19.9 Silicosis

Daniel E Banks

The most common health effect of occupational exposure to crystalline silica is silicosis, which remains the most common pneumoconiosis worldwide. This chapter will focus on the different clinical presentations and pathogenesis of silicosis, associated illnesses, their diagnosis and management. Silica exposure is discussed further in Chapter 46 and the health effects of coal mine dust which contains silica are addressed in Chapter 19.

Silicosis was first reported by the ancient Greeks and has been recognized throughout history.¹ The prevalence of this illness peaked in the last half of the 19th century and the early part of the 20th century, when mechanized industry was developing and the relationship between dust exposure and disease was less well understood. Yet, even today in developed countries, sporadic outbreaks of silicosis occur when workers are consistently exposed to silica particles of respirable size (0.5–5.0 μm in diameter)² at levels exceeding those recognized to be safe. The National Institute for Occupational Safety and Health reported that between 1968 and 1990 there were 13,744 deaths in the US where the death certificate mentioned silicosis. In more recent years the number attributable to silicosis appears to be lessening.³

Silicon dioxide, or silica, is the earth's most abundant mineral. Silica is considered to be either free (i.e., unbound to other minerals) or combined. Minerals with high amounts of free silica include quartz (including granite), flint, chert, opal, chalcedony, and diatomite. Combined forms of silica are called silicates and include, among others, asbestos, talc, and kaolin. This chapter will focus on the adverse pulmonary aspects of free silica exposure.⁴

Silica can exist in the crystalline or amorphous (non-crystalline) form. In the crystalline form, silica exists in different polymorphs (crystalline structures) as quartz, cristobalite, tridymite, coesite, and shistovite (Fig. 19.9.1). These are different in their structure, fibrogenicity, and biologic activity.⁵ Of these, quartz is ubiquitous in the environment and occurs as sand as well as a constituent in many rocks. Cristobalite and tridymite occur naturally in lava and can be formed by the heating of quartz or amorphous silica. All but shistovite are arranged as a tetrahedral crystal.

Amorphous silica is non-crystalline and relatively less fibrogenic. It does not cause lung fibrosis. It occurs as diatomite (skeletons of prehistoric marine organisms) or as vitreous silica (glass), the result of carefully melting and then quickly cooling free crystalline silica. Heating diatomite (a process known as calcining), with or without alkali, forms cristobalite and adds the respiratory toxicity of free crystalline silica. Concerns regarding the impact of other minerals associated with the surface of the quartz particle on fibrogenicity have been considered, but have been inadequately researched.⁶

Many opportunities for occupational exposure to crystalline free silica of respirable size exist in the workplace. Some commonly encountered occupations in which the risk of silicosis exists are listed in Table 19.9.1. The Occupational

Safety and Health Administration permissible exposure limit (PEL) is 100 $\mu\text{g}/\text{m}^3$ for an 8-hour work exposure.⁷ There remains debate regarding whether this is a sufficiently protective standard.^{8,9} In small, unregulated industries, as well as in numerous high-risk occupations, such as silica flour mill operations, sandblasting, drilling, and grinding, exposures have been documented to be excessive.¹⁰

The primary pulmonary illness attributable to silica exposure, silicosis, is caused by the inhalation of respirable size silica particles, and can be categorized by recognizable findings on the chest radiograph. The most typical presentations, simple silicosis and progressive massive fibrosis, appear different radiologically but are grouped under the category of classic silicosis because they are a part of the typical radiographic spectrum of this illness. Radiographically, simple silicosis appears as small (less than 10 mm in diameter) rounded opacities, typically predominant in the upper lung zones. Progressive massive fibrosis (also described as conglomerate silicosis) is the result of the coalescence of these small nodular opacities and appears as larger opacities (more than 20 mm in diameter), again typically distributed in the upper lung zones.

The other radiographic presentation of silicosis occurs only rarely and is referred to as silicoproteinosis, or acute silicosis. This condition appears as a basilar alveolar filling pattern following an overwhelming exposure to free crystalline silica over a short time span.

Bronchitis, a well-recognized effect of chronic dust inhalation, can occur with silica dust inhalation (see Chapter 19.4). Airway obstruction and lung function decline is most common with progressive fibrosis. In addition, silica exposure can be associated with autoimmune diseases (scleroderma, lupus erythematosus, rheumatoid arthritis (see Chapter 23.5)), nephropathy (see Chapter 25), tuberculosis (see Chapter 22), and lung cancer (see Chapter 30.1).¹¹

CLASSIC SILICOSIS

Classic silicosis encompasses a continuum of severity ranging from simple silicosis (presenting as nodular pulmonary fibrosis with or without symptoms) to progressive massive fibrosis (severely disabling restrictive lung disease). These features usually develop slowly and frequently require a working lifetime to develop. However, in a small percentage of workers, the radiographic features of simple silicosis lead to progressive massive fibrosis in less than 10 years. Workers with these findings are described as having accelerated silicosis. Development of these radiographic features so soon after beginning exposure to silica means that progression of disease and severe respiratory impairment is very likely to occur.

The diagnosis of silicosis

There are three requirements for the diagnosis of silicosis. The first is a history of silica exposure sufficient to cause

Figure 19.9.1: Scanning electron micrograph of a respirable sample of crystalline silica showing the diverse shape, size, and structure of these particles. Inset: An x-ray energy spectrometric analysis of a silica particle showing a distinct peak for silica (Si).

this illness. The second is the presence of chest radiograph features consistent with silicosis. The third is the absence of other illnesses that mimic silicosis. When all criteria are fulfilled, the diagnosis of silicosis can be made with confidence and additional clinical investigations are unnecessary. Uncommonly, particularly when other chest illnesses such as rheumatoid nodules, tumor, infection, other pneumoconiosis, or sarcoidosis cannot be clinically ruled out, and/or the exposure history is inconclusive, additional studies such as HRCT scan and lung biopsy are necessary to clarify the diagnosis.

When tissue for diagnostic analysis is required, an open lung biopsy is preferred, as more adequate tissue is obtained, and risk of pneumothorax from transbronchial biopsy is avoided. Because the silicotic lung is stiff in the upper zones and emphysematous in the lower zones, the incidence and morbidity associated with the development of pneumothoraces may be increased with a transbronchoscopic lung biopsy. However, transbronchial biopsy, in association with elemental analysis of bronchoalveolar lavage fluid for silica, has been used in the diagnosis of silicosis.¹²

Determining whether or not silica exposure in the workplace is sufficient to cause silicosis can be difficult and requires clinical judgment tempered by knowledge of the pitfalls in making the diagnosis. Silicosis generally requires prolonged exposure to respirable crystalline free silica at levels exceeding government standards. However, substantial individual differences in susceptibility exist. The most

Occupation	Exposure
Mining	Silica contaminates the mined material
Milling	Dry, finely ground silica (silica flour) for abrasives and filler
Quarrying and stone work	Slate, granite, and sandstone exposures
Foundry work	Silica as a mold: fettling and chipping to make a better molded product
Sandblasting	Ship building, oil rig maintenance, preparing steel for painting
Pottery making	Crushing flint and fettling are major sources of exposure
Glass making	Sand used to polish and as an abrasive
Boiler work	Cleaning boilers may result in exposure to refractory brick and clouds of quartz dust

Table 19.9.1 Major industries with silica exposure

important factors in assessing exposure include the length of employment, exposure measurements (if available), and whether or not the worker was provided with effective respiratory protection. As a rule, the worker's silica exposure occurs as a part of a process that makes the silica particle respirable size. Without exposure to respirable size silica particles silicosis does not occur. The adequacy of respiratory protection devices is highly variable.

The diagnosis of silicosis should not be dismissed even if the worker provides a history of the use of a personal respirator. For example, a worker employed as a sandblaster for 15 years who had used respiratory protection might have a chest radiograph showing a background of small rounded opacities with superimposed bilateral upper zone masses (consistent with progressive massive fibrosis). In this case, the clinical picture would be very consistent with silicosis and the respiratory protection most likely was not adequate. Although respiratory protection has been thought of as an effective measure of preventing dust exposure, not infrequently workers who wear respiratory protection are not sufficiently protected.¹³

Data regarding the silica dust levels in the workplace, if available, can provide important information, but for many reasons may not accurately reflect a worker's exposure to silica over many years. Cases of acute silicosis in surface coal mine drillers have been reported where the measured dust levels were within normal limits. In this example, the measurements were not representative of the overwhelming dust exposures. Therefore, although dust measurements can be helpful, understanding the conditions under which the samples were collected and having confidence that these measurements represent the usual workplace environment are essential.

Individual differences in susceptibility to the effects of silica exposure remain poorly understood, with some workers developing much more severe disease than others employed in the same environment. Dufresne attempted to understand the silica dust burden and particle sizes in those with differing degrees of silicosis. The amount of quartz exposure retained and the length that the particles remained in the lung is important, but there was considerable variability and the investigators were unable to linearly correlate duration of dust in the lung and lung

burden.¹⁴ Recent studies suggest that the risk and severity of silicosis may be related in part to tumor necrosis factor- α (TNF- α) and interleukin-1 (IL-1) polymorphisms.^{15,16}

Pathogenesis and histologic features of classic silicosis

Most forms of silicosis develop slowly. Usually 10 to 30 years are required from the beginning of exposure to the onset of clinical manifestations. Although host factors such as genetics, smoking, and underlying diseases may play a part in the development of silicosis, the most important factors include silica dust concentration in the air, duration of dust exposure, the crystalline structure of the silica particles, the percent of free silica, and the particle size.

Particles less than 5.0 μm in diameter are deposited in the alveoli, most often in the upper lung zones. Particles less than 1.0 μm in diameter are believed to be the most fibrogenic and most able to penetrate into the interstitium.¹⁷ When lung cells in culture were exposed to equal masses of quartz, the smallest size fraction generated the most potent inflammatory response.¹⁸ Depending on particle size, up to 80% of the silica dust is cleared quickly, with the small fraction of retained particles initiating the fibrogenic process.

The slow progression of simple silicosis in humans has made the study of the pathogenesis of this illness difficult. However, the use of animal models and in-vitro studies has made it possible to investigate the effects of exposure to silica particles. Studies of the factors in the BAL fluid collected from silica exposed workers have also provided insight into the pathogenesis of this illness.¹⁹ The pathogenesis of silicosis has recently been reviewed.²⁰ Briefly, inhaled silica particles interact with alveolar macrophages and other lung cells in a complex cascade of events resulting in lung inflammation, fibrosis, and tissue remodeling forming silicotic nodules.^{21,22} Key to the biologic response to silica appears to be its crystalline structure, highly reactive surface groups that generate free radicals and reactive oxygen species (ROS),^{23,24} and persistence in lung tissue.

A complex cascade of events has been described.²¹ Silica particles are directly cytotoxic and can react with cell membranes causing cell injury, oxidant damage, and release of inflammatory mediators. Silica particles can also react with scavenger receptors sites on alveolar macrophages, with the generation of ROS and inflammatory cytokines.

The primary cellular event in the pathogenesis of silicosis is the interaction between the silica particle and the alveolar macrophage. Retained silica particles are phagocytized by resident macrophages or penetrate the interstitium. Alveolar macrophages become activated, and an intense inflammatory response results with the production of ROS, activation of nuclear transcription factors NK- κ B, and AP-1,^{25,26} and release of a variety of inflammatory cytokines and mediators that recruit and activate inflammatory cells, including neutrophils and lymphocytes, promoting fibroblast proliferation and fibrotic responses. Key mediators include IL-1, TNF- α , transforming growth

Figure 19.9.2: Gough and Wentworth lung section from a granite worker showing simple silicosis. Sparse silicotic nodules are present in the lung parenchyma. Hilar lymph nodes are more prominent and show silicotic lesions. Note the scattered changes of centrilobular and paraseptal emphysema.

factor- β , fibronectin, and chemokines, as well as cytokines which may downregulate inflammation such as IL-10.²⁷⁻³⁵

The net result of this ongoing inflammatory process is the silicotic nodule, the histologic hallmark of silicosis. This nodule usually forms near the small bronchioles. In some workers with relatively low silica exposure, inhaled silica is efficiently cleared from the lung and deposited in the lymph nodes. In this instance, presentation of calcified regional hilar lymph nodes on the chest radiograph may be noted without an extensive background of small rounded opacities (Fig. 19.9.2). In most cases, however, the lung cannot effectively clear the dust, and nodules begin to form by the arrangement of a collection of dust-laden

Figure 19.9.3: Photomicrograph (230 \times) of a well-developed silicotic nodule, with central hyalinization and concentrically arranged collagen fibers providing the onion-skin appearance. Peripherally, a rim of dust containing macrophages is seen.

Figure 19.9.4: Photomicrograph (40 \times) of numerous silicotic nodules in close proximity that are beginning to coalesce, an early stage of the development of progressive massive fibrosis. The largest of these nodules shows central necrosis.

macrophages that is loosely surrounded by a reticulum of fibrous tissue. Eventually, a more defined central zone develops containing a mixture of hyalinized connective tissue and silica dust. This area becomes surrounded by relatively dust-free concentrically arranged fibrous tissue yielding an onion skin-like pattern (Fig. 19.9.3). Active inflammation and ongoing fibrosis occur at the periphery, a region composed of dust-laden macrophages, a halo of silica particles, and randomly arranged collagen fibers. As the nodules enlarge and coalesce, they form large conglomerate lesions typically found in the upper lobes (Fig. 19.9.4). These may encroach on the airways and pulmonary vasculature, and lead to a significant degree of pulmonary impairment. At some point, the central zone of this coalesced mass, now recognized as progressive massive fibrosis, may enlarge to a size exceeding its blood supply, resulting in central necrosis. Nodules may begin *de novo* or continue to enlarge even after exposure has ceased. Discontinuing silica exposure once silicosis is diagnosed is important but does not guarantee that the disease will not progress.

Polarized light microscopic examination reveals silica particles if they are present. Silica particles in tissue also may be demonstrated using the technique of scanning electron microscopy, and identified with mass spectrometry (Fig. 19.9.1).

Simple silicosis

Workers with simple silicosis usually do not have chest symptoms. Some, however, report a chronic productive cough, a feature likely similar to industrial bronchitis from dust exposure. Physical examination of the chest usually is unremarkable; audible coarse sounds are the result of coexisting bronchitis.

Roentgenographically, simple silicosis typically appears as an upper zone distribution of rounded opacities less than 1 cm in diameter (Fig. 19.9.5). These opacities are

Figure 19.9.5: This PA chest radiograph is taken from a 24-year-old worker employed for 5 years as a bagger in the production of silica flour. Small rounded opacities (ILO 2/2) are diffusely present in both mid- and upper zones, consistent with simple silicosis. The development of this extent of simple silicosis in such a short time is consistent with accelerated silicosis that may rapidly progress toward respiratory impairment, progressive massive fibrosis, and premature death.

indistinguishable from those seen in simple coal workers' pneumoconiosis (see Chapter 19.10). Hilar lymph nodes are often enlarged with a distinctive peripheral calcification, described as eggshell calcification.

High-resolution CT scans have been shown to have a good correlation with the nodular findings of silicosis on the chest radiograph, and a better description of the extent of emphysema compared to the chest radiograph.³⁶ Correlation between lung function tests and the chest radiograph and CT scan is variable. In simple silicosis it is primarily the degree of emphysema (in the presence of a history of cigarette smoking) rather than the extent of silicosis that determines pulmonary function.³⁷ Yet, the high-resolution CT scan has not been shown to clearly be more sensitive than the chest radiograph in the early detection of silicosis.³⁸ Gallium scanning has not been found to be sensitive or specific for silicosis.³⁹

Pulmonary function studies in simple silicosis do not usually demonstrate functional impairment. There may be a trend for values to progress toward airways obstruction with a decrease in FEV₁ out of proportion to the decrease in FVC, a mild diminution in TLC and ventilatory capacities, and decreases in the helium equilibration time and compliance as the extent of profusion of small rounded opacities increases. This is most clearly exhibited in those with progressive massive fibrosis. As the disease progresses, reduction in compliance usually precedes the reductions in vital capacity or forced expiratory flow rate.

Among working South African middle-aged white gold miners, men with simple silicosis had lower FEV₁ values compared to those exposed without radiographic evidence of disease. The frequency of bronchitis was similar in the two groups. Those with silicosis missed work more often due to chest infections than their similarly exposed counterparts. Miners with silicosis appear to have the same or slightly more airway obstruction than men without silicosis who have had similar total exposure to dust.⁴⁰ Others have shown that silica dust exposure, independent of silicosis, is associated with chronic obstructive airways disease.⁴¹ Pathologic studies demonstrating emphysematous changes support these findings.

Progressive massive fibrosis

Progressive massive fibrosis is the result of the conglomeration of small rounded opacities. It has been traditionally recognized that progressive massive fibrosis develops on a background of advanced simple silicosis. However, among coal workers who develop progressive massive fibrosis, not all have an advanced degree of simple coal workers' pneumoconiosis (see Chapter 19.10). Whether or not this also is the case in patients with silicosis is not clear.⁴²

The respiratory symptoms present in a worker with progressive massive fibrosis can be variable. They range from only a chronic productive cough to exertional dyspnea and, in some persons, ultimately to respiratory failure. With time, however, the coalescence of silicotic nodules takes a toll on the underlying pulmonary parenchyma in all, with the usual result being progressive respiratory impairment.

Physical examination demonstrates decreased breath sounds on auscultation and, if the illness is extensive, signs of cor pulmonale and impending respiratory failure.

Crackles usually are not audible, and clubbing, if present, is attributable to another cause.

The chest roentgenogram reveals confluent nodules greater than 1 cm in diameter on a background of small rounded opacities characteristic of simple silicosis. The confluence of these nodules begins peripherally and migrates centrally. As with simple silicosis, progressive massive fibrosis develops most prominently in the upper lobes (Fig. 19.9.6). As these fibrous masses in the upper lobe progressively enlarge, the hila are retracted upward and the lower zones become hyperinflated and appear emphysematous (Fig. 19.9.7).

Pulmonary function studies initially demonstrate a decrease in compliance, followed by decreases in lung volumes and diffusing capacity. If bronchial distortion and lower zone hyperinflation are present, the forced expiratory time is likely to be prolonged and airflow obstruction is measurable.

Deterioration in lung function commonly occurs despite discontinuing silica exposure, and apparently unrelated to commonly measured immune markers.⁴³ The likelihood of

Figure 19.9.6: Gough and Wentworth whole lung section from a miner employed for many years as a motorman. This shows a large, dark upper zone mass consistent with progressive massive fibrosis and calcified lymph nodes. Scattered mid-zone nodules as well as basilar emphysema are present.

Figure 19.9.7: This series of chest radiographs reflects the different presentations of progressive massive fibrosis. (a) Chest radiograph from a 56-year-old man taken 7 years after ceasing employment at a silica flour mill where he had been employed for 6 years as a bagger. He complained of symptoms of dyspnea and chronic bronchitis. He had an 8-year smoking history. Spirometry showed borderline restriction. The chest radiograph showed profuse small rounded opacities and progressive massive fibrotic lesions in the right upper and mid-zones. (b) Chest radiograph from a surface mine driller who had smoked heavily for many years. Asymmetric bilateral upper zone progressive massive fibrotic lesions are present. The larger and denser left-sided mass lesion raises concern of a pulmonary malignancy. (c) Chest radiograph from a long-time underground coal miner who worked as a driller showing the 'angel wing' changes that occur with progressive massive fibrosis. The wings are the bilateral peripheral massive fibrotic lesions, and the body of the angel is the cardiac silhouette. (d) Chest radiograph from a worker employed for many years in a glass factory with silicosis who then experienced a relatively aggressive downhill course. Investigation revealed infection with *M. tuberculosis*. Although he responded to multiple drug therapy, he still had severe progressive massive fibrosis, extensive emphysema, and impaired function.

progression directly correlates with the duration and concentration of silica exposure, the amount of silicosis determined on the chest radiograph at the time of diagnosis, as well as the presence or absence of mycobacterium infection. In addition, black workers have been reported to progress more rapidly than their white counterparts.

Progression appears to slow as time from diagnosis increases.⁴⁴⁻⁴⁶ Among non-smokers, it is usually those with progressive massive fibrosis who develop clinically important airflow obstruction and emphysema.

A recent report from Hong Kong reflects data from 648 workers with silicosis employed in numerous industries,

but primarily caisson workers, hard rock drillers employed in bridge and building foundation construction, and stone splitters.⁴⁷ Workers with silicosis averaged 24 years of exposure. Most had simple silicosis with no significant lung function impairment but complained of respiratory symptoms. Nearly half of the silicotics had radiographic evidence of current or past tuberculosis. Approximately 70% had minimal (category 1) profusion of small rounded opacities, another 5% had more profuse radiographic findings, while 25% had progressive massive fibrosis.

Accelerated silicosis

Accelerated silicosis is characterized by the same features as classic silicosis except that the time from initial exposure to silica to the development of radiographic changes and ensuing respiratory impairment is much shorter. The chest radiograph may demonstrate rounded opacities as early as 4 years after initial silica exposure. This relatively early onset of silicosis occurs as a result of exposure to grossly excessive levels of dust. Accelerated silicosis is associated with frequent and relatively rapid progression to progressive massive fibrosis with severe respiratory impairment.

Seaton reported on an outbreak of silicosis among eight stonemasons working with sandstone on a cathedral. Although a number had accelerated silicosis, one with similar exposure had adenopathy alone.⁴⁸ The authors concluded that workers with accelerated disease had had chronic but relatively low-grade exposure to silica dust many years prior to the current substantial exposure. This previous exposure may have obstructed the lymphatics and caused an inability to clear the silica from the alveolar space.⁴⁹ There are correlates in animal models. In different rat species, the importance of lymphatic clearance of dust has been documented in the response to silica.⁵⁰ Substantial, but not well understood variation in the pulmonary pathologic response to aerosolized silica exposure has been shown in different strains of inbred rats.⁵¹ It also appears that underlying epithelial injury accentuates the translocation of silica from the alveolus into the interstitium and lymphatic system.⁵²

Acute silicosis

This most aggressive form of silicosis follows a short duration of exposure to overwhelmingly high concentrations of respirable free silica. The worker has a relatively rapid onset of chest symptoms and progressive respiratory impairment that invariably leads to death due to respiratory failure. Although patients with this form of silicosis may have some features of classic silicosis, there are distinct clinical, radiographic, and histologic differences.

