balanced and appropriate approach can, however, lead to the impression of greater uncertainty than otherwise would be present. There is almost always going to be some degree of disagreement among experts on any critical issue; however, most experts will usually have broad areas of agreement. The procedure used by journalists to obtain information tends to focus on areas of disagreement, or experts who are at one end or another of the usual spectrum of opinions. Involvement of attorneys may further polarize the discussion.

OTHER FACETS OF EFFECTIVE RISK COMMUNICATION

Understanding the issue

It is crucial for effective communication to understand the dimensions of the issue of concern.^{39,40} As physicians we have all learned the importance of saying, 'I don't know', when we are in an area of medicine beyond our expertise. This certainly is also true when communicating to individuals or the public about risks. It is also crucial to appreciate the patient's or public's level of knowledge and empathize with their concerns in order to effectively communicate one's message.

Regarding the risks of chemical or physical agents, it is important to address toxicologic principles, including dose-response; the specificity of the effects of chemical and physical agents; and experience with animal testing as a controlled test for potential human response.

Many toxic compounds, namely direct-acting or intrinsic toxins, have thresholds below which there is no risk of an adverse effect. Others, such as mutagens and carcinogens for which it is assumed that any one molecule is capable of producing an effect, have very low-level risks at low concentrations. The relationship between dose and toxicity may be poorly understood by the public. In addition,

surveys illustrate that the public frequently does not understand the association between the environment and public health.⁴¹ The specificity of the effects of chemicals may also be poorly understood. The same person who readily understands that a knife, found near a person with a bullet wound in the heart, cannot be the murder weapon will readily assume that because asbestos can cause lung cancer it must also cause brain cancer.

A good analogy for physicians to use to communicate concepts of dose effects, and specificity of chemical and physical agents is to talk about medicines as chemicals. People understand that sufficiently high doses of aspirin can be lethal; conversely, an amount of aspirin can be so small that it will be of no value whatsoever in affecting pain. They also understand that aspirin is of no value for constipation and that a laxative will not decrease the pain of arthritis.

Tell the bad news

There is an obligation to report known or suspected health hazards (see Chapter 55). Not communicating such hazards when it is appropriate to do so is more than just loss of credibility or bad press; it is a major legal liability issue. Industry physicians who failed to inform workers about the information linking asbestos to lung cancer and mesothelioma have been subjected to law suits. An important corollary is that when industry finds out something has gone wrong, it should move to get the information out as quickly and openly as possible, preferably with a commitment to address and correct the issue.

An excellent example of the appropriate means to release information to the public is the issue of dioxins in paper products. The American paper industry became aware of the presence of varying amounts of dioxins in bleached paper products, which include such items as tampons, baby wipes, surgical gauze, food containers, and toilet paper. The industry organization, after an internal debate, elected to rapidly inform the public and the appropriate governmental agencies about the concern, along with a plan to investigate the causes and make any necessary process alterations. This issue received EPA acquiescence. Considering the personal intimacy of some of these paper items, the public response has been remarkably low key. Imagine, however, where the industry would be now if it had tried to hide the issue. Had such information 'leaked out' the EPA would have had enormous pressure to act confrontationally rather than co-operatively. Instead, there has been a constructive approach to obtain the scientific and technical information necessary to tackle this difficult problem.

Redundancy counts, and counts again

Communication to patients or the general public also requires reinforcement. The best time to tell people about a potential problem is before an adverse event occurs. Unfortunately, few people are listening or are interested

enough at that stage to pay attention. However, that does not mean that no one is paying attention. What it does mean is there is value in being proactive and in recounting what is known, assuming that only a small percentage of individuals, or of a larger audience is going to receive any one message. There is rarely one audience only, but rather a multiplicity of individuals who are reached through a variety of media, starting with school children and extending through senior citizen groups.

Redundancy has a negative connotation to it, and should rather be viewed as a consistent message. This strategy has worked very well for public interest groups, including environmental groups that have specific issues that are of concern to them. Continually presenting an issue until the point is made is an approach that has characterized effective environmental organizations.

Do not condescend

The most important lesson that physicians and other experts have to learn when dealing with the public is not to be condescending. Empathic recognition of the problem perceived by the public is always the best approach. For instance, an approach that is bound to fail is to respond to a concern expressed by the public about a chemical in food by pointing out that foods are themselves chemicals, or that illness and death are a part of life.