In 1900 an illness referred to as 'chalicosis pulmonum', that developed after employment in a Nevada quartzite mill for only 3 months, was reported.⁵³ Deaths of a large number of these workers occurred within a year after the onset of symptoms. In 1929, Middleton described a febrile illness associated with progressive respiratory failure after exposures to overwhelming amounts of free crystalline

silica among packers of abrasive soap powder in a London plant.⁵⁴ The first reported series of this aggressive manifestation of silicosis in the United States also involved exposure to abrasive soap powder. In 1932, Chapman described the death of three silica abrasive packers only 8–29 months after initial exposure.⁵⁵ Since these early reports, acute silicosis has been described in quartz tunnel drillers, sandblasters, silica flour workers, and surface coal mine drillers.

In each of these occupations, workers were exposed to high concentrations of fine, freshly fractured silica. As noted above, freshly fractured silica may well be more fibrogenic than 'stale' particles because of the ROS present on the freshly cut particles as described above.⁵⁶

In 1969, Buechner reported four sandblasters with acute silicosis and coined the term 'silicoproteinosis' to describe these histologic findings.⁵⁷ At autopsy, these sandblasters had periodic acid-Schiff (PAS) positive-staining proteinaceous material filling the alveolar spaces, silica particles in the lung, and histologic changes of alveolar proteinosis (Fig. 19.9.8). However, a review of the literature prior to Buechner's description suggests that many of the earlier patients had similar histologic features.⁵⁸

Workers with acute silicosis have been reported to present with an irritative, sometimes productive cough, weight loss, fatigue, and, occasionally, pleuritic pain.⁵⁹ The onset of symptoms usually is 1–3 years after the initial exposure; however, symptoms occurring less than a year after beginning sandblasting have been reported. Unlike the usually unremarkable chest examination of classic silicosis, crackles usually are present and likely reflect alveolar and airway fluid. Patients can rapidly develop cyanosis, symptoms of cor pulmonale, and respiratory failure. Survival after the onset of symptoms is typically less than 2 years. Infectious processes, particularly macrophage-mediated infections such as mycobacterial and fungal infections, frequently complicate the clinical course.

Figure 19.9.8: Photomicrograph (100x) of a lung section of a surface mine driller showing acute silicoproteinosis. Alveolar spaces are filled with a finely granular, PAS positive-staining exudate with eosinophils. Alveolar walls show thickening, with an infiltration of mononuclear cells and lymphocytes.

More recently, six cases of acute silicosis were described following varying times of excessive, overwhelming exposures to silica. Patients presented with cough and disabling dyspnea. Clubbing, not a typical feature in classic silicosis, was present in three and coarse chest sounds were audible in two. Lung function studies showed apparent restriction with severe decrease in diffusing capacity. BAL revealed lymphocytosis and neutrophilia. Four died of silicosis.⁶⁰

The chest radiograph typically reveals diffuse alveolar infiltration and obliteration usually associated with air bronchograms.⁶¹⁻⁶³ The picture is one of a ground-glass appearance, and small rounded opacities are usually not seen. The chest radiographic progression is rapid. With time, these areas of alveolar filling progress to large masses consistent with progressive massive fibrosis. Cavity formation may occur and be difficult to distinguish from superimposed mycobacterial or fungal infection.

The alveoli are filled with lipid and proteinaceous exudative material, which under light microscopy is relatively acellular, with a granular, PAS-positive staining appearance. Silicotic nodules, if present, are smaller and more irregular than those seen in classic silicosis. Diffuse interstitial fibrosis is seen. Alveolar and vascular obliteration also occurs. Electron microscopy studies have demonstrated diffuse hyperplasia of type II pneumocytes, with hyperproduction of lipoproteins.⁶⁴ Within the alveolar spaces there are desquamated type II pneumocytes, macrophages, silica particles, and phospholipids.

Acute silicosis usually can be diagnosed on the basis of a history of overwhelming silica exposure, the above-described clinical features, and a chest radiograph consistent with this illness. However, the illness is relatively rare and often physicians find it difficult to believe that such extensive dust disease can occur in such a relatively short time. Rarely lung tissue may be needed for an accurate diagnosis, and an open lung biopsy is recommended. Frequently, workers with acute silicosis also have mycobacterial infection. Despite appropriate therapy, these workers continue to deteriorate. The differential diagnosis includes alveolar proteinosis, desquamative interstitial pneumonitis, and lipid pneumonia, but these conditions can usually be excluded on the basis of the worker's history.

ASSOCIATED ILLNESSES

Silica exposure and mycobacterial infections

The association between silicosis and tuberculosis has been recognized since the mid 16th century and has been the subject of extensive epidemiologic studies. The reported prevalence of tuberculosis has varied from 75% in an autopsy study of silicotic South African gold miners in 1916⁶⁵ to 0.9% in 1975,⁶⁶ and to 3.9% in 1991,⁶⁷ and continues to increase in the face of silicosis and epidemic HIV infection. The incidence of tuberculosis is likely to be greater in workers with accelerated or acute silicosis.

Silica particles increase the susceptibility to mycobacterial infection by altering cell-mediated immunity⁶⁸ and macrophage function, diminishing the ability of the cellular milieu in the lung to defend itself against this infection.^{69,70}

Several concepts are important to the understanding of the risk of mycobacterial infection, especially tuberculosis, in those with silica exposure. First, silica exposure, by itself and in the absence of silicosis, is a risk factor for tuberculosis.⁷¹ Since only 34% of those with silicosis were recognized radiographically in one autopsy study, it is clear that recognizing silica exposure is important in determining risk.⁷² Second, the frequency of mycobacterial infection appears to increase as the extent of radiographic change attributable to silicosis advances, and can develop after the worker ceases exposure.⁷³ Third, in the absence of radiographic evidence of silicosis, as silica exposure increases the risk for tuberculosis also increases.⁷⁴ Fourth, in a case-control study, those with silica exposure and tuberculosis died, on average, 4 years earlier than those with tuberculosis lacking silica exposure history.⁷⁵

The diagnosis of tuberculosis in workers with silicosis sometimes can be difficult. Because tuberculous infections can be walled off in the lung by silica-induced fibrosis, a false-negative acid-fast-staining sputum smear may occasionally be present. Constitutional symptoms, such as fatigue, fever, dyspnea, and weight loss, can be seen in workers with worsening silicosis independent of a mycobacterial infection. Finally, the radiographic changes of tuberculosis may mimic advanced silicosis. The most important feature that enhances the clinician's suspicion for tuberculosis is radiographic progression over a short time period. This indicates superimposed mycobacterial infection until proven otherwise. A new infiltrate, coalescence of nodules in the upper lung fields, or cavitation of a pre-existing lesion mandates an aggressive search for mycobacterial organisms.

Recent studies have shown that the combination of silicosis and tuberculosis is more difficult to treat than tuberculosis alone, but multiple drug regimens achieve acceptable results. A 1989 study of South African gold miners compared multiple drug regimens.⁷⁶ A four-drug regimen for 4.5 months produced a relapse rate of only 3.8%. Other studies in which standard multi-drug anti-tuberculosis therapy was provided for 9–24 months have reported relapse rates of 0–5.1%. The epidemic of HIV infection in the South African gold mining population, in association with underlying silica dust exposure and silicosis, has led to epidemic mycobacterial transmission.⁷⁷⁻⁷⁹

Those with silicosis should undergo regular PPD skin testing. The frequency of this testing is not clear; however, in countries with a high endemic rate of tuberculosis, yearly testing is appropriate. If tuberculosis is less frequent, less frequent testing would be appropriate. If the results of the PPD test become positive without clinical evidence of active tuberculosis, at least 1 year of isoniazid therapy is indicated. Many advocate longer, even lifelong, antituberculosis prophylactic therapy in this setting because of the

possibility of extensive irreversible damage to the silicotic lung by this organism.

Silicosis and carcinoma of the lung

Since the initial report by Goldsmith in 1982⁸⁰ linking silica and lung cancer, a number of articles and reports supporting or disputing this relationship⁸¹⁻⁸³ have been published. In 1997, the International Agency for Research on Cancer (IARC) reviewed the evidence and concluded that there is sufficient evidence to judge silica a carcinogen for humans.⁸⁴ The risk of lung cancer is highest in workers with silicosis who also smoke. The risk in those exposed to silica but without silicosis is less clear. See Chapter 30.2 for further discussion.

Connective tissue disease (see Chapter 23.5)

Silicosis is associated with an increased prevalence of autoimmune serology, elevated gamma globulin levels, and an increased frequency of connective tissue disease.⁸⁵⁻⁸⁷ Although relatively infrequent, in one report of granite workers, approximately 1.5 per 100 workers with silica exposure developed morbidity due to arthritis, a prevalence greater than the general population.⁸⁸ Of the connective tissue diseases, scleroderma has probably been most commonly recognized in the past, with experimental data showing that silica dust is able to activate microvascular endothelial cells, mononuclear cells, and dermal fibroblasts *in vitro* in a fashion in common with pathophysiologic events known from idiopathic scleroderma.⁸⁹ This is recognized as a compensable occupational illness in several countries.⁹⁰ Steenland reported on a number of studies demonstrating increased rates of arthritis, scleroderma, rheumatoid arthritis, musculoskeletal disease, and renal insufficiency in silica exposed populations compared to non-silica exposed populations.⁹¹ Of these, the least well associated with autoimmunity was renal disease.

More recently a review of 583 cases with death certificates identifying silicosis with scleroderma, lupus erythematosus, or rheumatoid arthritis showed that the risk was increased 2.5–15-fold greater than the general population, with rheumatoid arthritis occurring most frequently.⁹² Importantly, these connective tissue diseases occurred in men, far different than the population of patients with connective tissue disease occurring in the absence of silicosis.⁹²

In 1953, Caplan noted that the course of coal workers' pneumoconiosis in workers with dust exposure could be influenced by coexisting rheumatoid arthritis. In this group of workers, upper zone peripheral nodules appeared more frequently in the lungs of workers with rheumatoid arthritis. This presentation of rheumatoid nodules in workers with silica exposure has been termed Caplan's syndrome.⁹³

Yet the role of the immune system is not well understood in silicosis. Antinuclear antibodies and elevated immunoglobulin levels have not correlated with the baseline profusion category of the chest radiograph, the rate of

chest radiographic progression, or the rate of lung function decline in sandblasters with silicosis.⁹⁴

Renal and extrapulmonary involvement (see Chapter 25)

Although the kidney may be the primary target organ for extrapulmonary involvement in silicosis, the data that relate renal changes to silica exposure are found mainly in a series of case reports and case series. Renal disease has been attributed both to a toxic effect of silica or an immunologically mediated process. The renal glomerular changes have not been consistent among the different workers with silica exposures, and there is no single clinical or laboratory finding of silica-induced nephropathy. We are unaware of reports showing increased levels of silica in the kidney or silicotic nodules in the kidneys of those with silicosis. It may be that the changes found in the kidney in these workers are immunologically mediated and are host- rather than silica-dose dependent.

One worker with acute silicosis developed acute glomerulonephritis and renal failure in the absence of underlying renal impairment.⁹⁵ The authors postulated a silica-induced defect in lipid metabolism in the renal cells. Six of 15 cases of silicosis in an autopsy study showed focal segmental glomerulosclerosis as well as pathology that included necrotizing and proliferative glomerulonephritis, mesangial hyperplasia, focal segmental obliteration of loops, and focal proliferative changes in Bowman's capsule.

A mortality study of silica-exposed workers found that mortality attributable to chronic nephritis was twice as high in silica-exposed workers compared with workers who had not been exposed to silica.⁹⁶ More recently, Rosenman showed that chronic kidney disease should be considered to be a complication of silicosis; however, it is not clear if this is a nephrotoxic or autoimmune effect.⁹⁷

Silicotic lesions have also been described in the liver, spleen, bone marrow, and remote lymph nodes. These lesions are presumably the result of lymphatic or hematogenous spread and have not been recognized to affect the function of these organs.

PREVENTION, MANAGEMENT, AND TREATMENT

Prevention of silicosis remains the goal among exposed workers. Product substitution of silica with less toxic particles in abrasive blasting, control of air-borne dust concentration through engineering interventions, and appropriate use of respiratory protective devices are available and are effective in preventing the development of silicosis. Yet, new cases continue to develop.⁹⁸

Since the initiation of dust control, the prevalence of silicosis has decreased dramatically.⁹⁹ In some mines and quarries, compliance with dust concentration has been achieved by instituting wetting techniques and improving ventilation. In other industries such as sandblasting, silica milling, and rock drilling, workers remain potentially

exposed above the acceptable limit of respirable free silica. The use of silica sand for blasting has been banned in England. In the United States, particles less toxic than silica are available for blasting. Since 1974, the National Institute for Occupational Safety and Health (NIOSH) has recommended the substitution of non-silica-containing particles in abrasive blasting.^{100,101} Yet, the use of silica for blasting continues and epidemics of acute silicosis recur among sandblasters.¹⁰²

Medical screening of silica-exposed workers is generally recommended, using questionnaires, chest x-rays, and spirometry. Primary and secondary prevention are further discussed in Chapter 46.

Once silicosis develops, the primary risks to the worker are progression of disease with progressive decline of lung function and development of mycobacterial infection. Both conditions can hasten the development of respiratory impairment in these workers. Cowie assessed the rate of decline in silicotic compared to non-silicotic South African gold miners over a 5-year period. The rate of FEV₁ and FVC decline increased with profusion of opacities, increasing from a yearly rate of decline in FEV₁ of 37 mL and FVC of 15 mL in silica-exposed without silicosis, to a yearly rate of decline in FEV₁ of 128 mL and FVC of 116 mL in those with the most extensive disease.¹⁰³ In another study, the clinical and chest radiographic data from 64 silicotics was retrospectively assessed over 15 years.¹⁰⁴ Sixteen developed progressive massive fibrosis. The mean yearly FEV₁ decline was 71 mL in progressors compared to 43 mL per year in those who did not develop progressive massive fibrosis.

Once a diagnosis of silicosis is made the worker should be removed from further silica exposure. Clinical suspicion of the development of mycobacterial infection must be high, particularly when there has been a decline in lung function or rapid worsening of the chest radiograph. Standard tuberculosis treatment regimens are effective.¹⁰⁵ Regional differences in drug resistance should be considered. Regular chest radiographs and performance of PPD skin tests are recommended. Mycobacterial infections should also be suspected and their diagnosis aggressively pursued when acute chest illnesses occur. There is concern among some investigators that PPD conversion may require more than one year of INH prophylaxis.¹⁰⁶

A number of treatment modalities specific for silicosis have been attempted in patients with the classic and acute forms of this disease.^{107,108} Interpretation of the usefulness of these approaches has been hampered by the fact that these are single case reports or small clinical or animal trials. No single therapy has been proved effective.

Corticosteroid therapy has been tried in patients with acute and chronic forms of silicosis.^{109,110} This approach may be helpful when silicosis is associated with autoimmune disease or in acute silicosis, and it may effectively improve lung function for a defined period of time. Isoniazid prophylaxis is appropriate when corticosteroid therapy is prescribed. Inhalation of aluminum powder has been shown not to be efficacious in inhibiting silicosis progression.¹⁰⁸

Treatment of pneumoconiosis with whole lung lavage was described in 1982 by Mason et al.¹¹¹ Although dust was removed from the lung, improvement in pulmonary function was not demonstrated. Therapeutic whole lung lavage has been used for workers who developed acute silicosis and silicoproteinosis following massive silica inhalation, but improvement in lung function has not been clearly demonstrated.¹¹²

Tetrandrine, a plant alkaloid with antioxidant and anti-inflammatory properties, is an ancient Chinese remedy for rheumatic diseases.¹¹³⁻¹¹⁵ It has been shown to arrest the progression of silicosis in small clinical trials.¹¹⁶ Additional studies are needed to evaluate this agent for use in the treatment of silicosis.

As with other end-stage pulmonary diseases, lung transplantation has been performed on workers with extensive silicosis.¹¹⁷ However, organ availability is limited and the treatment is usually offered to younger patients.

SUMMARY

Silicosis is a preventable interstitial occupational lung disease that has the potential to shorten a worker's life. Contraction of this illness results in an increased risk of mycobacterial infection, as well as the risk for progression despite ceasing exposure. Although further research on the mechanism of lung injury in silicosis and the potential modulation of this illness by different therapies will contribute to our therapeutic armamentarium for this disease, there are sufficient available data to protect workers. The extent to which current and future workers will be protected depends on the education of employers and employees, strict enforcement of industrial hygiene practices, and vigilance for circumstances where unacceptable exposures to respirable silica occur.

19.10 Respiratory Diseases of Coal Miners

Edward L Petsonk, Michael D Attfield

HISTORY

Coal production

The growth in coal mining was virtually coincident with the Industrial Revolution. Although shallow mining of coal seam outcrops is reported to have occurred since the 9th century, the 18th century brought increased demand for coal as well as the technology to pursue the mining of seams well below the earth's surface. By the early 1800s coal mining had become an important industry both in the United States and abroad. Employment in coal mining peaked about 100 years later in 1923, when over 800,000 coal miners were working in US mines. From that point, although production and consumption of coal continued to increase, mechanization progressively reduced the size of the work force. In 1999, average employment in coal mining work in the US was 108,244, down from 132,535 six years earlier. Between 1993 and 2002, annual US production remained stable at about 1 billion short tons of bituminous and 1.5 million tons of anthracite coal. Currently, about two-thirds of coal production is at surface mines, while about 57% of miners are employed at underground mining operations.¹

The principal US coal deposits are shown in Figure 19.10.1. Coal production has recently been fairly evenly divided between Eastern and Western coalfields, but the proportion of production has been increasing in Western states and now exceeds that of the Appalachian coalfields.

Health effects

In Europe, recognition of the adverse health consequences of coal mining followed the marked increase in the number of miners. Wedel, in 1672, wrote of 'miners asthma', but was probably referring to hard rock miners. According to Kerr, the term was first applied to coal miners in 1822. Laennec described the black pigment in the lungs of coal miners as 'melanosis' in 1806, and by 1819 clearly differentiated the condition from malignant melanoma. Several years later, the term 'miners' black lung' was used to describe the disease in Scotland. In 1919, silicosis became a 'certifiable disease' in the UK, and British miners with pneumoconiosis became eligible for certain benefits. Based on studies among South Wales coal workers, a high prevalence of pneumoconiosis became evident in the 1930s, and the condition 'coal workers' pneumoconiosis' (CWP) was differentiated from silicosis in the early 1940s.

Unfortunately, this awareness of CWP failed to cross the Atlantic. A mine explosion in Farmington, West Virginia, on November 20, 1968, was widely reported on television, and graphically illustrated to the nation the plight of coal miners in the US. This tragedy added momentum to the movement to improve coal mine health and safety conditions. 'Black lung associations' were organized in the coalfields. A 3-week long strike in the West Virginia coal mines,

one of the largest and longest strikes ever called on the single issue of occupational health, ended when the state legislature passed a bill in 1969 making CWP a compensable disease. By the end of 1969 the Federal Coal Mine Health and Safety Act had been passed into law. Dust control and safe practices in coalmines were mandated and backed up by inspectors with the threat of fines or closures, and the right of the miners' representatives to participate in inspections.

MINING JOBS

An understanding of mining techniques is useful in the evaluation of respiratory diseases of miners, since different activities involve exposures to different degrees of risk. Activities at coalmines are generally classified into face, non-face, and surface work. By virtue of multiple activities, some workers spend portions of their workday in two or more of these mine locations.

Face workers

Miners working at the edge of the unmined coal seam, or coalface, are engaged in the actual removal of coal from the working 'section' of the mine. Face miners are generally exposed to the highest concentrations of respirable airborne dusts, particularly carbon, but may also be exposed to silica dust when the cutting bits strike silica-bearing rock immediately adjacent to or within the coal seams. There are three primary methods of mining coal underground that have been employed in the US. They are discussed below.

Continuous mining

Room and pillar mining with 'continuous mining' machines is one of the commonly used coal mining techniques in the US today. Continuous miner operators and their helpers direct the rotating bits on the machine into the coal seam to rip out the coal. The loosened coal is pushed to the back of the machine, where a loading machine operator and helpers use a large scoop to load the coal into a rubber-tired buggy (shuttle car), or directly onto a conveyor line.

Pillars of unmined coal are left at the sides of the advancing tunnel to help support the roof. As the continuous mining machine advances, roof bolters and their helpers install steel plates to strengthen the unsupported roof of the tunnel. Holes are drilled into the hard rock above the coal seam and long steel bolts inserted, along with glues, to anchor these plates. Silica exposure is common in roof bolting, and there may also be exposure to resins and plasticizers in glues. Timber men install wooden posts to further stabilize the roof of the tunnel. Brattice men install curtains or tubing to direct the flow of ventilation at the working face. Shuttle car ('buggy') operators transport newly mined coal in rubber-tired vehicles (Fig. 19.10.2). Scoop car oper-

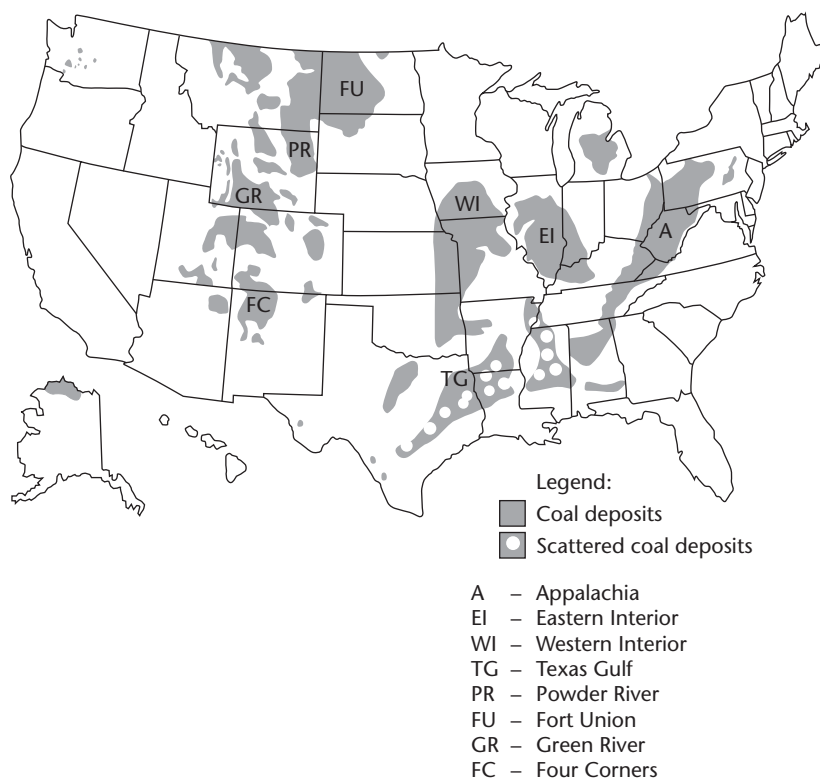

Figure 19.10.1: Map of United States coal deposits.

Figure 19.10.2: Coal miner operating rubber-tired shuttle car.

ators run battery-operated vehicles throughout the mine, transporting coal or mining supplies. Mobile bridge operators operate portable conveyor lines to move coal away from the face. Section maintenance workers repair and maintain the underground heavy equipment at the face in all mining methods.

Longwall mining

'Longwall mining' is currently the most cost-efficient and highly productive method of underground coal mining. Production using this technique is increasing as an alternative to room and pillar mining. The longwall machine

spans several hundred to a thousand feet or more along the active coalface. A rotating drum (shear) or a plow moves back and forth along the face, breaking coal loose from the seam and allowing it to fall onto a conveyor line. A series of hydraulic 'jacks' support the roof along the face, and are advanced as the coal is removed. Behind the longwall device, the unsupported roof is simply allowed to fall. This minimizes the loss of the coal in pillars and the need for roof support activities, as in room and pillar mining. To develop the mining section in advance of the longwall machine, one or two continuous miner crews are generally operated. However, to run the longwall section itself, a smaller crew of longwall operators, mechanics, headgate operators, and jack setters is required.

Respirable dust exposures in longwall mining have been difficult to control. In recent years, nearly 40% of reported dust measurements on longwall sections have been over the 2 mg/m³ respirable dust standard, compared with 10–15% on continuous mining sections.

Conventional mining

Little coal is mined in the US today using the 'conventional mining' technique, although many current miners have used this method in prior jobs. In this system, cutting machine operators and helpers make a deep cut in the coal face at the bottom of the seam. 'Shot firers' drill deep holes in the area of the cut and place explosive charges to blast the coal free. 'Hand loaders' or loading machine operators shovel the coal into vehicles, which then transport it away from the face. In addition to dust, important exposure to nitrogen oxides from the explosives may occur using this technique.

Non-face workers

Several underground mining activities relate to reducing dust or methane gas hazards. Masons construct plastic, cloth, or block barriers to keep the flow of air directed across the working face. Rock dusters scatter hygroscopic powdered limestone along the cut faces of the mine tunnels, to moisten and trap loose dusts and reduce the danger of explosion. Although this job may involve considerable visible dust and irritation, the lung toxicity of the limestone is considered to be lower than the other mine dusts. Electricians, mechanics, and welders may work with equipment throughout the mine.

Workers on non-face transportation have several types of exposure. The coal is loaded at the working face (see above) and transported to the main haulageways, where it is dumped into train cars or a conveyor belt and taken out of the mine. Motormen operate the train locomotives. To improve traction on the steel rails, motormen drop sand or other abrasives on the rails. The materials are fragmented into respirable particles and resuspended by passing trains, creating a mixed dust or silica exposure hazard. Belt men patrol the conveyor belts, assuring the continued movement of coal, and shoveling up spilled coal. In some mines, diesel exhaust exposure may be present from diesel-powered vehicles.

Surface workers

With a few important exceptions, surface workers generally are exposed to lower levels of respirable dust. Surface maintenance workers frequently perform welding and cutting on equipment, and may be exposed to welding fumes as well as asbestos from shields and gloves. Tipple operators and preparation plant workers are frequently exposed to higher levels of dust during the cleaning, processing, and loading of the coal. Lampmen and others at the mine portal often have little dust exposure.

Equipment operatives at surface coal mines, particularly high-wall drillers and their helpers, and to a lesser extent bulldozer operators, frequently experience important silica exposures while drilling and removing overburden. Surface coal miners have dust exposures that are generally lower than those of underground miners, but a risk of both simple and complicated pneumoconiosis remains.²

In summary, modern mining techniques bear little resemblance to the pick-and-shovel techniques of the early 1900s. Highly mechanized equipment allows mining more coal with far fewer miners. Unfortunately, the high production intrinsic to these operations may lead to dust levels that are difficult to control, and strict attention is necessary to avoid unhealthful conditions.

TERMINOLOGY

Overview

When dealing with respiratory diseases of coal miners, it is important to be familiar with disease definitions. Differing

terms and different definitions have been used for clinical, epidemiological, pathological, and legal or legislative purposes.

In the clinical arena, use of the term 'pneumoconiosis' tends to be restricted to the radiologic or pathologic appearances relating to the accumulation of lung dust deposits and the associated tissue reactions. This usage is often interpreted to exclude other lung abnormalities, such as those associated with bronchitis or emphysema, although, as noted below, focal emphysema is often considered an integral component of the pathologic lesion of coal workers' pneumoconiosis. Such distinctions between the different mining-related disease processes may facilitate the diagnosis, treatment, and study of disease, but has tended to lead to fragmented understanding and assessment of the totality of lung disease associated with exposure to coal mine dust.

Generic definitions of pneumoconiosis, which include all dust-related effects on the lung, are also widely used. Some of these definitions are employed more in the non-clinical sphere, particularly with regard to legal/legislative activities, and include dust-related effects that may not be radiographically apparent, such as dust-induced chronic airflow obstruction. The lay term 'black lung' is a generic term used by miners for lung disorders associated with their work.

Since the radiographic pattern of CWP may be quite distinctive, pneumoconiosis in coal miners often has been defined based upon a radiographic appearance. For example, in research publications, confirmation of CWP may require that several readers concur in the finding of a certain shape and profusion on a chest film (for example, 1/0 rounded opacities using the International Labor Office system of classification of radiographs for pneumoconiosis) (for more detail, see Chapter 19.1). Although this approach increases precision, it may reduce sensitivity for several reasons: (1) it is recognized that readings of 0/1 rounded opacities also correlate with mine dust exposures; (2) the profusion of *irregular* as well as rounded opacities seen on the chest radiograph increases with increasing mining exposures; (3) the routine chest radiograph may be normal in the presence of clinically important and pathologically identifiable interstitial lung disease; and finally (4) several dust-related diseases, including bronchitis and emphysema, may not be apparent radiographically.³ In spite of this, in the United Kingdom, for example, airflow obstruction among coal miners is compensable only for miners who also have radiographic evidence of pneumoconiosis.

Post-mortem lung pathology has shown that nodular radiographic changes correlate quite well with pathology: ILO q-type opacities on chest films are associated with coal macules and micronodules, while r-type opacities are associated with macronodules. The profusion of p opacities, and to a lesser extent q-type opacities, has been found to reflect the dust content of the lung at autopsy. With regard to large opacities, about two-thirds of those seen on chest films are subsequently confirmed on pathology. However, routine chest x-rays are not entirely sensitive for detecting CWP lesions, which may be found pathologically or on high-resolution computed tomography in miners with

normal routine chest films. Among miners whose lungs revealed progressive massive fibrosis (PMF) on pathologic examination, 22% had prior chest x-rays showing no radiographic large opacities.^{4,5}

In summary, for clinical purposes, coal miners with typical radiographic or pathological findings of pneumoconiosis are properly diagnosed as having coal workers' pneumoconiosis. For legal and compensation purposes, a broader definition of 'pneumoconiosis' is used, which includes dust-related effects that may not be radiographically apparent.

Specific medical terms relating to respiratory diseases in coal miners

Simple CWP. This lesion is defined clinically in miners showing multiple radiographic shadows up to 10 mm in diameter. These dust-related shadows are usually rounded, although irregular shadows may also be noted in combination with rounded opacities, or occasionally alone. The pathological correlates of the chest radiograph are discussed in the text.

Complicated CWP. This lesion is also defined clinically based on a chest radiograph showing a dust lesion or lesions over 10 mm in diameter. Complicated CWP is found most often on a background of smaller rounded opacities, with the risk increasing with increasing profusion. Progressive massive fibrosis (PMF) is a term often used interchangeably with complicated CWP, although not all of the larger rounded shadows seen in coal miners will progress with time.

Silicosis (see Chapter 19.9). This is the chronic interstitial lung disorder caused by the inhalation of respirable crystalline silica. Radiographically, silicosis is also characterized by small rounded opacities, which may coalesce to form shadows larger than 10 mm (complicated silicosis or PMF). Although silicosis is pathologically distinct from CWP, the two disorders often cannot be distinguished radiographically. The lungs of coal miners frequently show lesions consistent with both disorders.

Bronchitis (see Chapter 19.4). Sometimes referred to as industrial bronchitis, this dust-related disorder is characterized by excessive cough and sputum production. Sputum production is deemed excessive when it occurs on most days for at least three months a year for two or more years. The pathology of this disorder has been less well studied.

Focal emphysema. A form of airspace enlargement with tissue destruction, found in association with, and an integral part of the macular lesion of simple CWP.

LUNG PATHOLOGY

Pigmented lesions

The most characteristic and striking pathologic changes in the respiratory system of coal miners are associated with the accumulation of dark pigment, primarily located in lung macrophages. Localized dust macules are considered pathognomonic of CWP.⁶ They are located at the level of the respiratory bronchioles, and are generally associated with deposition of reticulin, and with destruction of adja-

cent alveolar walls (focal emphysema), but with only minimal collagenous scarring (Fig. 19.10.3). With increasing dust deposition, the pigmented macule progressively enlarges, becoming solid and palpable. Adjoining macules may coalesce. At this stage, the lesions show clear collagen deposition, and are labeled nodular lesions. Destructive vascular lesions are commonly associated with nodules.

With further progression of the disorder, coalescence of nodules can result. The massive lesions of complicated CWP (progressive massive fibrosis) may also appear. These lesions are greater than 1–2 cm in diameter, and are usually seen in upper lobes or superior segments of lower lobes of lungs with extensive pigment deposition (Fig. 19.10.4). PMF lesions may be unilateral, bilateral, and multiple, and may show cavities containing black liquid. The lungs of miners with complicated CWP also usually show pathologic changes of bronchitis and extensive emphysema.

Figure 19.10.3: Coal dust macule.

Figure 19.10.4: Gross pathology of complicated coal workers' pneumoconiosis

Cardiovascular changes consistent with *cor pulmonale* can also be seen. Right ventricular hypertrophy has been correlated with the thickening of pulmonary vessel walls seen in association with increasing severity of CWP, and emphysematous changes in miners' lungs.^{7,8}

Factors facilitating progression to complicated CWP are not entirely understood. Excessive lung dust deposition is clearly the basis for the condition. The greatest risk factor for subsequent development of complicated CWP is the miner's radiographic category of simple CWP, with an additional effect of increasing age. The risk of progression to PMF in a miner with category 2 simple CWP is 3–4 times that of a miner with category 1. Exposures at a young age increase the duration of residence of the dust in the lung and also the risk of PMF.⁹ In the past, mycobacterial infection was frequently associated with PMF, and was considered a precursor to its development. It is now accepted that PMF lesions often develop in the absence of infection. The role of excessive silica exposure is still debated, although PMF can clearly develop in workers with scant silica exposure. Miners, particularly those with simple or complicated CWP, have an increased frequency of autoantibodies and other serologic abnormalities. However, no clear role in disease pathogenesis of these findings has been defined.

Although it is rarely reported in the United States, dust-exposed miners with rheumatoid arthritis may develop a syndrome known as rheumatoid pneumoconiosis, or Caplan's syndrome (see Chapter 23.5). Features include multiple large (up to 5 cm) lung nodules developing rapidly, often over several months, with little or no background profusion of simple pneumoconiosis. The pulmonary lesions may cavitate, and occasionally will precede the onset of the joint disorder. Pathologically, the lesions are distinct from the typical lesion of PMF, and are similar to rheumatoid nodules.

Even in non-miners, the extent of pigment in the lungs generally increases with age. It is also greater in cigarette smokers than non-smokers. However, in the absence of occupational exposures, the deposition of pigment will very rarely be sufficient to form macular lesions.

Typical lesions of silicosis are described elsewhere (see Chapter 19.9). Overall, classical silicotic nodules have been reported at autopsy in the lung of 12.5% of coal miners. Higher prevalences are observed in certain jobs, such as motormen (25%), and in miners with complicated CWP (over 50%).¹⁰

Emphysema

The occurrence of emphysema in CWP has been recognized since the time of Osler, and is considered by some observers to be an integral component of the dust macule. Cigarette smoking may also result in emphysema of the centrilobular type, which differs from the emphysema due to coal dust only in the extent of lung involvement and the absence, in non-miners, of associated dust pigment. Generalized emphysema can be seen in the lungs of both smoking and non-smoking coal miners. After taking tobacco use into account, the extent of emphysema corre-

lates with prior mine dust exposure, as well as the amount of dust retained in the lung. Opinions differ among pathologists as to whether the emphysema associated with the dust macule is different in any way from that related to tobacco use. However, the severity of airflow obstruction measured during life correlates significantly with the extent of pathologic emphysema in the coal miners' lungs at autopsy, suggesting an important functional effect.¹¹

Bronchitis

The prevalence of chronic cough with sputum production is elevated in miners, increasing with mine dust exposure. It is generally accepted that coal mine dust deposition in the airways over prolonged periods of time leads to mucous gland enlargement and proliferation of goblet cells. However, few investigations have been performed regarding the histology of the airways and mucous glands in coal miners. The lungs of miners with complicated CWP frequently show the changes of chronic bronchitis. Some autopsy studies of miners have also shown a significant correlation between prior coal mine dust exposure and the proportion of mucous glands in the bronchial walls (the Reid Index). This is considered evidence that dust exposure contributes to the pathologic changes, as well as to the clinical symptoms, of chronic bronchitis. No significant relationship was found between airway mucous gland changes and the severity of pneumoconiosis.

In British coal miners there is a markedly different geographical distribution of mortality from pneumoconiosis versus chronic bronchitis and emphysema, suggesting that the exposures and mechanisms for these responses are different.¹²

Mycobacterial infection

Tuberculosis and non-tuberculous mycobacterial infections are seen in coal miners. The risk of these infections is generally considered to be increased with heavier dust exposures, particularly in miners with PMF. Some miners also have lesions of silicosis, which represent a greater risk factor than CWP alone for these infections. As in the general population, response to appropriate chemotherapy is usually good for tuberculous infections, and less satisfactory for most atypical mycobacterial disease. Tuberculosis is no longer considered an important factor in the development of complicated CWP in most countries, but is still associated with PMF onset and results in increased mortality among coal miners in some countries (e.g., China).¹³

Other conditions

Coal deposits also contain other variable components, including minerals such as crystalline silica and kaolin, as well as a polycyclic aromatic hydrocarbons (PAHs). In 1997, the International Agency for Research on Cancer determined that inhaled crystalline silica is a human carcinogen.¹⁴ Thus, there has been an ongoing concern for a potential lung cancer risk among coal miners. In contrast to the finding

Pigmented lesions:
Dust macule
Coal nodule
Progressive massive fibrosis (PMF)
Silicotic nodule
Centrilobular emphysema
Bronchitis
Rheumatoid pneumoconiosis

Table 19.10.1 Pathologic classification of coal mine dust-induced changes

with crystalline silica, no consistent increase in lung cancer has been observed in relation to inhalation exposure to coal mine dust. However, several studies have reported an increased risk of gastric cancer among coal miners (see Chapter 30.5).¹⁵

Extracting coal requires the application of large amounts of mechanical energy to the coal, and injuries remain a constant threat to miners. In 2000, the US rates of fatal and non-fatal lost-time injuries in coal mining were 0.040 and 5.18 per 200,000 employee work-hours, respectively, or about three deaths and 356 non-fatal injuries per 10,000 miners annually. Discussion of injury risks is found in Chapter 31.

In summary, several pathological lesions have been identified in the lungs and airways of coal miners (Table 19.10.1). Some are rarely seen in the absence of extensive inhalation of coal mine dust, and therefore are accepted as generally related to occupational exposure. Some lesions have been correlated with the appearance of characteristic changes of CWP on the chest radiograph. Other lesions, while similar to those found in the general population, are seen with greater frequency in workers exposed to coal mine dusts. In the lungs of underground coal miners, macules, nodules, and massive lesions, as well as the emphysema associated with these lesions, and silicotic nodules, are accepted as almost uniformly related to mine dust exposures. In contrast, overall emphysema scores, carbon pigmentation, and possibly Reid indices are increased in miners' lungs in relation to their mine exposures, but can also be increased by other inhaled agents, depending on the relative exposures to mine dusts and other materials such as tobacco smoke.¹¹

PATHOGENESIS

Observations from both human and animal studies have implicated overloading of lung clearance mechanisms in coal mine dust-related disorders. Excessive exposures trigger impairment of alveolar macrophage (AM)-mediated lung clearance, progressive accumulation of particle-laden macrophages, and subsequent inflammatory changes in the lung.¹⁶ Once deposited, dust particles are thought to trigger release of mediators, including reactive oxygen species and related antioxidant protection mechanisms, as well as cytokines, growth factors, and related proteins. Tissue damage and remodeling in the respiratory tract results from modifications of the extracellular matrix. A number of animal and human studies have addressed these molecular mechanisms of lung injury from coal mine dust inhalation.

With dust exposure, increases in leukocyte recruitment as well as neutrophil adhesion have been observed, resulting in retention of inflammatory cells in the lung.¹⁷

Alveolar macrophages obtained from healthy subjects, exposed in vitro to coal dust particles, demonstrate release of tumor necrosis factor alpha (TNF- α) and interleukin-6 (IL-6). Alveolar macrophages from miners with CWP release higher levels of TNF- α and interleukin-1. Macrophages from dust-exposed workers with respiratory impairment also release increased amounts of oxidant species.¹⁸ Bronchoalveolar lavage fluids from miners with CWP show an influx of mononuclear phagocytes, with an increased spontaneous production of oxidants, fibronectin, neutrophil chemotactic factor, and also of IL-6 and TNF- α . This spontaneous cytokine release is associated with an increased expression of cytokine messenger ribonucleic acid. Additional studies are needed to more fully characterize the cellular events and mediators responsible for the unique pattern of airway and parenchymal lung injury that is seen with coal mine dust inhalation.

RADIOLOGY

Radiographic changes in coal miners

Several patterns of abnormality on routine posteroanterior chest radiographs have been related to coal mine dust exposure. Most commonly, fairly discrete small nodular radiographic shadows are seen in the lung fields. These densities are usually rounded in shape, although they may be irregular, and are seen in greater numbers in the upper and middle, compared to the lower lung zones, with prominent lower zone involvement seen only occasionally. Typically the largest diameter of the small nodules categorized as simple CWP is 3 mm or less, but may be up to 10 mm. With increasing lung dust deposition, the number of opacities observed in a lung zone (profusion) increases. The normal vascular shadows of the lung become obscured.

Further progression may be indicated by a coalescence of the small opacities into a combined density, which may be quite homogenous. By convention, if a dust-related radiographic shadow is larger than 10 mm, it is categorized as complicated CWP or progressive massive fibrosis (PMF). Shadows of PMF are frequently bilateral, occurring in the upper and mid-lung zones. As they enlarge they may migrate toward the hilum, forming a sharp lateral margin delineated by a zone of emphysematous lung. Often the lesions are parallel to the chest wall, and are seen to have a greater diameter on the posteroanterior film than on the lateral view. If ischemic necrosis of the lesion occurs, a central cavitation or lucency may be noted.

Small irregularly shaped radiographic shadows are also observed in the lungs of miners. The finding of irregular densities, in contrast to small rounded densities, has more consistently been associated with a reduction in gas transfer and/or ventilatory lung function. The tissue pathology associated with these radiographic shadows is unclear. They have been correlated with increasing dust exposure, increasing age, and cigarette smoke, and are thought to

have multiple causes, including both pathological emphysema and dust-induced fibrosis.

Under the ILO classification scheme, the small, rounded type of radiographic changes seen early in CWP are usually classified as 'p' or 'q' type opacities. The larger 'r' type opacities are more commonly associated with silicosis. As mentioned, irregular opacities (ILO type 's', 't', or 'u') may also be noted. A typical radiographic appearance of simple CWP is shown in Figure 19.10.5. The detail shows the opacities to be less than 3 mm in diameter ('q' type), and the profusion was interpreted as category 2.

Course and progression

Much of the information on the course and progression of radiographic changes in coal miners has been derived from long-term epidemiologic studies of coal miners in Britain. These were greatly facilitated by the concurrent collection of dust exposure data. In the main, these studies have shown that the overwhelming determinant of simple pneumoconiosis is the extent of exposure to coal mine dust per se. In addition, different coals are categorized by their 'rank', a characteristic which appears to have some influence on disease development. Rank is a factor which is related to the hardness and degree of metamorphosis of the coal due to heat and pressure.

High-rank coals, such as anthracite, have been associated with a greater risk of CWP and lung function deficits than lower rank and softer coals, such as bituminous coal or lignite. Silica may also play a role in the development of radiographic changes in underground coal miners, especially when experienced at high concentrations.¹⁹ No other environmental factor has been shown to have a major effect. Tobacco use appears to have little effect on the development of the radiographic findings of CWP.

The main recognized risk factor for development of PMF is the category of simple CWP, particularly ILO categories 1/2 or greater.²⁰ Hence prevention of simple CWP must remain a priority. Recently it has been shown that there appears to be an exposure-response relationship between PMF and dust exposure in miners without radiographic evidence of simple CWP. Other factors pertinent to PMF development are coal rank, age of the miner, and residence time of dust in the lungs. Even though clear and consistent exposure-response trends have emerged from the many studies undertaken in the United Kingdom and elsewhere, much unexplained variability remains for both simple and complicated CWP. Large variations between mines in prevalence of diseases are seen that cannot be explained by recourse to available information on dust levels and composition.

The current federal dust standard in the US is 2 mg/m^3 (but may be further reduced when silica levels are high). This limit was derived from early British work which indicated that progression to category 2 or greater simple CWP would be prevented at this dust level. By this means, it was expected that further progression to PMF would be eliminated. As an additional health measure, an x-ray screening program was set up to identify miners with signs of CWP, and to offer them the right to work in a reduced dust envi-

Figure 19.10.5: (a, b) Chest radiographic pattern of category 2 simple coal workers' pneumoconiosis with detail.

ronment, and have their work environment monitored more frequently. Dust-induced lung functional changes in the absence of radiographic changes were not considered during promulgation of the US standard.

Since the establishment of dust controls in the US, the prevalence of radiographically apparent CWP among underground miners has declined considerably.²¹ Unfortunately, recent work from Britain and elsewhere suggests that the current US disease prevention strategy may be flawed. First, the more recent exposure-response models predict somewhat higher levels of disease than did the early work for the same dust exposure. In particular, 2 mg/m^3 is no longer associated with zero incidence of category 2 or greater (Fig. 19.10.6). Second, as noted earlier, it has been shown that PMF can develop when prior radiographs show no identifiable changes of simple CWP, and that this development is dose-related. Moreover, results from Britain have shown a substantial amount of PMF developing on a category 1 background. A survey of retired miners in Northern France also demonstrated the onset of simple or complicated CWP in 24% of miners who had normal radiographs at retirement. Finally, as discussed below, radiographic surveillance programs do not identify miners with dust-related reductions in ventilatory lung function that are not associated with radiographic changes of pneumoconiosis.

There is additional evidence that current US prevention strategies may not be entirely protective. Henneberger and colleagues found that, even after the establishment of a 2 mg/m^3 respirable dust standard, exposures among US coal miners were associated with an increased risk of respiratory symptoms.²² As well, miners exposed for a working lifetime to the current US standard of 2 mg/m^3 respirable dust appear to have an elevated risk of dying from pneumoconiosis and COPD.²³

In summary, there is no doubt that the current US health and environmental standard has led to a reduction in disease levels compared to those in the past, and there has been a significant decline in CWP mortality in the US, particularly among miners over age 45.²⁴ However, several recent reports have challenged the efficacy of the current US dust standard, and imply that it may be less protective than originally intended. A recent publication extensively reviewed current

Figure 19.10.6: Predicted prevalence of radiographic coal workers' pneumoconiosis by mining tenure, assuming dust concentration of 2 mg/m^3 , 83% carbon. Based upon British Field Research. (Adapted from Attfield⁴⁵ © 1992 American Public Health Association.)

knowledge of the health implications of coal mine dust exposures.²⁵ Based upon a critical review of the published scientific studies, the authors calculated the excess health risk (beyond that due to non-occupational factors including tobacco smoking) during work at the current US exposure limit for respirable coal mine dust (2 mg/m^3). Utilizing published exposure-response studies, it was estimated that for miners of low-rank bituminous coal working at the current exposure limit over a working life (45 years), 11–16.5% will develop pneumoconiosis, with 2–3% developing progressive massive fibrosis. Lower risks were projected for Western coal fields, and higher risks during the mining of Eastern higher rank and anthracite coals. In a similar calculation, clinically significant airflow obstruction (FEV_1 less than 65% of predicted normal) is projected to develop in 1–2% of miners working at the current dust exposure limit. Based upon these and other findings, a reduction in permissible exposures to 1 mg/m^3 was recommended. Additionally, since health risks would not be eliminated by the exposure reduction, medical monitoring was recommended using questionnaires and spirometry, in addition to chest radiographs.²⁵ However, at the time of writing, neither the exposure reduction nor monitoring recommendations have been implemented (see below)

Contemporary trends in CWP

Several radiographic surveys of selected mines, performed as part of the US National Coal Study, provide information regarding the prevalence of radiographic CWP in the US. The prevalence of the more advanced simple CWP (category 2 or greater) in miners with over 30 years tenure declined from about 11% in the first round of radiologic studies in 1971, to 8% in 1980, and to about 2% in 1988. The overall tenure-adjusted prevalence of CWP declined over the four surveys (Fig. 19.10.7). Some of the observed decline was found to be related to differences in the x-ray readers, as well as the use of a new version of the ILO chest

Figure 19.10.7: Trends in observed prevalence of radiographic category 1/0 or greater rounded only or combined opacities, adjusted to common job tenure. Based on the US National Study of Coal Workers' Pneumoconiosis. (Adapted from Attfield & Castellano⁴⁶ © 1992 American Public Health Association.)

Figure 19.10.8: Recent trends in observed prevalence of radiographic category 1/0 or greater combined opacities by job tenure. Based on the US National Coal Workers' X-ray Surveillance Program. (Adapted from Wang ML, Petsonk EL: Pneumoconiosis prevalence among working US coal miners participating in federal chest x-ray surveillance programs: 1995 to 2000. *Am J Epidemiol* 153; 11:S127, by permission of Oxford University Press.)

radiograph classification system. When miners were grouped by mining tenure, and the proportion of miners with radiographic evidence of complicated CWP was analyzed, a clear decline was seen between the initial and final round of surveys. However, trends over the last decade were not as apparent.

In addition to the National Coal Study, an ongoing National Coal Workers' X-ray Surveillance Program is administered by NIOSH. Miners may participate in this program and receive chest radiographic examinations during the first 6 months and after 3 years of employment, and at approximately 3–5-year intervals thereafter. The classifications of radiographs taken under this program have been analyzed through 2000. The prevalence of category 1 or greater pneumoconiosis has generally declined for miners in each tenure category (Fig. 19.10.8). The proportion of participating miners showing complicated CWP also decreased since 1970 for all tenure groups. Thus, results of both the US National Coal Study and the US Coal Workers' X-ray Surveillance Program document a large reduction in the prevalence of radiographic changes of CWP in US coal miners since 1970.

Participation in the National Coal Study was over 90% in the first round, but was lower in later rounds. The US Coal Workers' X-ray Surveillance Program participation rates have been 50% or less. Although confidence in the analysis of trends is somewhat reduced by the participation rates, it does appear that the mandated programs of environmental and medical monitoring initiated under the Federal Coal Mine Health and Safety Act of 1969, in conjunction with transfer options and compensation of affected miners, have had an important effect in reducing the prevalence and incidence of CWP in US coal miners. Cases that continue to occur are more often noted in smaller mines and certain states.

Newer imaging techniques

In the past two decades, computerized radiographic techniques, gallium lung scanning, and magnetic resonance

imaging have become widely available. Because traditional chest radiography is insensitive to early pathologic interstitial and emphysematous changes, interest has focused on these newer modalities in the non-occupational lung disorders. Limited evaluations of the usefulness of newer imaging techniques have been performed relative to the pneumoconioses. High-resolution computed chest tomography has been reported to be a more sensitive technique in identifying emphysema, as well as early pneumoconiosis among miners.²⁶ Coalescence of pneumoconiotic nodules and PMF lesions have been identified on CT scans when they were not apparent on routine radiographic evaluations.

Increased activity on gallium scanning of the lungs has been noted in several pneumoconioses, but this is non-specific and may be less prominent in coal workers. Magnetic resonance imaging in the pneumoconioses has no currently demonstrated utility. Digital image processing has become widely used in the past few years for display, storage, and transmission of chest images. Computer-assisted pneumoconiosis interpretation of digitized images is being currently evaluated. However, at this time, additional studies are needed to define the role that digital processes should play in the evaluation of coal miners' lung diseases.

FUNCTIONAL CONSEQUENCES

Pathogenesis

The inhalation of sufficient coal mine dust affects the function as well as the structure of the lungs. Functional consequences can generally be divided into two categories: (1) effects related to the movement of gas into and out of the lungs (the 'bellows' function); and (2) effects related to the transfer of gases between the alveolar air and lung capillary blood.

Bellows function

Resistance to airflow into and out of the lungs of coal miners may be increased by bronchitic changes in the larger airways, by airway distortion, and by emphysematous destruction of elastic lung tissue at the level of the bronchioles and alveoli. These changes reduce the rate of maximal airflow, producing an obstructive ventilatory defect, demonstrated by reductions in the FEV₁% (FEV₁/FVC ratio) and the forced expiratory flow in the middle 50% of the vital capacity (FEF₂₅₋₇₅). In contrast, dilation of small air spaces can lead to overinflation and gas trapping, while fibrotic lesions, particularly of the massive type, reduce the volume of air contained in the lungs (total lung capacity).

Both of these latter changes can result in a reduction of the forced vital capacity (FVC) and forced expiratory volume in one second (FEV₁), producing a restrictive or mixed restrictive and obstructive pattern of abnormality on spirometry. It can be seen that, based on the predominant pathology, miners may show obstructive, restrictive, or often mixed patterns of dysfunction on spirometry related to their dust exposure. Recent studies have

suggested that the loss of lung function due to dust exposure is not linear with time; rather, during the first months of exposure, there is an initial rapid loss of lung function, and subsequently a slower exposure-related decline.^{27,28}

Gas exchange

Reduced ability to transfer gases in the lungs of miners can likewise result from multiple structural abnormalities. Dilation and distortion of small airways, as well as the fibrotic changes due to dusts, result in a heterogeneous delivery of inspired air into the alveoli. Destruction of capillaries and small vessels reduces the uniformity of lung perfusion. These effects combine to result in the mismatching of lung ventilation and perfusion and subsequent hypoxemia in the systemic arterial blood. The destructive loss of capillaries alone may also be sufficient to reduce the combined surface area of the alveolar-capillary membrane to an extent that gas transfer is impaired, particularly on exertion. In advanced disease, airflow obstruction may be so severe that alveolar ventilation is insufficient for metabolic demands. In this situation, hypoxia with hypercapnia results. An additional cause for hypoxia is reduced cardiac output, primarily seen in association with cor pulmonale and right ventricular dysfunction. Additionally, excessive ventilation on exertion has been associated with dyspnea in the presence of normal measures of lung mechanics.

INVESTIGATIONS OF COAL MINERS

The functional consequences of coal mine dust inhalation have been documented through both clinical and epidemiologic studies. Most studies of large groups of miners have used routine spirometry, evaluating the expiratory flows and forced vital capacity. Smaller groups have been studied utilizing other techniques. Series of miners have also been reported from clinics emphasizing disability/impairment evaluations. Although disability series are of interest, the representativeness of miners in these series is undetermined, exposure information is often scant or absent, and a control group is generally lacking. Their overall usefulness in the study of the effects of coal mine dusts on lung function is thus quite limited.

Epidemiologic studies

Most information regarding ventilatory effects of coal mining has been derived from large field studies of miners in the United States and the United Kingdom. Studies from other countries have been reported, and show generally very similar findings. Both cross-sectional and longitudinal evaluations of the US and British studies have been published. The lung function findings from both countries are quite consistent and are summarized below. The miners who were exposed to the dustiest environments show lower mean FEV₁ levels than those in less dusty mining jobs. More importantly, exposure-response rela-

tionships of FEV₁ with estimated dust exposure or with exposure surrogates such as tenure underground have been reported for miners in both countries. Other ventilatory function indices, such as FVC, FEV₁/FVC ratio, and flows at both higher and lower lung volumes have also been shown to be inversely related to estimated dust exposure.

Evidence of an effect on airflow at low lung volumes implies obstruction in small airways. In addition to the cumulative effects of dust, a large but non-progressive reduction in average lung function is seen in the group of miners who develop the symptom of a chronic productive cough. Groups of working miners from both the US and UK have been studied longitudinally over an approximately 11-year period. Results of these studies were quite similar, and showed that, as the miners' dust exposures increased, there was a resulting progressive decrement in lung function, as measured by the FEV₁, over the period of follow-up. Differences in the effects were seen between miners at different collieries. The effects on lung function associated with dust exposure were present after adjustment for smoking, and were typically observed to occur in all three smoking groups (never smokers, ex-smokers, and current smokers). The smoking and mine dust effects appeared to be independent and additive, but not synergistic. Thus, the average reduction in ventilatory function associated with exposure to mine dusts in smokers was similar to that in never-smoking miners. No disproportionate dust effects were noted in the smoking miners. In fact, the observed dust exposure effect, rather than being greater in current smokers, was often somewhat less.^{29,30}

In miners who also smoke cigarettes, comparisons have been made between the excess reductions in lung function associated with mining exposures versus those associated with tobacco use. Since both effects are dose related, estimates of relative effect on lung function are conditional on the levels of exposure to tobacco smoke and to dust exposure chosen for the comparison. In the longitudinal study of US miners, for example, the average tobacco consumption in the smoking miners was 14 cigarettes per day. This was observed to result in an average excess loss of FEV₁ of 96 mL over 11 years in smoking miners compared to non-smoking miners. Eleven years of working at the coal face was associated with an average loss of FEV₁ of 84 mL in miners (non-smoking or smoking). For all miners, including those in less dusty work (average dust concentration 1.2 mg/m³), the mean dust-related decline in FEV₁ over 11 years was 36 mL.

It has been suggested that although mean dust-related functional declines may be of similar magnitude to smoking effects, the tobacco and mining effects might be distributed differently. Under this hypothesis, tobacco effects among smokers are confined to large deficits in a small group of susceptibles, whereas mining effects are small but occur in most miners. Based on this hypothesis, equivalence in mean functional deficits attributed to dust and smoking could conceal very different functional consequences. However, several recent observations tend to contradict this hypothesis. Miners with non-specific airway hyper-responsiveness do show accelerated declines in lung function, but these miners do not appear to expe-

rience a disproportionate effect of dust exposure or smoking.³¹ Miners with severe ventilatory deficits attributed to coal mine dust have also been identified, and studies of smoking and non-smoking miners have revealed similar increases in the proportions of severe impairments from dust- and smoking-related effects.^{32,33}

Recent studies have demonstrated additional mine-related risk factors for lung function declines. Excess declines have been associated with exposures to explosive blasting and also to potentially contaminated water sprays used for dust suppression. Less steep rates of FEV₁ decline have been found among miners who use respiratory protective devices.³⁴ These findings suggest that additional health benefits can result from further improvements in the mine environment.

Miners' ventilatory lung function has also been compared to their chest radiographic changes of CWP, categorized using the ILO classification scheme. Higher categories of CWP, particularly complicated disease, are often associated with large reductions in FEV₁, and other functional consequences, as discussed below. Lower categories of simple CWP are not consistently associated with identifiable abnormalities on spirometry, after taking into account the functional losses associated with mine dust exposure, tobacco use, and the development of bronchitis. The relationship of the nodular lung disease of simple CWP and reduced lung function has repeatedly been investigated. Some studies observe a significant deficit in spirometry among miners who develop nodular simple CWP,³⁵ while others have not found an effect of nodular disease on lung function independent of the effects of emphysema.³⁶ Conversely, reduced lung function has repeatedly been observed among non-smoking miners without radiographic pneumoconiosis, and a negative x-ray does not exclude the possibility of occupationally related lung disease.^{37,38}

Laboratory studies

Lung mechanics

Static lung compliance is often normal, but may be abnormally low or high in coal miners. High compliance, suggestive of emphysema, is the more common abnormality. Miners with PMF may have marked compensatory emphysema and high lung compliance; in others with PMF, the fibrotic process appears to predominate, and stiff lungs with low static compliance are seen. Miners with pinpoint ('p' type) opacities also appear to have dilation of peripheral airspaces.

Gas transfer

The transfer of gases in the lungs of coal miners has been evaluated using both the single-breath and the steady-state techniques to measure carbon monoxide diffusing capacity. Certain miners were found to have abnormalities on these tests. Reduced diffusing capacities are more commonly observed in miners with either pinpoint ('p' type) or irregular ('s' or 't' type) opacities of simple pneumoconiosis, and in those with complicated CWP, when compared to those with 'q' type opacities. Recent studies

among Chinese coal miners have found simple CWP to be a significant contributor to decrements in pulmonary function, including diffusing capacity.³⁹

The findings related to gas exchange on exercise in coal miners are less well defined. Many authors have reported on highly selected groups of miners referred for disability evaluation. Estimated dust exposures were often not determined. Diminished gas transfer and/or excessive ventilation on exercise have been found in some groups, but not in others. Miners with PMF often have shown severe gas exchange abnormalities on exercise. Those with increasing airflow obstruction also generally have corresponding defects in gas exchange on exercise. When the functional correlates of radiographic pneumoconiosis have been carefully evaluated in miners without important airflow obstruction, it appears that simple pneumoconiosis, particularly categories 2 and 3, can lead to identifiable abnormalities of gas exchange on exercise. These changes have been attributed to the emphysema that often accompanies the radiographic changes.

In summary, low categories of pneumoconiosis, particularly the 'q' type opacities, in the absence of airflow obstruction, often appear to be associated with little or no gas exchange impairment. In contrast, miners with a finding of airflow obstruction, higher category of CWP, and either irregular or pinpoint opacities may show impairment of gas exchange, particularly on exertion.

Pulmonary hemodynamics

Increases in pulmonary artery pressure, at rest and on exercise, have been documented in some coal miners. Abnormalities are more commonly seen when the miners have measurable airflow obstruction. When the hemodynamics were compared to radiographic findings, abnormalities were most commonly seen in miners with complicated pneumoconiosis, silicosis, or pinpoint ('p' type) opacities of simple CWP. In the absence of airflow obstruction or one of these radiographic features, pulmonary hypertension appears uncommon in coal miners.

Summary

Miners may show several functional abnormalities in relation to the inhalation of coal mine dusts. Radiographic changes in PMF are often associated with multiple abnormalities. Certain patterns of simple pneumoconiosis (irregular and rounded pinpoint opacities) appear to be associated with gas exchange impairment. Studies of miners vary regarding the relationship between ventilatory function and radiographic category of simple CWP. In contrast, deficits in expiratory flow and volumes on spirometry appear to be related to the intensity and duration of dust exposures, independent of radiographic category of simple CWP. An additional reduction in ventilatory function is often seen in miners with symptoms of bronchitis. Spirometric abnormalities measured during miners' lives are correlated with pathologic changes in emphysema, which in turn have been correlated with measures of both dust exposure and lung dust retention.

The extent of pathologic emphysema is strongly related to coal dust content of the lungs, as well as to age and smoking. The dust effects in miners who smoke cigarettes appear to be additive to the effects of tobacco use; no disproportionate effect has been identifiable among coal miners who smoke. In smoking miners, FEV₁ reductions associated with a year of working at the mine face are of similar magnitude to the average annual smoking effect. When work at less dusty jobs is included, the average dust-associated reduction in ventilatory function over one year appears to be smaller than the average effect of a year of smoking. In addition, evidence indicates that dust exposure leads to severe lung function changes in some miners.

MORTALITY

A number of studies of coal miners from the US, the UK, and the Netherlands have investigated mortality rates among miners compared to the general population. These studies have identified increased deaths from pneumoconiosis, bronchitis, and emphysema, as well as accidents, but reduced mortality from a number of causes, including lung cancer and ischemic heart disease. The deficits observed in cause-specific mortality rates have been attributed to the strict prohibition of smoking in underground coal mines and to the healthy worker effect. As mentioned above, several studies have observed an elevated risk among coal miners for death due to gastrointestinal cancer (possibly related to incidentally ingested carcinogenic aromatic hydrocarbons in coal).

When mortality has been studied in relation to dust exposures, increasing mine dust exposure has been associated with risk of death from all causes, pneumoconiosis, bronchitis, and emphysema, after accounting for smoking and age. Mortality rates are also increased with the presence of radiographic pneumoconiosis, particularly PMF.^{23,40} Miners who have deficits in FEV₁ or who experience accelerated losses of ventilatory lung function have an increased risk of death from cardiovascular and non-malignant respiratory diseases. A study from the Netherlands found that, in addition to a high standardized mortality rate for coal workers' pneumoconiosis, Dutch miners had significantly increased mortality from chronic airflow obstruction, and this was particularly evident among those without pneumoconiosis. Spirometric impairment was predictive of COPD mortality.⁴¹

A recent study reported mortality and questionnaire follow-up for 634 US coal miners whose lung function had been monitored over an average of 11 years. When evaluated after an additional 10–18 years, the group of miners with excessive FEV₁ losses reported a greater onset of respiratory symptoms and illness, and had experienced increased mortality from cardiovascular and non-malignant respiratory diseases, compared to their colleagues with more stable lung function.⁴² Overall, the findings from the mortality studies among coal miners emphasize the importance of early detection of both radiographic abnormalities and lung function declines, as well as the

initiation of effective interventions to prevent disease progression and death in affected miners.

DIAGNOSIS

Coal workers' pneumoconiosis

Pathologic changes of CWP may be found in the absence of radiographic evidence of pneumoconiosis. However, the radiographic picture of coal workers' pneumoconiosis is often sufficiently distinctive that, in the presence of an adequate exposure history, a diagnosis can be made with reasonable certainty. A lung biopsy is rarely needed. The question of what constitutes an 'adequate exposure history' is determined by the timing, duration, intensity, and other characteristics of the reported occupational exposures. Underground work prior to the institution of federal dust control regulations in 1970–73 likely represents a high risk of exposure. In this setting, pneumoconiosis developed in some miners with less than 5 years of exposure. Several jobs, as discussed above, offer recognized risks for silicosis. Face work, particularly in longwall mining, is still occurring with exposures commonly over the 2 mg/m³ respirable dust standard. In the absence of these higher risk settings, a careful workup should be performed before diagnosing radiographic CWP in a miner with less than 5–10 years of coal mine exposure. Stability of the radiograph, or slow progression over a period of 2–5 years, is expected.

More rapid change should also prompt a search for alternative processes. Hilar or mediastinal adenopathy and pleural effusion are also not likely to be due to CWP alone. For example, the appearance in a coal miner with 10 or more years of underground mining experience of bilateral small rounded radiographic opacities in low profusion and principally in the middle and upper lung zones should be accepted as diagnostic of CWP. Some miners with this presentation have complaints of cough and sputum. Basilar lung crackles are usually scant or absent. Infectious processes, other interstitial lung disorders, and metastatic neoplasm should be carefully considered if fever, weight loss, clubbing, chest pain, hemoptysis, or progressive dyspnea or malaise are present. A broad list of differential diagnoses should be considered if the initial radiograph shows unilateral disease, predominant irregular opacities, or a high profusion of small rounded densities. Finally, prominent gas exchange abnormalities are also unusual early in the course of simple CWP.

Of great diagnostic concern is the development of a large radiographic opacity in a coal miner. The differential diagnosis must include malignancies and mycobacterial or fungal infections, as well as complicated CWP. PMF, which typically develops in the upper lung zones on a background of simple nodular densities, is often bilateral. Stability or slow progression over several years is consistent with complicated CWP. If doubt exists, then an appropriate workup should be completed before accepting the diagnosis of a dust-induced lesion. Caplan's syndrome (rheumatoid pneumoconiosis) may present as multiple larger

nodules appearing without a definite background of simple CWP. The nodules may appear rapidly, i.e., over a period of weeks. A similar radiographic appearance may be seen with pulmonary metastases, but joint examination and serology will almost always reveal the confirming evidence of active rheumatoid disease.

MANAGEMENT

Medical screening and monitoring

Pre-placement medical testing is primarily intended to identify workers with existing medical conditions which would increase the health risk associated with coal mine employment. Periodic medical screening may utilize questionnaires, standard chest radiography, and spirometry. A program offering periodic chest radiographs to all underground coal miners in the US is currently mandated by federal regulations. This program serves to highlight potential areas of continuing medical and environmental problems. Due to the long latency of CWP, at times it can be difficult to relate contemporary environmental exposures to the cases identified. Miners with pneumoconiosis identified during screening qualify for administrative actions. They are entitled to increased frequency of personal environmental monitoring and offered the option to work in a reduced dust environment. This may require job transfer with maintenance of pay.

Periodic medical screening using spirometry is currently recommended, but not mandated. Pulmonary function testing is targeted toward identifying individuals with progressive airflow obstruction. To avoid the development of disabling lung impairment, workers with accelerated loss of lung function should be counseled regarding reducing current and future exposures to dust, if possible, as well as controlling other recognized risk factors (e.g., tobacco smoke).

General medical management

Medical management of a symptomatic coal miner with pneumoconiosis and/or airflow obstruction is similar in many ways to that of patients with non-occupational chronic lung diseases, but with emphasis on three principal areas: control of exposures, detection and treatment of complications, and compensation for disability. These are discussed below.

Exposure control

Control of symptoms in underground coal miners must address the mine environment, in addition to other potentially aggravating exposures, such as tobacco use. The miner should be encouraged to obtain and review the results of contemporary periodic air monitoring, to determine compliance of his or her work area with respirable dust and silica regulations.

A recommendation that the miner transfer to a surface job or a less dusty underground job is often the most viable option for reducing exposure to environmental dust.

Miners, particularly those not close to retirement, who have identifiable airflow obstruction, accelerated longitudinal decline in lung function, or radiographic changes of pneumoconiosis should be counseled regarding transfer to a less dusty environment. Miners who develop symptomatic bronchospasm in dusty environments can at times suppress the symptoms through the use of inhaled medications and oral bronchodilators. However, transfer is often necessary in order to control symptoms without resorting to more hazardous forms of therapy, such as systemic corticosteroid therapy. Transfer rights with retention of wage rates and benefits are available only for underground coal miners with radiographic abnormalities identified through radiographic surveillance, under current US mining regulations. Radiographs may be submitted to NIOSH for an official interpretation to determine eligibility.

In contrast to the situation in the US, dust control is less well established in coal mines in other countries. For example, in Poland, recommended dust levels may be exceeded in over 90% of measurements.⁴³

Engineering controls are accepted as the primary method of exposure control, and recommendations for continuous use of respiratory protective equipment are rarely practical in underground coal mining. Occasionally, however, a miner with prominent cough or bronchospasm may be able to continue working underground while participating in a formal respiratory protection program. There is evidence that use of respirators can diminish the adverse respiratory health effects from exposure to current levels of coal mine dust.³⁴

Attention should also be paid to non-occupational respiratory hazards. In smoking miners, recommending smoking cessation is an initial step in exposure management. Referral to volunteer organizations or other formal cessation programs, prescription of nicotine delivery systems when appropriate, and unambiguous advice from the healthcare provider are effective approaches.

Detection and treatment of complications

Dust-induced fibrosis, emphysema, and chronic airflow obstruction are irreversible changes. Interventions should be targeted toward detecting, treating, and preventing complications. Management of conditions etiologically unrelated to mine dust exposure may also be complicated by lung impairments related to dust effects.

Periodic monitoring of spirometry and chest radiographs is useful to determine the rate of progression of the disorder and to detect onset of complications. An initial electrocardiogram may be helpful for subsequent comparisons. In miners who present with symptoms and signs of illness, assessment of gas exchange at rest and exercise may be indicated. The subsequent performance of these evaluations must be tailored to the clinical course of the individual miner. Infectious exacerbations, including acute bronchitis and pneumonia, may occur in affected miners. Broad-spectrum antibiotics and physical therapies are helpful in reducing symptoms during episodes of purulent sputum production.

The treating clinician should take care to exclude both tuberculosis and non-tuberculous mycobacterial infections. Particularly in miners with silicosis, the risk of these infections is increased and the response to chemotherapy is less satisfactory (see Chapter 19.9). Tuberculin reactivity should be tested in all miners with CWP, since over 10% may have silicosis, which confers a 30-fold increased risk for development of active tuberculosis. In tuberculin-positive miners with radiographic pneumoconiosis, active disease must be carefully excluded. Once this has been accomplished, isoniazid preventative therapy is recommended for those with positive skin tests and no contraindications or risk factors for isoniazid-resistant infection. Nine months of daily treatment reduces the subsequent risk of developing active disease. Shorter regimens of chemoprevention including rifampin have also been effective but are not considered the first choice for miners with abnormal chest radiographs and a low risk of INH-resistant strains.

Inhaled and/or oral bronchodilator therapy should be attempted in most symptomatic miners. Prolonged courses of inhaled steroids have been shown to control symptoms and reduce non-specific bronchial hyper-responsiveness. Short, tapering courses of systemic corticosteroids may be helpful for acute exacerbations. However, it is rarely, if ever, justified to use long-term systemic steroids to allow a miner to remain working in a dusty environment.

Whole lung lavage, reported for two miners with silica exposure and pneumoconiosis, resulted in considerable removal of inorganic dust from the lungs.⁴⁴ However, there is currently no evidence that the course of disease is improved by this drastic measure.

Cor pulmonale with right heart failure due to CWP is treated the same as cor pulmonale due to other etiologies.

A coordinated rehabilitation program, with attention to nutrition, emotional stresses, pharmacologic and physical therapies, and judicious exercise may improve the clinical status of the disabled miner. As in patients with other irreversible disorders, discussions regarding the use of life-support and mechanical ventilation are appropriate in miners with severe but clinically stable lung disease.

Compensation/disability

Miners with lung impairments may be eligible for compensation under the Federal Black Lung Benefits Program, as well as through state pneumoconiosis and workers' compensation plans. In advising individual miners, the healthcare provider should be familiar with the specific requirements of the programs. Particular note should be taken of the statute of limitations, since the date of filing a claim relative to the establishment of a diagnosis of work-related disease may be critical in determining eligibility for benefits. Legal counsel often is necessary in establishing eligibility (see Chapter 57.1).

19.11 Other Pneumoconioses

James R Donovan Jr, James E Lockey

This chapter discusses less commonly seen chronic lung diseases caused by metals and minerals. The clinical evaluation of such patients is discussed briefly here and also in Chapter 19.1. Specific elements that can cause pneumoconioses are described. The fibrogenic potential of mineral dust is dependent on various physical and chemical properties of the dust, the dose retained in the lung, and specific physiologic and immunologic characteristics of the individual.¹ Silicon dioxide (SiO₂) as free silica is the most common naturally occurring fibrogenic dust. Silicates are silicon dioxide combined with various cations. The crystalline structure of silicates can vary from a platy occurrence or habit, such as mica, to a very fibrous habit, such as crocidolite or amosite asbestos.

Specific silicate ore sources such as talc can exist in a very pure deposit, or can contain minor concentrations of free silica or intergrowths of other minerals such as the amphibole tremolite. Proper mineralogic analysis of samples of an ore body taken from different locations and ongoing analysis of environmental samples from the workplace are crucial in the recognition, evaluation, and control of potential pulmonary health risks. Material Safety Data Sheets may not provide enough information to adequately characterize the physical and chemical properties of a specific silicate or potential contaminant minerals or metals.

Frequent natural contaminants of silicate ore bodies are the amphiboles tremolite, actinolite, and anthophyllite. These are considered non-commercial amphibole asbestos, in contrast to the commercial amphiboles amosite and crocidolite and the serpentine chrysotile asbestos. Other amphibole minerals such as winchite and richterite, that are not currently regulated by the Occupational Health and Safety Administration, can also be found as natural contaminants.² The non-commercial amphiboles exist in an asbestiform or highly fibrous habit or in a non-asbestiform or relatively non-fibrous habit. The term asbestiform refers to a fiber configuration, which is long and thin with high length-to-width (>3:1) or aspect ratios. When mechanical force is applied these amphiboles cleave along their specific crystalline planes and form short, squat cleavage fragments, mostly of a non-asbestiform variety, or long thin fibers, mostly of an asbestiform variety. Characterization of the mineralogy of the non-commercial amphiboles has been an area of ongoing confusion. The health implications of the non-commercial non-asbestiform amphiboles have not been adequately defined.

CLINICAL EVALUATION

The diagnosis of the pneumoconioses discussed in this chapter can be particularly challenging as exposures usually span many years and are rarely to a single agent, and the clinical features are usually non-specific. The radiographic and pulmonary function evaluation of patients for occupationally induced lung disease is covered in

Chapter 19.1. A standard posteroanterior chest radiograph should be interpreted for parenchymal and pleural changes by a physician trained and experienced in using the ILO International Classification of Radiography of the Pneumoconioses, the B-reader.

CT and high-resolution CT of the chest are more sensitive than the standard chest radiograph for detecting pleural changes, and for differentiating pleural adipose tissue from discrete and diffuse pleural thickening.³ The sensitivity and specificity of high-resolution CT (HRCT) in the evaluation of diffuse interstitial fibrotic changes are excellent with a high degree of clinical application. Use of the high-resolution CT in the prone and supine positions will differentiate peripheral interstitial fibrotic changes from normal hydrostatic fluid changes that disappear with change in body position. HRCT has demonstrated predominant, sometimes characteristic findings for each type of pneumoconiosis, and represents a major advance in the accurate characterization of these parenchymal disorders.

Pulmonary function test results can be normal, or they may be of a restrictive, obstructive, or mixed obstructive-restrictive pattern, particularly in patients with progressive massive fibrosis. Progressive decrements of FVC over several spirometric measurements can be a sensitive indicator of an early and potentially progressive interstitial fibrotic process.

Although bronchoalveolar lavage (BAL) is not routinely indicated, it is a relatively non-invasive procedure and has been used in the evaluation of patients at risk for inorganic dust-induced lung disease with unusual presentations.^{4,5} Evaluation of lavage fluid with energy dispersive spectrometry can provide information on the composition of inhaled dust. Cells obtained by BAL can be examined for the presence of dust particles. Such studies may confirm exposure, but it is unclear whether they correlate with exposure, tissue burden or disease. The BAL cell count and differential, and lymphocyte cell subset analysis into helper (CD4+) and suppressor (CD8+) T cells can suggest certain diagnoses, such as hypersensitivity pneumonitis, but are not diagnostic of any particular disease or pneumoconiosis.

Histologic examination of lung parenchyma generally provides the most definitive pathologic diagnosis, but frequently cannot determine etiology. Tissue obtained by open lung biopsy is less prone to sampling error than that obtained by transbronchial biopsy and is sufficient for qualitative and quantitative mineral dust analysis. Light microscopy with special staining techniques can detect parenchymal changes that develop in response to retained particles. Light microscopy is adequate for detecting ferruginous bodies. Phase-contrast light microscopy can detect uncoated fibers 0.2 mm or greater in diameter. Scanning electron microscopy can detect similar size particulates, and with energy dispersion x-ray analysis can identify elemental composition. Transmission electron microscopy can detect the smallest particulates, and with

selected area electron diffraction it can characterize crystalline structure. Mineralogic analysis should always be interpreted in conjunction with the other information regarding the patient.

As with other more common pneumoconiosis, the diagnosis of diseases in this chapter depends on a careful occupational history documenting sufficient exposure to cause the disease, consistent clinical evaluation, including radiographic features and physiology, and the exclusion of any more likely non-occupational disorders. Mineralogic analysis, although not routinely available, is particularly helpful when the exposure history is inconclusive or the clinical presentation atypical.

SPECIFIC ELEMENTS THAT CAUSE PNEUMOCONIOSES

Aluminum (see Chapter 39.1)

Aluminum is derived from alumina (Al_2O_3), which is produced from the naturally occurring hydrous aluminum oxide ore, bauxite. Bauxite ore can contain various impurities, including quartz and cristobalite as well as clay minerals. The decomposition of alumina into metallic aluminum occurs in electrolytic cells known as pots located within potrooms. Aluminum metal powder is produced in a flake and granulated form. A lubricant oil such as stearin is added to the flake aluminum powder to permit easy separation of the aluminum particles. Uncertainties about aluminum-related pneumoconiosis are derived from the complexity of the exposure and the low prevalence of disease in spite of the extensive use of the metal.

A group of potroom workers involved in manufacturing alumina abrasives from bauxite developed diffuse progressive radiographic and pathologic fibrotic changes predominantly involving the upper lung fields. This rare condition, referred to as Shaver's disease, has been postulated by some investigators to be related to the silica present in the production process.⁶

Exposure to aluminum powder used in the manufacturing of explosives in Great Britain and Germany during the First World War has been associated with changes similar to the findings in Shaver's disease. These findings were most likely related to exposure to high levels of aluminum metal dust that was stamped and ground into a fine powder. Aluminum metal powder is considered more fibrogenic than aluminum oxides and silicates, but exposure is rare. A case study of an aluminum potroom worker with diffuse interstitial fibrosis and restrictive changes on pulmonary function tests demonstrated a markedly elevated aluminum particle burden as well as short aluminum fibers.⁷

Symptoms of reversible chest tightness, shortness of breath and wheezing have been reported by aluminum potroom workers, and have been termed potroom asthma. (see Chapter 39.2) Diagnostic criteria and good environmental measurements have not been standardized in many of the studies of this syndrome. Estimated annual

incidence of potroom asthma varies from 0.06% to 4.0%. Exclusion of workers with a history of asthma or atopy in some of the studies may have caused these estimates to be artificially lowered. The role of smoking has not been determined. Causative factors that have been implicated include particulate and gaseous fluoride, total respirable dust, sulfur dioxide, and aluminum fluoride compounds.

Pneumoconiosis from exposure to aluminum metal or oxide of aluminum is rare. It would appear that high exposures with corresponding high lung burdens are required to induce pulmonary damage. A longitudinal study of nearly 1000 aluminum smelter workers demonstrated no accelerated decline in lung function.⁸ The rarity of this particular pneumoconiosis is most likely a reflection of decreased exposure through improved working conditions and environmental control measures. Limited case reports have described a granulomatous alveolitis in workers exposed to aluminum, with increased CD4+ T lymphocytes, similar to sarcoid and chronic beryllium disease, and suggesting an immune-mediated response to aluminum.⁹

Antimony (see Chapter 39.10)

Antimony is mined and smelted in various areas of Central and South America, South Africa, the United States, China, and Russia. During the mining and milling process, there is potential for exposure to free silica. Within antimony smelting plants, the predominant exposure is to antimony trioxide and antimony pentoxide. Small amounts of free silica and arsenic oxide have also been identified in airborne dust samples of smelting plants.

Alloyed with lead or other metals, antimony is used in battery plates, solder, and pewter. Non-metallic uses include manufacturing flame-resistant fabrics, and pigments for ceramics, paints, and rubber compounds.

Exposure to antimony oxides during the smelting process can induce simple pneumoconiosis, particularly in those workers with 10 or more years of exposure. Small, round opacities with a diameter usually less than 1.0 mm are densely distributed in the middle and lower lung fields. Complicated pneumoconiosis has not been described, nor has progression after removal from exposure. Some airway obstruction with hyperinflation was identified in one study but without adjustment for tobacco use. No isolated restrictive abnormalities were noted, and the rest-and-exercise blood gas determination and diffusing studies were essentially normal.

Exposure to antimony ore during the mining and milling process can cause changes consistent with silicosis or mixed-dust pneumoconiosis (defined in a later section). Radiographic changes most commonly involve the upper and middle lung fields, and the round opacities usually are greater than 1.0 mm in diameter.

Exposure to antimony oxide has been associated with vesicular skin eruptions with residual hyperpigmentation as well as nasal septal perforation. Antimony trichloride and pentachloride are highly toxic and can cause acute pulmonary edema.

Barium

Barite, which is the natural form of barium sulfate (BaSO_4), is mined in the United States, Canada, Mexico, and Europe, and the source of the ore can often be contaminated with free silica and/or other minerals. The great majority of barite is processed into refined barium sulfate, which is used in oil and gas drilling. Approximately 10% of barite is converted into barium-containing compounds such as lithopone, which is used in the glass, paint, and rubber industries.

The inhalation of barite dust by miners or excessive exposure to barium-containing compounds can induce the pneumoconiosis baritosis (Fig. 19.11.1). The chest radiograph is striking due to the high radiodensity of barium, with small, round dense opacities that can involve all lung fields. Radiographic changes have been observed to diminish with cessation of exposure. Baritosis is not associated with any increased pulmonary morbidity or mortality and should be considered a benign pneumoconiosis. Fibrosis and accompanying respiratory symptoms apparently do not occur unless there is concomitant exposure to free silica. Barium sulfate contrast material used for radiographic procedures can be seen on chest x-ray if aspirated or instilled in the lung, but is considered inert.

Figure 19.11.1: Baritosis is caused by inhalation of barium sulfate or barite ore. Patients are asymptomatic and the radiographic changes may improve after removal of the individuals from exposure. (Courtesy of Jerome F. Wiot, MD, University of Cincinnati.)

Graphite

Natural graphite exists as amorphous and crystalline carbon that is mined in North and South America, Europe, Asia, and Africa. Natural graphite contains various amounts of free silica as well as other impurities, including iron oxide, clay, mica, and other minerals. Synthetic graphite is produced by heating coal or coke higher than 2200°C (3992°F). Synthetic graphite is crystalline and contains only trace amounts of free silica. Historically, the mining and curing of natural graphite and the production of synthetic graphite was a dusty process in comparison to most current work practices.

Graphite is very resistant to thermal shock and is used in foundry facings and crucibles, in steel and cast iron manufacturing, as neutron moderators in atomic reactors, and in carbon electrodes.

Both simple and complicated pneumoconioses have been attributed to graphite dust exposure. The preponderance of cases are a mixed-dust pneumoconiosis, partially attributed to the free silica contaminant of the graphite dust. The role of silicon dioxide in graphite pneumoconiosis remains controversial, but both simple and complicated pneumoconioses have been reported in workers with only trace amounts of silica exposure or none at all. The clinical findings and pathogenesis of graphite pneumoconiosis are similar to coal worker's pneumoconiosis.¹⁰

Iron

Welders and other workers exposed to dust or fumes of metallic iron and iron oxide can develop a benign pneumoconiosis termed siderosis. Small, dense opacities distributed throughout the lung field can be demonstrated on chest radiograph, similar to simple silicosis. No symptoms or pulmonary function impairments are associated with pure siderosis. The pathologic findings in siderosis are perivascular and peribronchiolar aggregations of iron oxide dust particles, both in macrophages and in extracellular tissue.

A significant percentage of workers exposed to iron oxide encounter other occupational exposures that may represent a significant pulmonary hazard. Foundry workers, for example, are potentially exposed to various types of metal alloys as well as free silica, vermiculite, asbestos, and welding and oxyacetylene metal cutting fumes, as well as isocyanates. The resultant chest radiographic changes and pulmonary function abnormalities under these circumstances may be reflective of a mixed-dust pneumoconiosis rather than pure siderosis.

Kaolin

Kaolin, also called china clay, is a hydrated aluminum silicate that is found in the southeastern United States (primarily Georgia), and in Great Britain (Cornwall), Germany, Czechoslovakia, Egypt, and Japan. The principal industrial uses are in the manufacture of refractory ceramic bricks and fibers; as filler in plastics, rubber, paints, adhesives,

and pharmaceuticals; and as an absorbent. Kaolin ore may contain appreciable quantities of free silica (quartz), micas, and feldspars, as well as various cations. Remarkably, Georgia kaolin contains very little free silica.

Simple and complicated pneumoconioses have been described in kaolin mine and mill workers, and can also be found in user industries. A 63-year-old male employed for 43 years in the polishing room of a clothes textile mill, who died of respiratory failure, was found on lung biopsy to have extensive fibrosis and substantial quantities of kaolin. Chest radiographs of kaolin workers have demonstrated predominantly irregular but also small, round opacities involving all lung fields at various levels of profusion. Large opacities have also been seen. Pleural thickening has been noted in mild kaolinosis. The overall prevalence of pneumoconiosis in current kaolin mine and mill workers has ranged from 7.2% to 13%.

Results of pulmonary function tests in kaolin workers with simple pneumoconiosis have tended to be normal or demonstrate a mild restrictive pattern. Workers with complicated pneumoconiosis may have normal pulmonary function or demonstrate an obstructive, restrictive, or mixed obstructive-restrictive pattern.

Pathologic examination of pulmonary tissue from (Cornish/china) (kaolin) clay and stone workers demonstrated both interstitial and nodular fibrosis. The interstitial fibrosis ranged from localized fibrosis around the respiratory bronchioles to diffuse fibrosis with obliteration of alveoli and honeycombing, and the severity of the conditions correlated with kaolin dust content of the lung. The nodular fibrosis varied in size (3 mm to 10 mm in diameter) and number (two to seven nodules per section), and correlated with quartz dust content of the lung. Complicated pneumoconiosis was seen in both groups. Histologic findings in five kaolin workers from Georgia with complicated pneumoconiosis demonstrated extensive kaolin deposition that was associated with peribronchiolar macules and nodules. Silica was not identified in the lung tissue from Georgia kaolin workers.

Synthetic vitreous fibers (see Chapter 46)

Man-made vitreous fibers (MMVF) are a generic group of synthetic amorphous glassy silicates fiberized from molten raw material.¹² Mineral wool includes slag and rockwool, and it is produced primarily from iron ore furnace slag and naturally occurring rock. Glass fiber includes glass wool, continuous glass filament, and special purpose glass fiber, and is produced from molten glass consisting of borosilicate and low alkaline silicate glasses with various amounts of stabilizers (aluminum, titanium, and zinc) and modifiers (sodium, calcium, barium, potassium, lithium, and magnesium). Refractory ceramic fiber is produced from kaolin clay or aluminum and silica.

Mineral wool is manufactured by a rotary or wheel centrifuge process. Glass wool is manufactured by a rotary and blowing process, continuous glass filament by drawing or extruding molten glass through set diameter holes, and special purpose glass fiber by a flame attenuation

process. Refractory ceramic fiber is produced by a steam-blowing or wheel centrifuge process. A phenolic binder with oil as a lubricant and dust suppressor is commonly added in the manufacturing process of mineral and glass wool. During the curing process, the binder is normally fully polymerized and is chemically inert in the final product.

The average diameters of MMVF are dependent on the production process and end-use of the product. The average diameter for mineral wool is 3.5 to 7 μm ; glass wool, 1 to 15 μm ; special purpose glass fiber, less than 3 μm ; and refractory ceramic fiber, 1 to 5 μm . Large variations in fiber diameter can occur for these classes of MMVF. Even though the average diameter may be set at 5 μm , a significant number of fibers have diameters within the respirable range of less than 3.5 μm diameter and less than 250 μm in length due to the nature of the production process. Continuous glass filaments average 3–25 μm in diameter and are manufactured by a method that maintains a more precise fiber diameter.

MMVF greater than 5 μm in diameter can cause mechanical skin irritation and itching, and irritation of the eyes and mucosal surfaces, especially in newly exposed individuals. Workers with atopic dermatitis or dermographism may not be able to tolerate MMVF exposure because of a lower itch threshold. A high concentration of fiber can cause upper and lower respiratory tract irritation that is transient in nature and resolves with removal of the affected individual from exposure.

There are two major ongoing mortality studies of United States and European mineral wool and glass fiber manufacturing workers. Within the United States the most recent study of the mineral wool and glass fiber cohort reported a small but statistically significant excess risk for lung cancer. This pattern, however, was not found to be associated with measures of exposure, such as duration of employment, fiber exposure estimates, or time since first employment.^{13,14} An excess in lung cancer seen in one glass fiber manufacturing plant may have been due to differences in local versus the national prevalence of cigarette smoking.¹⁵ The most recent analysis of the US workers from five rock and slag wool plants demonstrated an increased lung cancer mortality based on national but not local expected rates. The excess risk was concentrated in short-term workers and not related to measures of respirable fiber exposure. Interestingly there was an increased mortality from nephritis and nephrosis compared to both national and local rates, which needs to be further studied.¹⁶

The mortality study of European mineral and glass wool workers also demonstrated a significantly increased risk for lung cancer mortality compared against national mortality rates. For glass wool workers, however, there was no association with duration of employment or time since initial employment and with removal of short-term workers, no excess lung cancer was noted. In regard to the rock and slag wool cohort the investigators felt a possible relationship with exposures during the early phase of mineral wool production was not as clear as in previous studies but fiber exposure may have contributed non-specifically to

the mortality results.¹⁷⁻¹⁹ Within the European cohort there was no increased mortality from bronchitis, emphysema, or asthma.²⁰

Clinical studies of workers involved with mineral wool and glass fiber manufacturing generally have not demonstrated any significant increase in chest radiograph or pulmonary function abnormalities. A morbidity study by Weill and Hughes in the United States in 1983 reported a possible relationship between exposure duration and ILO profusion categories 1/0 and 1/1. A follow-up survey in 1993 by Hughes et al. reported an overall prevalence of small opacities of 1.6%, which was similar to a non-fiber exposed comparison group. There was an association with indices of exposure at profusion level 1/0 but not 1/1. The authors concluded that there were no adverse clinical, functional, or radiographic effects of fiberglass and mineral wool manufacturing in the study population. Similar results have been found in other studies of mineral and glass wool manufacturing workers with the exception of a potential interaction between fiber exposure and heavy cigarette smoking and airway obstruction.²¹

End-user studies of mineral and glass wool exposure are limited. Workers using rotary spun fiberglass in appliance insulation for 15 years or longer were reported to demonstrate a 3.5% prevalence of irregular opacities at profusion level 1/1 to 2/1. Asbestos contamination within the plant site may have been a contributing factor.²² Lower FEV₁ values in MMVF-exposed insulation workers, adjusted for self-assessed former asbestos exposure, have also been reported. The health risk to end-users from exposure to mineral and glass wool is certainly less than that associated with asbestos exposure. Further studies of end-users with no previous occupational exposure to asbestos are needed.

Refractory ceramic fiber (RCF) is primarily used in industrial environments requiring high temperature insulation, such as in oven and kiln wall linings and the aerospace industry. Extended use of RCF above 1000°C (1832°F) causes partial conversion to cristobalite, a type of crystalline silica. Animal inhalation studies at a maximum tolerated dose of 30 mg/m³ of RCF have demonstrated the induction of mesothelioma, lung cancer, and interstitial and pleural fibrosis. Subsequent multiple-dose studies at 3, 9, and 16 mg/m³ demonstrated minimal fibrosis at the two higher concentrations and one mesothelioma at the 9 mg/m³ exposure.^{23,25}

Within the US an initial cross-sectional evaluation of pulmonary function in workers involved with RCF manufacturing demonstrated a reduction in FVC in current (165 ml) and past (156 ml) male smokers and a reduction in FEV₁ (135 ml) in current male smokers and employment in production job tasks for 10 years. For females there was a reduction in FVC among non-smokers of 350 mL per 10 years employment in production job tasks that was not seen in never-smoker males.²⁴ The results of European studies were similar indicating a probable interactive effect between smoking and RCF exposure and small decrements in FVC and FEV₁.²⁶ A longitudinal evaluation of pulmonary function obtained between 1987 and 1994 for those male workers with five or more tests demonstrated

no further decline in FVC or FEV₁ values that most likely was related to the lowering of workplace exposures.²⁷

A recent chest radiograph analysis of US RCF manufacturing workers demonstrated an association between latency, duration of employment in a production job, and cumulative RCF exposure and pleural plaques. Of those workers with over 20 years in a production job task, 8% demonstrated pleural changes. The overall prevalence of pleural changes was 2.7%. There was a trend towards early interstitial changes but not at a statistically significant level.²⁸ A previous case-control study confirmed that potential previous asbestos exposure did not account for the changes. The European study indicated a relationship between time since first RCF exposure and pleural changes as well as a relationship with age and previous asbestos exposure.

The International Agency for Research on Cancer (IARC) classified biopersistent MMVF such as RCF and certain special-purpose glass wools as group 2B or possible human carcinogens. The more common insulating glass wool, rock and slag wool, and continuous glass filaments are group 3 or not classifiable as carcinogenic to humans.²⁹

Ongoing animal and human studies will continue to refine knowledge concerning possible health risks associated with exposure to various types of MMVF. Maintaining exposure at 1 respirable fiber/cm³ or less as a time-weighted average especially for biopersistent MMVF should help maintain a margin of safety for exposed workers. This is especially important for secondary and end-users when exposure levels may not be adequately controlled and where the data are inadequate to evaluate the potential health risk.

Mica

Micas are a group of complex aluminum silicates containing either alkaline metals or iron and magnesium. The muscovite form is a potassium aluminum silicate that is transparent and resistant to heat and electricity. It is used in stove windows and in the manufacture of paints, wallpaper, and lubricants. Other forms of mica are used as fillers in cements, asphalts, and pharmaceutical products; as a component of drilling muds in the oil industry; and within the electrical industry. Mica is mined in India, Canada, Brazil, Russia, and the United States. Human exposure is through mining and milling and through the application of micas in production processes.

Mixed-dust pneumoconiosis and silicosis in mica miners have been reported but appear related to contamination with free silica. The evidence that mica without silica can cause a pneumoconiosis with interstitial fibrosis is based largely on case reports and limited surveys of mica workers. Such reports have described pneumoconiosis secondary to grinding muscovite, which is believed to be nearly silica free. Objective findings have included: crackles involving the lung bases on chest auscultation, restrictive changes on pulmonary function tests, and small opacities on chest radiographs involving the lower lung fields. Pathologic changes noted are ill-defined fibrotic nodules as well as

more widespread interstitial fibrosis. Mineralogic analyses of the lung tissues have demonstrated the muscovite form of mica free of other minerals.³⁰

Mixed-dust pneumoconiosis

Mixed-dust pneumoconiosis is the terminology applied to lung disease caused by simultaneous exposure to crystalline silica and other dusts, such as iron oxides, coal, oil shale, and graphite. Anthracosilicosis and silicosiderosis are examples of specific mixed-dust pneumoconiosis. Occupations in iron, steel, and non-ferrous foundries and in arc welding and oxyacetylene metal cutting in an environment where there is free silica exposure have been associated with mixed-dust pneumoconiosis. The degree of fibrosis is related to the amount of free silica involved.

Classic whorled silicotic nodules are less common than in pure silicosis, perhaps secondary to a modifying effect on the free silica from an accompanying non-fibrogenic dust. Irregular peribronchiolar and perivascular collagen fibrosis is seen with increased content of iron, carbon, or other mineral dusts. The chest radiographic changes are isolated round or round and irregular opacities involving the upper lung or whole lung fields. Progressive disease can occur, but is less common than with silicosis. The occurrence of tuberculosis in mixed-dust pneumoconiosis is higher than that in the general population.

Oil shale

Oil shale is a sedimentary rock that contains oil. After being mined and crushed, the ore is heated to 350°C to 500°C (662°F to 932°F), releasing oil vapor, which is then condensed into liquid in a process called retorting. The oil shale industry existed in Scotland from 1850 until 1962. In the western United States, vast deposits of oil shale exist as a yet unused energy source. Oil shale contains minerals similar to low-rank coal, and can contain free silica, ash, kaolinite and mica.

A survey of Scottish oil shale workers demonstrated a prevalence of simple pneumoconiosis (ILO profusion category 2/1 or greater) ranging from 1.6% to 5.8% in miners and 0.6% to 3.6% in retort workers, and a few cases of complicated pneumoconiosis. Pulmonary function abnormalities of a mixed obstructive-restrictive pattern were identified in oil shale workers with simple pneumoconiosis. The decrements in lung function persisted after allowance for age and smoking status.³¹

In the early years of the industry, skin and scrotal cancer were described in workers producing paraffin products and in cotton mill workers using lubricating oils produced from oil shale. A mortality study by Seaton et al.³² of oil shale workers first employed prior to 1953 demonstrated an excess of deaths from skin cancer.

Polyvinyl chloride (see Chapter 41)

Under normal temperature and pressure, vinyl chloride monomer is a gas and is used as a chemical intermediate in

the polymerization of polyvinyl chloride (PVC) resin. A cross-sectional study by Soutar et al. of over 800 men in a PVC manufacturing facility demonstrated a relationship between PVC dust exposure and dyspnea, decrements in FEV₁ and FVC, and chest radiographic abnormalities. The changes in FEV₁ and FVC were small but consistent with a mixed obstructive-restrictive pattern. Chest radiographic changes were consistent with small, rounded opacities of ILO profusion category 1/1 or less.³³ Case reports with available pathology have demonstrated desquamative interstitial pneumonitis and interstitial fibrosis associated with a restrictive pattern on pulmonary function tests. Phagocytized PVC material in pulmonary macrophages has been seen in lung biopsy material. In a few instances, elevated urine and blood levels of phthalic acid derivatives were demonstrated.

Talc (see Chapter 46)

Talc is a hydrated magnesium silicate that exists in several crystalline forms, ranging from talc plates to the more uncommon talc fibers. Talc deposits can be mineralogically complex and, depending on the ore source, can range from pure talc to talc ore with intergrowths of the non-commercial amphibole asbestos minerals, tremolite, actinolite, and anthophyllite, as well as silica. The non-commercial amphiboles are primarily of the non-asbestiform variety that fracture into short prismatic and acicular cleavage fragments along their crystalline plane with the application of mechanical force. Longer fibers approaching a more asbestiform variety, however, have also been identified as well as occasional chrysotile asbestos.

When talc is discussed in the industrial setting, it can refer to a variety of minerals that have physical properties similar to talc, such as chlorites, pyrophyllite, and dolomite. The mineralogic variability of talc deposits as well as the use of the term talc to denote physical properties of various minerals rather than the specific hydrated magnesium silicate has caused persistent problems in interpreting the health effects from occupational exposures. A variety of minerals in addition to talc, including mica, kaolin, asbestos, and silica, have been identified on mineralogic analysis of lung biopsies from talc-exposed workers.

Within the United States, talc is predominantly produced from mines in New York, Vermont, North Carolina, Texas, Montana, and California. Talcs containing admixtures of previously listed minerals are used in industrial applications including the manufacturing of ceramics, paper, plastics, rubber, wall covering materials, asphalt, and electrical insulation. The pure talc deposits, such as those found in Montana, Vermont, and inland California, are used in consumer products such as cosmetics, deodorants, food processing, and as fillers in pharmaceuticals.

Three forms of pneumoconiosis have been associated with inhalational talc exposure: talcoasbestosis, talcosilicosis, and pure talcosis. A fourth form is associated with intravenous administration of medication intended for oral use

in which pure talc is used as a filler. Talcoasbestosis has been associated with talc from the Gouverneur Talc District of upper New York State.³⁴ Miners exposed to talc mined near or in New York State have demonstrated radiographic and pathologic changes commonly associated with exposure to commercial asbestos. This includes irregular opacities involving the lower lung fields, and pleural and diaphragmatic plaques with calcification. Characterization of the mineralogy of the ore and the dust generated from the mining and milling processes has been a subject of ongoing debate.

Owing to the potential for mixed-dust exposure that includes the previously mentioned non-commercial amphibole asbestos, platy talc, homogeneous talc fibers, heterogeneous fibers composed of various elemental constituents, and in some circumstances, silica, the pathologic findings can be complex. Changes consistent with diffuse interstitial fibrosis with asbestos bodies, silicotic nodules, and granuloma formation with giant cells containing birefringent particles have been identified. Early mortality studies reported high mortality rates due to pneumoconiosis and lung cancer. Subsequent studies that were able to control for confounders such as smoking and previous occupational exposures have not substantiated an association with lung cancer.

Talcosilicosis is caused by the inhalation of talc associated with free silica. The free silica content of air during talc mining operations in Italy has been measured as high as 18%. Radiologic changes in cases from Italian and California coastal talc mining operations demonstrated diffuse round and irregular opacities, and peripheral conglomerate masses. The pathologic changes were consistent with silica exposure, with both silica and talc particles identified in the lung tissue. An increase in mortality from non-malignant respiratory disease in Italian miners was secondary to silicosis and silicotuberculosis.

Talcosis is caused by the inhalation of talc that is essentially free from other mineral contamination. Talcosis has been identified from occupational as well as non-occupational exposure, such as habitual use of excessive amounts of cosmetic talcum powder. An unusual case of pulmonary talcosis involved a respiratory technologist who admitted to regularly inhaling large amounts of hospital baby powder. This produced an asthma-like condition that was refractory to steroids and methotrexate, documented with lung biopsy.

Another example involved a 62-year-old woman who had been initially diagnosed with sarcoidosis until a biopsy revealed the presence of numerous birefringent particles in centrilobular lung zones, which were further characterized as impure talc, free of asbestos or silica. Her occupational history showed only that she had worked from age 14 to 18 in a factory making rubber hoses, with exposure to talc. This suggested that even a relatively short, but intense exposure to talc more than 40 years previously could be a cause of progressive lung fibrosis. Radiographic changes include round and irregular opacities that can be diffuse or limited to the upper (Fig. 19.11.2) or lower lung fields. Pathologic changes include focal fibrosis adjacent to small

Figure 19.11.2: Talcosis is caused by inhalation of pure talc. This patient was employed in the Montana talc mines for 20 years and was asymptomatic, with normal pulmonary function tests. There are round opacities (ILO category 1/1) involving the upper lung fields.

airways and vessels to more diffuse fibrosis in workers with prolonged exposure to high concentrations of talc. Foreign body granulomas and multinucleated giant cells have also been identified. Chest radiographs can be normal in workers with focal pathologic changes. Pulmonary function tests in cases of talcosis range from normal to a restrictive or mixed restrictive and obstructive pattern. IARC reported that there was inadequate evidence for cancer in humans resulting from talc that does not contain asbestiform fibers.

Accidental aspiration of talc by infants or habitual use of excessive amounts of cosmetic talc can induce significant pulmonary disease, including bronchiolitis and extensive fibrosis with granuloma formation. When injected intravenously by individuals abusing oral medication in which talc is used as a filler, a foreign body granulomatous reaction can occur ultimately resulting in secondary cor pulmonale.

The spectrum of talc-related pneumoconiosis is associated with the heterogeneity and physical characteristics of the mineral, the intensity and duration of exposure, and individual differences in the pathologic reaction to the mineral. In general, it appears that higher concentrations of pure talc are required to induce pathologic changes in the lung in comparison to talc contaminated with asbestos and silica.

Tin

Tin occurs naturally in various tin-bearing minerals that are mined on several continents. Tin miners are exposed to silica, lead, arsenic, as well as other metals and are at risk for the development of nodular silicosis. Major industrial uses for tin include as a component of protective coatings, solder, jewelry, pewter, bronze, and various metal alloys.

Workers exposed to tin dust or fumes can develop radiographic changes consistent with dense small diffuse opacities. This condition, referred to as stannosis, is associated histologically with lung macules and macrophages laden with tin oxide particles (Fig. 19.11.3). Stannosis is considered a benign pneumoconiosis with no significant pulmonary symptoms or pulmonary function impairment associated with the radiographic findings.

Vermiculite

Vermiculite is a micaceous hydrated mineral with an aluminum-iron-magnesium silicate composition. With the application of heat, vermiculite expands up to 20 times its original size. Expanded vermiculite is used in insulating and fire-resistant materials, aggregates and filler in cements, plastic and flooring materials, agricultural products such as potting soil, and as carriers for fertilizers and other chemicals. The ore is shipped in an unexpanded form and is expanded at local facilities.

Vermiculite ore is frequently contaminated with various asbestiform minerals, mostly fibrous tremolite-actinolite, depending on the source of ore. The pulmonary health

effects of vermiculite exposure appear related to the degree of contamination by these asbestiform fibrous amphiboles.

Vermiculite ore from a mine and mill near Libby, Montana (which closed in 1990), was contaminated with 5%–10% non-commercial fibrous asbestos, actinolite, and some tremolite. Other asbestiform minerals contaminating the Montana ore include winchite and richterite.³⁵ A morbidity and mortality study by Amandas et al. of the Montana vermiculite miners and millers demonstrated an increased risk of lung cancer, as well as pleural and parenchymal abnormalities on chest radiography, typical of those induced by asbestos,³⁶ as well as four persons with mesotheliomas.

A recent screening evaluation was completed of over 6000 current and former residents of the Libby, Montana, area, including former workers of the vermiculite mine or mill, as well as residents who lived in the area for 6 months or longer prior to 1991. Eighteen percent of participants had pleural abnormalities on chest radiographs, which increased to almost 40% in those individuals 65 years or older. The radiographic changes were noted not only in former mine and mill workers but also in residents with bystander exposure only.³⁴

Vermiculite ore from the Enoree region, South Carolina, is believed to have low concentrations of the non-commercial asbestos tremolite and actinolite, mostly of the non-asbestiform variety. The mean concentration of fibers from bulk dust samples was 0.27 fiber per milligram of dust, with 37.9% fibers identified as tremolite-actinolite and 15.9% identified as talc anthophyllite. Air-borne fibers were thinner and shorter than the bulk dust samples, and air-borne concentrations were reportedly below 0.32 fiber/cc by transmission electron microscopy. A radiographic survey of 86 current and former employees demonstrated small opacities of ILO profusion category 1/0 or more in 4.7% and pleural thickening in 8.1%. However, a similar prevalence of radiographic findings was seen in a non-exposed group of employees.

Vermiculite from South Africa contains the non-commercial fibrous amphibole asbestos anthophyllite, as well as potentially small amounts of tremolite. A cross-sectional study of radiologic findings and lung function in 172 vermiculite workers demonstrated small opacities of profusion 1/0 or greater in 1.2%, pleural changes in 3.5%, and pleural calcifications in 1.7%. The changes were reportedly similar or lower than a comparison group not exposed to vermiculite.

Adverse health effects of vermiculite exposure may result when the vermiculite is contaminated with asbestiform minerals, primarily fibrous tremolite-actinolite. Routine monitoring of the source of the ore for amphibole contamination, and analysis of air-borne dust particulates can help limit tremolite-actinolite fiber exposure and the health risks known to be associated with asbestos exposure.

Zeolite

Naturally occurring zeolites are a family of hydrated aluminum silicates that exist in approximately 40 non-

Figure 19.11.3: Stannosis is secondary to inhalation of tin oxide. The chest radiograph demonstrates multiple, round high-density shadows evenly distributed throughout both lung fields. (Courtesy of Jerome F. Wiot, MD, University of Cincinnati.)

fibrous and fibrous zeolite species. The main natural deposits in the western United States occur along the margins of the Great Basins (Utah, Nevada). Non-fibrous synthetic zeolite with no identifiable health risk is produced for its selective absorption and ion-exchange characteristics.

The fibrous zeolite species erionite morphologically resembles commercial amphibole asbestos fibers. Epidemiologic studies of several villages in the central Anatolia area of Turkey known as Cappadocia have identified an increased incidence of mesothelioma, lung cancer, and pleural and parenchymal changes commonly associated with commercial asbestos exposure.³⁷ The equal occurrence of mesothelioma in males and females at an unusually young age supports an environmental etiology. Mineralogic analysis of environmental samples and lung tissue demonstrated fibrous zeolite (erionite) as well as tremolite and chrysotile. Animal studies have confirmed that fibrous erionite is fibrogenic and carcinogenic.

Within the United States, a heavy equipment operator from Nevada with a pulmonary histologic pattern similar to asbestosis was found to have fibrous and non-fibrous aluminum silicate particles within the lung parenchyma. Using scanning electron microscopy with energy dispersion x-ray analysis, the particulates were found to be identical to a sample of fibrous erionite obtained from northern Nevada.

The health data associated with fibrous zeolite (erionite) exposure indicate that other naturally occurring fibrous minerals may, in fact, cause health abnormalities that are now associated with asbestos exposure. The occurrence of natural deposits of zeolite in certain areas of the western United States warrants caution during earth-moving construction projects, and other dispersive activities in areas with these types of geologic formations.

Chapter 20

Disorders of the Eye, Ear, Nose and Throat

20.1 Ophthalmologic Disorders

Lea Hyvärinen, Susan H Forster

INTRODUCTION

Ophthalmologic disorders can occur in a variety of different work environments. Visual and ergonomic issues impact on a large number of office workers. Ergonomic problems and injuries caused by poor ergonomics are not reported as effectively as cases related to trauma and toxic exposures. The reported incidence of occupational injuries that lead to temporary or permanent visual disability approaches 70,000 workers in the United States each year.¹ Many of these injuries are preventable.

Diagnosis is often challenging as signs or symptoms may be subtle and not clearly attributable to a given cause. Work-related disorders of the eyes and visual pathways often mimic other diseases. Underlying eye and visual pathway disorders may increase susceptibility to workplace exposures. Health professionals need to be informed of the working conditions or the hazards that exist in the workplace. Allergic reactions are common in industrial, agricultural, and office settings but are also attributable to exposure in non-work environments, which often present a confounding factor. An affected group of workers from the same industry may seek medical help from a variety of different sources, which makes identification of clusters of work-related disorders difficult. Thus, there remains an important role for specialists who are knowledgeable about the work environment and potential work-related risks. In addition to accurate diagnosis of individual cases, clinical investigations of groups of workers are important to document a causal relationship between ocular or visual changes and work.

Finding an occupational link to illness sometimes requires ingenuity. For example, recent investigation by Schuman et al.² showed an increase in the incidence of visual field defects in wind instrument players presumably secondary to the transient elevation of intraocular pressure while playing high resistance wind instruments.

Assessment of visual function is an important part of pre-employment medical screening and monitoring of the workforce. Assessment techniques used today do not cover important visual functions, like motion perception in traffic-related occupations or contrast sensitivity in monitoring exposure to toxic substances.³

CLINICAL EVALUATION

An evaluation of a worker with a possible eye disorder or vision problem consists of a careful history and an examination. In addition to assessment of individuals and clusters of workers with presumed work-related exposures,

evaluation prior to employment is important to determine the worker's capacity to perform in that work and to consider its possible ill effects to each given worker's health. In the evaluation not only are measurements made but also the worker's vision is assessed in terms of the requirements of each particular occupation.

In most occupations visual tasks are related to four main functional areas: (1) orientation and mobility; (2) tasks resembling activities of daily life, i.e., finding objects at work and using tools and instruments; (3) communication; and (4) sustained near-vision tasks like reading and writing. In cases of evaluation of visually impaired workers their special ergonomic needs require consultation with local and nationwide services.⁴

History

An occupational case history should include pertinent symptoms and their onset and duration. Certain symptoms should always lead to questioning about possible exposures, and exposure to a known toxic substance should lead to questions about specific symptoms. An exposure may result in acute or chronic symptoms with a latency period between exposure and onset of symptoms from seconds to years. Visual symptoms are often vague and can sound like psychogenic complaints. When a worker complains of blurred vision or a change in the quality of vision, the physician should consider the possibility of a neurologic disorder or a reaction caused by an environmental exposure or pharmaceutical agent.³ Color vision and contrast sensitivity are often first affected. The treating physician should have access to information on all chemicals that the worker may be or has been exposed to and their known effects on the eyes and vision.

Physical examination

Patients may complain of ocular pain, irritation, itching, or periocular swelling. Severe pain and photophobia (light-induced pain) in a red eye suggest intraocular involvement and warrant immediate ophthalmologic evaluation. Discharge from the eye is caused by conjunctival irritation or conjunctivitis. Itching is typical of allergic reactions. Blurred vision, difficulties in seeing, ergonomic and spectacle problems are other common complaints.

The physical examination should include the following: (1) testing of visual acuity and color vision, (2) visual field testing, (3) testing of ocular motility, (4) external examination, (5) fundus examination, (6) laboratory and electro-

physiologic tests. Many tests are beyond the scope of the occupational physician and require referral to a neurologist or an ophthalmologist with special interest in occupational health.

Visual acuity

Measurement of visual acuity is nearly always included in an examination of the eyes and vision. Although it does not define the pathology or state of health of an eye or of visual pathways,⁵ it provides some basic information about visual functioning. Testing should be done at the distance marked on the test. If the patient generally wears distance glasses, testing should be done using the glasses unless documentation of uncorrected vision is specifically required. Visual acuity is tested first binocularly, and then for each eye separately. The Landolt C optotype and number charts are universally accepted, but the EDTRS and the old Snellen chart are also acceptable in the United States. Luminance at the chart needs to be 80 candelas per square meter or higher. Lightboxes make it possible to have standard luminance wherever the test is used.

Visual acuity is recorded for binocular vision and each eye separately. If glasses are used this is noted. Visual acuity values can be recorded in one of two ways, i.e., (1) as the last line read correctly (for example, if a person reads the 20/30 line and two letters on the 20/25 line, the result is given as 20/30, ignoring the partially correct line); or (2) more precisely, the last line read correctly plus the number of letters read correctly on the following line (in the previous example, as 20/30 +2). Visual acuity measurements with a near card complete testing at distance. Near vision is particularly relevant in assessment of vision ergonomics of office workers, although an office worker with asthenopic symptoms (eye strain) needs referral to an eye care professional for thorough evaluation of the refractive correction and demands of the working conditions.

Visual acuity is measured at low contrast for quick detection of early changes in the optics of the eye, changes in the function of the retina or subtle pathway damages. In most occupations measurement at 2.5% contrast is sufficient, but in occupations that require visual functions at very low contrast levels, such as quality control or handling large white surfaces, regular measurements at 1% contrast are warranted. The occupational low contrast tests are used in lightboxes.

In visual acuity testing the threshold of recognition is measured. However, it is not possible to function at acuity threshold. A reserve capacity two to three times greater than the threshold is needed to work comfortably. This can be easily measured at the workplace by asking the employee to move backward and measure the distance from which he or she can read the text with which he or she works. For example, many computer screen texts can be read with distance glasses at a distance of 2–4 m. Thus there is a 3–6 times reserve capacity in visual acuity.

Color vision

Color vision appears to be particularly sensitive to toxic exposures, including a number of different solvents, mercury,

and certain pharmaceuticals. There are two types of color vision tests: screening tests and quantitative tests. Screening tests such as Ishihara pseudoisochromatic plates and Waggoner H-R-R plates are designed to detect even minor inherited deviations of color perception. The Ishihara plates detect only red–green confusion while the Waggoner H-R-R plates detect blue–yellow defects also. These tests are not quantitative. The severity of color vision deficiency of a healthy worker is assessed using the Farnsworth Panel D-15 test, the Good-Lite 16 Hue test or the Lanthony desaturated test that utilize arranging color pigments so they are adjacent to colors of similar hue. The Farnsworth-Munsell 100 Hue test is used in diagnostic work when lesions in the retina or in the pathways are suspected. Each eye is tested separately. This test is more cumbersome and time consuming to administer and more costly to run, but is helpful in assessing changes due to neurotoxic substances.

All color vision tests must be used under daylight type illumination, either at a window facing north or using a blue incandescent bulb. A wrong color temperature of light may lead to incorrect test results. During the last 10 years color vision changes have continued to be reported due to exposure to styrene, toluene, perchlorethylene, carbon disulfide, metallic mercury, and mercury vapor.

Visual field testing

Visual field tests can be divided into two types: those that test peripheral field and those that examine central field. Though only roughly quantitative, confrontation fields are the most frequently used visual field test in occupational medicine. They are easy to administer and do not require the use of any specialized equipment. Each eye is tested separately with the patient facing the examiner. After occluding one eye the patient is asked to look at the examiner's opposing eye. The examiner then brings his hands or a test object slowly into view from the periphery, from an area of non-seeing to an area of seeing, and asks the patient to report when the test object is seen. This should be done in all four quadrants of peripheral vision. Binocular testing, that is with neither eye occluded, is helpful in the assessment of a worker's functional vision.

Automated visual fields and Goldmann visual fields provide quantitative techniques to evaluate visual fields; islands of loss of vision (scotomas) within the visual field can be documented. Field defects in the lower part of the visual field increase risk of accident, especially if work areas are poorly lit and tools or other materials obstruct walkways.

In cases of homonymous hemianopia it is important to know that a test result from Goldmann or automated perimetry can be misleading. In lesions of the posterior part of the visual pathway, motion perception may be present in the 'blind' hemifield and thus the worker is not visually impaired.⁶ This is important to know when assessing vision for a driver's license.

The Amsler grid test, used in some places, is a simple, rough way of evaluating function in the optic pathways and macula. Subtle changes are not detected with this test. Distortion or missing individual letters and irregularities in

straight lines are subjective symptoms of minute changes in central visual field. Consultation by an ophthalmologist is necessary, even if visual acuity is unchanged.

Ocular motility and pupils

Disturbances in eye movements are followed especially in workers exposed to neurotoxins. Early signs are difficult to note because the change may be only in saccade accuracy and in reduction of saccade maximum velocity. They can be measured using quantitative eye-tracking equipment. Paresis of an extraocular muscle causes diplopia that increases when the head is turned in the direction of the paretic muscle. Convergence insufficiency and the presence of nystagmus should be noted, as well as pupillary reactions to light and convergence.

External and fundus examination

The physical examination in occupational healthcare should start with observation of the outer eye using a penlight. If the lid margins are erythematous, it is worth compressing the meibomian glands to see whether they produce clear oil, a thick whitish or yellowish mixture, or, sometimes, pus. The cornea's clarity and its epithelial surface can best be seen through a magnifying device. Fluorescent staining of the cornea is helpful and should be used frequently. The examination should also assess the depth of the anterior chamber after trauma, pupillary reactions to light, convergence and the red reflex. Also, obvious pathologic changes in the nerve head or macula should be noted.

Electrophysiologic and other laboratory testing

Laboratory testing is uncommon at the initial stage of an evaluation of potentially work-related ocular and visual symptoms. Infections of the lid margins may require bacterial culture in resistant cases. When exposure to a chemical is suspected, measurement of the chemical and its metabolites in body fluids (when available) may be performed. If exposure to neurotoxins presents a risk, photographic documentation of the retina or optic nerve head is indicated, even if color vision, visual acuity, and contrast sensitivity with best optical correction are normal.

CLASSIFICATION OF OPHTHALMOLOGIC DISORDERS

Disorders of the cornea and conjunctiva

Allergic conjunctivitis

Allergic conjunctivitis occurs in nearly all occupations and is caused by a long list of workplace and other environmental allergens. The clinical picture is often complicated by postinfection allergic reactions. When allergic conjunctivitis occurs in conjunction with systemic allergic manifestations, it becomes a part of a more extensive clinical evaluation related to the other affected organs, and is discussed in Chapters 19.2 (Asthma), 20.3 (Upper airway disorders), and 29 (Dermatologic disorders).

The role of work-related factors is the first question to be considered. If there are no known workplace antigens or irritants but symptoms worsen at work, dry eyes from low humidity in the workplace or decreased blinking during near work activities may be contributing to the symptoms.

Clinical features Symptoms of allergic conjunctivitis are not specific, i.e., mucous discharge, dryness, itching, burning, foreign body sensation, and tearing. Thin threads of mucus in the lower fornix are almost pathognomonic of an allergic reaction. Symptoms are caused by the changes in the quality of the tear layer overlying the cornea and conjunctiva. Mucus that normally protects the cornea as an even layer becomes thick and uneven. Small areas of the cornea remain unprotected and dry quickly. Nerve endings located in the superficial layers of the cornea are stretched and cause a foreign body sensation. It is important to explain the symptoms to the patient because the pain can be intense and the irregular tear film can blur vision transiently.

Diagnosis In making a diagnosis, it is important to make sure that there is no infection complicating the picture. Chronic blepharitis is common and must be treated before diagnostic testing for allergic conjunctivitis is possible. Treatment includes warm compresses and ointments, which contain hydrocortisone, gently rubbed on the lid margin in the evening. If thick cheesy discharge can be expressed from the meibomian glands the use of systemic tetracycline is considered.

Although blepharitis is not a work-related disease, nor does it necessarily disturb work, it should be treated because the chronic inflammation slowly closes the ducts of the meibomian glands. When this happens, the protective oil layer disappears, and the person is left with irritated eyes because of an abnormal tear layer. This in turn may lower the patient's resistance to mucous membrane irritants.

The case history is key in determining the likely etiology of allergic conjunctivitis. The type and duration of symptoms during working days and weekends should be recorded. Environmental factors should be noted, including ventilation, sources of irritating and allergic exposures, such as carpeting, cleaning agents, smoking, various chemicals used in the workplace (including those used by adjacent workers). Suspicion about workplace factors, as opposed to non-occupational environmental irritants or allergens, should heighten if the patient reports resolution of symptoms after a temporary change in the workplace, or during a vacation or sick leave. Through careful investigation, it may be possible to narrow the number of suspected allergens or irritants to a few. If the employee is entitled to compensation because of work-related disease, the diagnosis needs to be confirmed using exposure in well-controlled laboratory conditions.

Treatment Often a single specific allergen or irritant cannot be identified and empirical treatment is a reasonable approach to the problem. Reduction or prevention of

exposure to the allergen or irritant is preferred, but often this is not possible, or only to a certain extent. Uncertainty defining a single specific agent should not prevent appropriate reasonable interventions to reduce exposure to allergens. Allergic conjunctivitis is frequently treated symptomatically: cool compresses may provide relief in acute reactions, artificial tears are also helpful. In any treatment, avoidance of any preservatives in the medications used, especially benzalkonium chloride, is important. Topical mast-cell stabilizers and antihistamines are effective. Systemic antihistamines may be helpful, particularly when systemic allergic symptoms coexist. Because of the possibility of increased intraocular pressure, potentiation of herpetic or fungal keratitis, and of cataract formation, topical steroids should be prescribed only by an ophthalmologist.

Dry eye syndrome

Dry eye syndrome is common. Though not caused by the work, the symptoms are often worsened by low humidity at the workplace. Symptoms are similar to those of allergic conjunctivitis and generally worsen as the day goes on and with near vision tasks. Treatment with artificial tears is helpful. Use of a humidifier may be helpful in low humidity environments such as can occur with air-conditioning or forced hot air heating. Punctal plugs may be indicated if symptoms persist.

Other disorders of the conjunctiva and cornea

Irritation of the cornea resulting from chemicals, high or low temperature, dust, and other irritant exposures should be distinguished from an allergic reaction. Exposure to irritating agents may worsen an underlying allergic condition. Chemical irritation may lead to accumulation of fluid under the corneal epithelium, as is the case after exposure to triethylamine. Resultant minute subepithelial corneal vesicles, which can be seen only on microscopic examination, can cause blurred, hazy vision.⁷ Exposure to tertiary amines may cause corneal opacities.⁸

Ultraviolet (UV) light-induced keratoconjunctivitis is still a common problem, despite awareness of the condition and exposure risks. The symptoms first appear within hours after UV exposure and vary from a slight irritation to severe sloughing of the epithelium with intense pain and tearing. UV light is absorbed in the cornea and the lens, with only minimal amounts reaching the retina in normal eyes. Regular plastic lens materials absorb UV light. Those working in areas with potential UV exposure should use protective lenses with side shields. Glass lenses vary in their transmission of UV light and should have UV coating when needed.

UV burns of the cornea should be treated with sterile ointment, tight bandaging and pain medication. In addition to acute corneal damage, subacute damage may also occur from lower levels of exposure to UV light. Symptoms include dryness or foreign-body sensation in the late night and early morning hours. Chronic exposure may lead to thickening of the conjunctiva and changes in the corneal surface. Since it is often difficult to find an eye drop that

protects the irritated cornea well enough to make the patient symptom free, prevention measures are important.

Disorders of the lens

Some epidemiologic studies of workers with UV-B light exposure support the correlation between a high level of exposure to UV-B light and cortical and posterior subcapsular cataracts. Since most eyeglass materials effectively absorb UV light, workers who wear regular glasses are less exposed to environmental UV radiation outside their working hours than are those who do not use spectacles or sunglasses. Eyeglass use should thus be carefully evaluated in studies on work-related lens changes to correctly assess the role of exposure to UV radiation at work. Because there are so many contributing factors involved, the role of work-related radiation in cataracts is usually hard to prove.

Exposure to organic nitrate explosives has been reported to be associated with cataract formation.⁹ In the 1980s increased prevalence of cataracts was noted in glass and metal workers, felt to be related to short-wave infrared radiation.¹⁰

Disorders of the retina and optic pathways

Chemicals with potential for affecting retinal function are commonly used, but in most developed countries exposure is well below the levels that are toxic to the retina. Light-induced retinal damage can occur from phototoxicity or thermal injury.¹¹ The former is typically caused by short-wavelength light, the latter by visible and infrared light. Short-wavelength blue light also causes degradation in the image quality. This can be prevented by absorbing the blue light using special filter lenses. Blue light seems to have particularly unfavorable effects on the elderly retina.

Exposure to lasers can cause serious, permanent loss of central vision. The damage is usually caused by the energy absorption within the melanin granules of the retinal pigment epithelium. Laser burns are classified into four categories: Grade 1, retinal edema; Grade 2, retinal coagulation necrosis; Grade 3, necrosis with hemorrhage; and Grade 4, hemorrhage bursts into the vitreous. Small laser burns have clinical importance only when they occur in the center of the macula. It is advisable to take photographs of the maculae of workers at risk and to record any lesions in the retinas of workers prior to working in areas where there is risk of exposure, to avoid confusion with future laser light-induced scars. Extended exposure to very low-level laser energy may cause subtle damage to the retina; this has been reported in ophthalmologic surgeons who perform laser coagulations regularly over a period of several years. The damage is measurable only with extremely sensitive techniques and does not lead to functional losses.¹²

A number of solvents have been reported to cause altered color vision, most commonly in the blue-yellow axis, even at relatively low levels of exposure. Impaired color vision has been reported following chronic exposure to styrene, toluene, perchloroethylene, n-hexane, carbon disulfide and solvent mixtures.¹³⁻¹⁷ Carbon disulfide has also been

reported to cause changes in the retinal capillary bed resembling diabetic retinopathy.^{18,19} In one follow-up study, such changes persisted four years after exposure had ceased.¹⁸

Eye strain and visual ergonomics

Many occupations have become more and more office based, using computers instead of manual labor. Therefore visual ergonomics have become important, especially in planning the working conditions of presbyopic employees. Their spectacles need to be fitted so that the reading addition in the lens is placed at a height that corresponds to the direction used in reading the computer screen and other materials. Presbyopic technicians, librarians, nurses, etc. – all employees who have need to read while looking upwards – need specially fitted glasses in order to see properly.

Symptoms of eyestrain include sore eyes, headaches, and fatigue, often associated with intensive close work, including reading and use of video display terminals.^{20–23} Environmental and ergonomic factors are important contributors. Poor contrast or small text may force workers to function too close to their visual threshold.

If the direction of gaze is too high, blinking decreases, and dry spots appear now and then on the cornea, causing discomfort. Computer tasks may require long periods of intensive attentional search, leading to fatigue. Employees working under pressure may feel tense and fail to relax neck, facial, and eye muscles for micropauses (2 to 5 seconds).

Poor placement of a video display terminal may cause glare from a window or artificial lighting (Fig. 20.1.1a). Elevated placement of a video display terminal may require the worker to look up, causing neck muscle tension. All visual target areas should be placed so that the head posture is comfortable and nodding is avoided (Fig. 20.1.1b). This usually means that surfaces to be read are placed lower in the visual field. When visual targets are placed lower, not only is the head posture better, but also eye irritation becomes less common as the lid aperture becomes smaller, blinking more frequent, and thus the tear layer on the cornea more stable. Existing office furniture seldom makes good visual ergonomics possible.

Visual comfort requires pleasant luminance levels. Illumination should be adjustable at each workstation. Glare sources should be avoided, as glare degrades visual function. Workers with eyestrain should also have their eyes checked for a change in refractive error or the need for reading glasses. Eyestrain increases with increased duration

of time working at a video display terminal, and the near point of accommodation increases and convergence decreases in parallel with these symptoms.²⁰

Shared workstations need to be adjustable so that workers of different heights may be positioned comfortably for the task. Nowadays, most workstations require looking at several distances. Regular bifocal glasses with small reading additions may cause an uncomfortable neck posture if the screen is placed too high. From the large selection of progressive lenses, only lenses with a large area for near work and a broad enough progression area should be fitted for office work.

An intelligent choice of lenses is possible only when the structure of work is described clearly enough to the ophthalmologist or optometrist. This means that the workers need to have charts to mark their different working distances. When the new glasses are used at work, fine-tuning of distances and heights of visual target areas is often needed before head posture and movements are comfortable – glasses need to fit the work and the work must be arranged to fit the glasses. When both adjustments are done, even demanding office work is comfortable while the worker uses regular progressive lenses.

Accidents

The CDC indicates that eye injuries are a leading cause of work-related diseases and injuries in the United States.²⁴ Between 5% and 19% of all industrial accidents involve eye injuries.²⁵ NIOSH estimates that approximately 900,000 occupational eye injuries occurred in the United States in 1983, 84% of which were considered minor. The incidence of occupational injuries that lead to temporary or permanent visual disability approaches 70,000 workers each year,¹ and many of these are preventable. Appropriate eye protection is commonly not worn. According to the National Eye Trauma System Registry, only 1.5% were wearing safety glasses.²⁶ In a West Virginia study, a rate of 567 compensable ocular injuries per 100,000 workers was reported, most injuries occurring in the areas of agriculture, construction, and manufacturing, with a large predilection for males.²⁷ Time lost from work varies with the severity and type of injury.

Superficial foreign bodies

Superficial foreign bodies are the most commonly occurring work-related eye injuries.²⁸ A foreign body may cause

Figure 20.1.1 Work at VDU with poor (a) and good (b) visual ergonomics. (a) Large window behind the worker makes the text on the screen nearly impossible to read. (b) Workstation for office work is designed to fit presbyopic as well as younger workers. The computer screens are placed low and at a distance that makes shifting of gaze from one screen to another easy. Regular progressive, multifocal lenses can be fitted to function well in this kind of workstation.

a corneal or conjunctival abrasion or become embedded in the cornea or conjunctiva. Fluorescein stains the damaged epithelium and helps to locate the foreign body. After it is removed, antibiotic ointment is applied. Corneal abrasions usually heal within 48 hours but it is wise to use ointment nightly for a week.

Complications of corneal abrasions include infection and recurrent erosions. Infection should be suspected if a discharge develops and immediate referral to an ophthalmologist is required. Recurrent erosion is a common complication and occurs when the basement membrane that underlies the superficial epithelium of the cornea is disrupted. This prevents firm adherence of the corneal epithelium to the basement membrane and the corneal epithelium then breaks down after minor trauma, such as rubbing of the eye. Therefore it is wise to cover the eye with a patch for the first few nights.

Penetrating ocular foreign bodies

If a penetrating injury is suspected, the eye should be covered with a sterile patch when the patient is sent to the emergency clinic. No medications are used. Though only representing a small proportion of work-related eye injuries, penetrating eye injuries represent a substantial portion of work-related permanent severe vision loss.²⁸ The incidence of occupational injuries leading to temporary or permanent visual disability approaches 70,000 workers each year.

Safety should be an integral part of vocational training. According to the National Eye Trauma System Registry, 2939 penetrating eye injuries were reported between 1985 and 1991. Of these, 21% occurred at the workplace, fewer than 10% of the injured were wearing eyeglasses or goggles, and only 1.5% were wearing safety glasses.²⁶ Comprehensive workplace strategies to prevent eye injuries are essential, including workplace modifications, use of appropriate personal protective equipment, worker education, and appropriate trained personnel. Prevention of traumatic injuries is discussed further in Chapter 31 (Traumatic Injuries).

Chemical injuries

Though less frequent than mechanical eye injuries, chemical injuries may occur in laboratory, agricultural, or industrial settings and represent a significant threat to vision. Numerous chemicals can cause serious ocular injury, especially strong acids and bases. Immediate irrigation is essential to minimize permanent vision loss. Therefore bottles with irrigation fluid must be near all workstations where dangerous chemicals are used and the workers must be trained to find and open the bottle even when they cannot open their eyes. Irrigation is continued until the worker is brought to the health station or the ambulance arrives. The full extent of the injury may not be apparent at the time of the initial assessment. Irrigation is continued while transporting the patient to an emergency room for further treatment.

Alkali burns tend to be more caustic and thus more damaging than acid injuries. However, both have the potential to cause severe vision loss. Prevention of acci-

dents is important. Protective eyewear should always be worn when handling corrosive or caustic fluids and gases, preferably behind a protecting window or screen.

Electromagnetic radiation

Visible, ultraviolet, infrared, microwave, and laser energy have all been implicated in work-related eye injuries. Visible and ultraviolet wavelengths have been associated with pterygium and macular degeneration. Infrared exposure in glass and metal workers has been associated with cataract formation.

Microwaves may be associated with cataract formation. In workplaces where microwave exposure is possible and where maximum exposure is kept below the World Health Organization exposure limit of 10 mW/cm²/0.1 hour, no cataractous changes have been found. The various lasers used today in industry pose different risks of morbidity to the eye depending on wavelength and type of laser. Workers should have an eye examination and photographic documentation of any eye pathology prior to working in places where there is risk of exposure to laser. Protective shields or goggles need to be used.

Prevention

Prevention is the most important consideration in occupational eye disorders and damage to the visual pathways. According to the Bureau of Labor statistics, 60% of workers who suffer eye injuries did not wear eye protection at the time of the injury; 40% of those who wore protection wore the wrong kind of protection. Appropriate eye protection is probably the most important single intervention to decrease the incidence of eye injury in workplaces. Eye disorders related to exposure to allergens and irritating substances, chemicals and radiation are preventable.

Recommendations to prevent eye injuries and disorders at work include: (1) making an assessment of operations and exposures that pose a risk; (2) checking for visual problems in routine health exams; (3) reducing exposures by requiring the use of appropriate protective eyewear, and worksite and engineering modifications; (4) planning for eye emergencies; (5) reviewing written procedures and strategies for preventing and dealing with eye injuries. These efforts should minimize the number of eye injuries and disorders that occur in the worksite. Similarly, all neurotoxic chemicals in the environment should be known and carefully avoided in the workplace.

The other important area in prevention of work-related vision and ergonomic problems is better planning of workstations and improvement in the fitting and quality of glasses of presbyopic office workers. With good planning of working posture and glasses, neck and lower back problems in office workers are fully preventable. At the same time, working capacity improves.

SUMMARY

There are many etiologies for occupational eye disorders including injuries, exposures, inappropriate spectacle correc-

tion for the task, and ergonomic factors. Sensitivity to these factors may help avoid occupational eye disorders and damage to visual pathways. An important factor in decreasing the incidence of occupationally related eye pathology is the use of eye protection in the workplace. The ophthalmologic effects of potentially neurotoxic chemicals are a more difficult problem. Each year thousands of new chemicals are introduced with unknown effects on the eyes or visual pathways. These potentially harmful chemicals warrant further investigation.

20.2 Occupational Hearing Loss

Peter M Rabinowitz, Thomas S Rees

‘Artillerymen, blacksmiths, and the blasters in mines often become deaf, and this seems to be dependent upon defective energy of the acoustic nerve, from having been so frequently over excited.’¹

INTRODUCTION

Noise-induced hearing loss (NIHL) is the second most common form of acquired hearing loss, after age-related loss (presbycusis),² and has long been recognized as a problem in occupations associated with prominent noise. Noise is the most pervasive hazardous agent in the workplace. In 1981, there were an estimated 9 million US workers exposed to hazardous occupational noise levels.³ Despite job loss in noisy industries and the widespread institution of hearing conservation programs, NIHL is currently one of the most common occupational diseases and the second most frequently self-reported occupational injury. NIHL is listed as one of the eight most critical occupational diseases and injuries requiring research and development activities within the framework of the National Occupational Research Agenda (NORA).

Even when away from the workplace, people have exposure to hazardous noise levels from recreational, social, and community sources⁴ (see Chapter 35). Although NIHL is permanent, irreversible, and prevalent,⁵ it is preventable.⁶ In addition to the major problem of NIHL, the ear is susceptible to other environmental factors, both physical and chemical, that are of potential clinical significance. The most important of these are summarized in Table 20.2.1. While a wide range of factors can affect hearing, this chapter will focus on the effects of excessive noise on the auditory system.

Mechanisms of hearing

The ear is a complex organ, capable of transforming airborne sound waves into mechanical energy, transferring this mechanical energy into electrochemical signals and then to neural impulses, which are processed as auditory information. The external ear collects sound waves and funnels them through the 2.5–3 cm long external ear canal to the tympanic membrane. The tympanic membrane, approximately 9 mm in diameter, transforms the air-borne sound waves into mechanical vibrations, which are transmitted through the ossicular chain of the middle ear (malleus, incus, and stapes).

The mechanical transmission of energy through the ossicular chain is mediated by the tensor tympani and stapedius muscles, which act as a damper for excessive sound energy. The stapes, the smallest bone in the body, rests in the oval window of the cochlea (inner ear). The transduction of mechanical energy to electrochemical neural potentials takes place in the cochlea. Physical displacement of the oval window sends a fluid wave through the cochlea. There are approximately 16,000 sensory hair cells in the cochlea, asso-

ciated with approximately 31,000 sensory nerve fibers. The hair cells are stimulated by the fluid wave within the cochlea and nerve impulses are then transmitted via the 8th cranial nerve to the auditory centers of the brain.

CLINICAL EVALUATION OF HEARING LOSS

Otologic evaluation

It is the healthcare provider’s responsibility to determine whether or not the worker has incurred an occupationally related hearing loss. This opinion can only be formulated after obtaining a detailed work and health history, complete otologic examination, audiologic examination, and, if indicated, specialized testing.

The history should include age, family history, ototoxic drug use, presence of tinnitus, vestibular symptoms, noise exposure (occupational and non-occupational), neurologic symptoms, aural fullness, ear pain, ear discharge, as well as hearing loss onset, progression, fluctuation, and symmetry. Past and present occupational and non-occupational noise exposure must be documented. The type of noise exposure and duration should be determined. The use of hearing protection devices should also be documented. The patient should be questioned regarding non-occupational noise exposure including use of firearms, power tools, chain saws, snowmobiles, motorcycles, small aircraft noise, and other sources. Other possible causes of sensorineural hearing loss including ototoxic drugs, central nervous system infections, radiation to the head and neck, head injury, and family history should be explored.

The healthcare provider should ideally seek information about the work environment, such as noise levels, characteristics of the noise, and audiograms taken prior to employment, periodically during employment, and at the time of termination of employment. Unfortunately, such information is often not available, thus requiring the examiner to depend on the patient’s self-report of the noise exposure. It is estimated that workers in an 85 dB environment will have to speak loudly, while those in 85–90 dB will have to shout to communicate at arm’s length. As the surrounding noise reaches 95 dB, communication only occurs with shouting, even if the workers stand next to each other. Certain environments are known to be inherently very noisy, such as saw mill or chain saw work, metal chipping in foundries, and various construction jobs. Questionnaires can be quite helpful in documenting details of the otologic history and ensuring that important questions are not omitted.

The physical examination should include a head and neck examination, with special attention to the external ear and tympanic membrane. The mobility of the tympanic membrane is assessed with pneu-moto-scopy. Evaluation of the cranial nerves and cerebellar function should be included in patients with suspected neurologic

Disorder	Causes
Noise-induced hearing loss	Chronic noise exposure
Noise-induced tinnitus	
Acoustic trauma	Sudden intense noise or excessive pressure
Ototoxicity due to chemicals including medications	Organic solvents, heavy metals, carbon monoxide, NSAIDs, ASA, cisplatin, aminoglycosides, furosemide
Damage to auditory cortex	Neurotoxins
Ear disorders due to diving	Noise, barotrauma, air embolism
Radiation-induced damage	Radiation to head and neck
Trauma to external and middle ear	Slag burns, foreign objects

disease. Laboratory and radiologic studies are useful in the evaluation of some otologic conditions.

Audiologic evaluation

Basic evaluation

The clinical assessment of hearing loss includes the completion of an audiogram (Fig. 20.2.1). The frequency scale along the abscissa is measured in hertz (Hz) for the octave frequencies of 250 Hz through 8000 Hz. The most critical frequencies for speech reception and understanding are 500, 1000, 2000, and 3000 Hz; these frequencies are used in the AMA computation of binaural hearing impairment (Table 20.2.2), as will be discussed later.

The intensity scale on the ordinate of the audiogram is measured in decibels (dB), ranging from a very faint hearing level (HL) of -10 dB up to a very loud level of 110 dB HL. Sensitivity thresholds are obtained for each frequency,

	Hertz (Hz)						
	500	1000	2000	3000	4000	6000	8000
Right ear (dB)	25	35	35	45	50	60	45
Left ear (dB)	25	35	40	50	60	70	50
1. Unilateral impairment: (Average dB at 500, 1000, 2000, 3000 Hz) – 25 dB (low fence) \times 1.5% = Percentage of unilateral impairment Right ear = $(25 + 35 + 35 + 45 \div 4) - 25 \times 1.5\% = 15\%$ Left ear = $(25 + 35 + 40 + 50 \div 4) - 25 \times 1.5\% = 18.8\%$ 2. Bilateral impairment: (Percentage of unilateral impairment in better ear \times 5) + (Percentage of unilateral impairment in poorer ear) \div 6 = Percentage of bilateral impairment $(15 \times 5) + (18.8\%) \div 6 = 15.6\%$							

Table 20.2.2 Sample audiogram and calculation of impairment (AAO-79 method)

and for each ear separately using earphones. This air conduction (AC) testing measures the responsiveness of the entire auditory system, from the ear canal through the middle ear to the cochlea and associated neural pathways to the brain; any loss by air conduction testing may be due to a disorder anywhere in the entire auditory system.

The use of pure tone bone conduction (BC) audiometry defines the general anatomic location of the hearing disorder, since sound transmission by bone conduction bypasses the outer and middle ear. An oscillator is placed behind the ear to be tested and sensitivity thresholds are obtained for the frequencies 250 Hz through 4000 Hz.

Many factors can affect the quality of audiometric data. Audiometric equipment requires annual electroacoustic calibration and routine biologic checks. The testing environment necessitates a very quiet room without excessive ambient noise levels per ANSI S31-1999. The competence and experience of the test examiner are of paramount importance. While certified audiometric technicians can adequately perform routine hearing tests, certified clinical audiologists should be used for difficult cases as well as all compensation claims.

In addition to pure tone threshold measurements, the basic audiologic evaluation includes the measurement of threshold sensitivity for speech and the assessment of word recognition abilities. The speech reception threshold (SRT) test serves primarily as a reliability check on the pure tone threshold levels. Familiar two-syllable words are presented to each ear separately through earphones and the intensity level at which 50% of the words are correctly repeated is defined as the SRT. The SRT should agree within ± 10 dB with the pure tone average (PTA) threshold levels at 500, 1000, and 2000 Hz. When the SRT and PTA do not agree, an exaggerated hearing loss should be considered. The SRT is most often obtained at a softer dB level than the PTA in persons who exaggerate their hearing loss. Careful re-instruction and the use of modified test procedures are warranted in such cases, in an effort to obtain a valid test.

A hearing impairment may be reflected not only in a sensitivity loss but also in impairment in the ability to

Pure tone average (dB HL)	Classification	Effects on speech understanding
0–25	Normal	No significant difficulty
25–40	Mild	Difficulty with soft speech
40–55	Moderate	Difficulty with normal speech
55–70	Moderately severe	Difficulty with loud speech
70–90	Severe	Can only understand shouted or amplified speech
90–110	Profound	Usually cannot understand even amplified speech

Table 20.2.3 An example of a classification system for degree of hearing loss

understand speech, even when speech is sufficiently loud. The assessment of word recognition (speech discrimination) analyzes the patient's ability to understand speech when presented at comfortably loud levels; it is not a threshold or sensitivity test. Standardized lists of 25–50 single-syllable words (i.e., darn, art, chief, etc.) are presented to each ear separately at comfortably loud intensity levels. These words are repeated back by the patient and the percentage of correct responses is the word recognition score. Scores may range from 0% to 100%; scores of 90–100% are considered normal.

Special evaluation

Additional audiologic tests are sometimes needed in hearing assessment; these tests are used to rule out exaggerated hearing loss or to define the site of the hearing loss in the auditory system. If concern exists for an embellished response, additional tests may be utilized to identify true organic hearing levels. The use of tympanometry provides information regarding the mobility of the middle ear system. This is an objective test procedure, which measures the middle ear pressure, the ear canal volume and the mobility of the tympanic membrane/middle ear system. Since NIHL is due to sensorineural pathology, abnormal tympanometric results may suggest middle ear (conductive) involvement contributing to the patient's hearing loss.

Electrophysiologic measurements, such as brainstem auditory evoked potentials (BAEPs; also known as auditory brainstem response, ABR), can help in determining the general degree of a hearing loss without requiring a subjective response from an individual. Electrocochleography measures the electrophysiologic activity originating within the cochlea and can supplement information provided by BAEP/ABR audiometry, but is less commonly used in clinical practice.

Transient and distortion product otoacoustic emissions (OAEs) is another objective measure of hearing function that is gaining wider acceptance. The outer hair cells of a healthy ear emit faint sounds (echoes) when moderate-level clicks or tones are presented to the ear. Robust OAEs are usually obtained in ears with thresholds less than or equal to 30 dB HL. Voluntary thresholds in excess of 30 dB HL with normal OAEs suggest exaggerated hearing loss. While OAEs do not quantify the exact amount of hearing loss, they do provide the clinician with a means of validating the voluntary audiometric results.

The evaluation of asymmetric sensorineural hearing loss, or clinical suspicion of 8th nerve or central auditory

involvement, requires special audiologic procedures to define the site of auditory impairment. The evaluation of the integrity of the stapedius (acoustic) reflex by impedance measurement is a helpful test in differentiating between cochlear and 8th nerve involvement. BAEPs are also used to differentiate cochlear involvement from 8th nerve involvement.

Audiometric test interpretation

Degree of hearing loss

The results obtained from the air conduction evaluation provide quantitative information as to the amount of hearing loss. Classification systems have been devised in an effort to relate the amount of air conduction hearing loss to the expected degree of handicap imposed by a hearing loss. Such systems typically use the PTA to estimate various hearing loss categories and the expected effects of the loss upon speech understanding. An example of such a classification system is shown in Table 20.2.3.

Further discussion of the interpretation of the degree of hearing loss will be presented in the section dealing with hearing loss impairment assessment.

Location of auditory impairment

The general anatomic area of the hearing loss can be determined by comparing the air conduction and bone conduction thresholds. A conductive hearing loss is present when air conduction results demonstrate a hearing loss but bone conduction results are within the normal range (Fig. 20.2.2). The etiology of the conductive loss cannot be determined by the audiogram alone, as any obstruction in the sound-conducting mechanism of the ear, from the external canal (e.g., cerumen impaction, foreign body) through the middle ear (e.g., middle ear effusion, otosclerosis), may be the cause of the conductive hearing loss.

When a hearing loss is detected by air conduction and similarly by bone conduction, a sensorineural hearing loss is present. The hearing disorder could be located in the cochlea, the associated neural pathways, or in both sensory and neural auditory system (Fig. 20.2.3). NIHL presents as a sensorineural hearing loss. A loss in hearing sensitivity for bone conduction with a greater loss by air conduction represents a mixed hearing loss (Fig. 20.2.4). Correction of the conductive component by medical or surgical treatment should result in a sensorineural hearing loss alone, as reflected by the bone conduction thresholds.

Noise-induced hearing loss (NIHL)

Clinical effects

In general, NIHL is related to significant sensory cell loss within the cochlea. The mechanism by which the sensory cells are lost is probably a combination of physical and metabolic stress. In the case of temporary threshold shifts, metabolic exhaustion of the sensory hair cells is likely. A growing body of literature suggests that reactive oxygen species produced in response to noise overexposure play a

role in this process.⁷ Nerve fiber degeneration also appears to take place secondary to the loss of the inner hair cells of the cochlea.

Early NIHL in the 3000–4000 Hz region of the audiogram correlates with hair cell degeneration in the region of the organ of Corti, located near the base of the cochlea. Sensory and neural elements are progressively destroyed in the basal and more apical regions following continued noise exposure, with resultant hearing deterioration in the adjacent low and high frequency ranges.

Sounds of sufficient intensity and duration will damage the ear and result in temporary or permanent hearing impairment. The hearing loss may range from mild to severe and may also be accompanied by tinnitus. Tinnitus can be experienced in many forms, such as ringing, hissing, buzzing or clicking, etc. It can be disabling, dramatically affecting and diminishing the quality of life. It is estimated that as many as 36 million Americans have tinnitus, with 7 million experiencing severe tinnitus.⁸ The effects of noise on hearing can be divided into several categories.

1. *Acoustic trauma* is the sudden loss of hearing caused by an intense single incident noise blast or explosion. Most cases of acoustic trauma are caused by impulses from explosions, such as bombs, blasts, and gunfire. There have been reports recently of airbag-induced otologic injuries, characterized by a variety of otologic pathologies, including sensorineural hearing loss, conductive hearing loss, mixed hearing loss, tinnitus, and disequilibrium.⁹ Due to the very high sound intensity, the auditory system may be damaged both in the middle ear and the cochlea, since the acoustic insult may exceed the physiologic protective capabilities of the auditory system. In addition to tympanic membrane rupture, the middle ear ossicles may become dislocated, causing a conductive hearing loss. A

sensorineural hearing loss can often occur due to direct mechanical injury to the sensory cells of the cochlea, or fistulas between the inner and middle ear. Acoustic trauma can produce hearing losses that are more severe than seen with NIHL, especially in the low and middle frequencies. In addition to immediate hearing loss, affected individuals may also complain of vertigo, tinnitus, and pain. The injury may be unilateral or bilateral, depending upon the direction of the blast. Sensorineural hearing loss from acoustic trauma may exhibit some recovery from initial levels; patients need to be followed for 4 to 6 months to determine if the hearing loss is permanent. The precipitating episode is usually very dramatic, with onset of hearing loss apparent to the patient.

2. *Temporary threshold shift (TTS)* is a temporary hearing decrease following noise exposure. Following loud noise exposure, the individual reports a high frequency tinnitus, a feeling of aural fullness, and a sensation of muffled hearing. These symptoms gradually resolve after removal from the noise, and hearing recovers to baseline within hours. With repeated exposure to the offending noise, hearing recovery may be slower and may not be complete. If the hearing recovery is incomplete, a permanent threshold shift has occurred. The industrial worker who is exposed to loud noise and has TTS after each workday and on weekends is a typical example. The hearing usually recovers initially; however, repeated noise exposures result in diminished hearing recovery and permanent NIHL.

3. *Permanent threshold shift (PTS)* is a persistent and irreversible hearing decrease following repeated exposures to loud noise. It is the result of an accumulation of noise exposures repeated on a regular basis over a number of years. It is usually bilaterally symmetric and often accompanied by high frequency ringing tinnitus. While persons who experience acoustic trauma can define the exact time of onset of the hearing loss, those with PTS cannot report a time of onset, since the hearing loss is insidious and gradually worsens over years. PTS usually occurs without the affected individual being aware of it until the hearing loss progresses to involve the critical frequencies for speech understanding. Since PTS is permanent, it is referred to as a NIHL.

Clinical presentation of NIHL

Noise over-exposure typically causes a high frequency hearing loss. The earliest effects tend to occur in the regions around 4000 Hz, with recovery at higher frequencies. This creates a characteristic 'notching' of the audiogram.¹⁰ The exact location of the 'notch' depends on multiple factors including the frequency of the damaging noise, the shape of the ear canal, and cochlear sensitivity.¹¹ This 'notching' is in contrast to age-related hearing loss (presbycusis), which also produces high frequency hearing loss but in a down-sloping pattern without recovery at 8000 Hz. Therefore, in early noise-induced hearing loss, the average hearing thresholds at 500, 1000, and 2000 Hz are better than the average at 3000, 4000, and 6000, and the hearing level at 8000 Hz is usually better than the deepest part of the 'notch'.

Figure 20.2.5: An audiogram showing the progression of noise-induced hearing loss, from a mild high-frequency impairment to a severe hearing impairment.

Early NIHL, producing a mild sensorineural loss in the 4000–6000 Hz region, has little effect upon the individual's ability to understand speech. However, if the hearing impairment extends to the important speech frequencies at and below 3000 Hz, the individual will begin to experience increasingly greater difficulties in speech understanding. Continued progression of NIHL due to cumulative effects of loud noise exposure results in a more severe hearing loss in the 3000–6000 Hz area, and may extend into the middle and lower audiometric frequencies (Fig. 20.2.5). This may reduce the prominence of the 'notch' and, in conjunction with the progressive effect of aging, make it difficult to distinguish between age-related and noise-induced loss without access to previous audiograms.

NIHL initially affects the perception of the high frequency consonant sounds (such as s, f, th, sh). Speech may seem to be garbled and indistinct. The presence of competing background noises and voices, such as in restaurants and groups, further reduces speech understanding. Persons with NIHL typically complain of being able 'to hear but not understand speech'. Such difficulties in speech understanding increase with the spread of the hearing impairment into the frequencies of 500 through 3000 Hz. While initially many persons with noise-induced hearing loss may not seek help for their condition,¹² the difficulties in speech understanding can lead to fatigue, anxiety, stress, and reduced quality of life. The eventual result of progressive hearing loss is social withdrawal and isolation.¹³ Other associated conditions may be depression and increased risk of accidents.¹⁴

Progression of hearing loss after removal from noise

Recent reports from audiometric examination of individuals in the Framingham Study suggest that individuals

with notched audiograms, presumably due to noise exposure, may continue to have progression of these notches later in life.¹⁵ However, there is no firm evidence that previously noise-exposed ears are either more sensitive to future noise exposure or that hearing loss due to noise progresses once the exposure to noise is discontinued. It is clear that NIHL can interact with presbycusis, exacerbating age-related effects.

Asymmetric hearing loss

When an individual has incurred greater noise exposure in one ear than in the other ear, the audiogram may show an asymmetry in hearing threshold levels for the two ears. When evaluating asymmetric sensorineural hearing loss, it is necessary to determine whether or not the working environment was such that the working conditions exposed one ear to more noise than the other ear. For example, truck or tractor drivers may suffer greater hearing loss in the ear closest to the engine exhaust, and a worker whose ear is facing a particularly offending noise source during work may also experience greater hearing loss in the ear closest to the noise source. Most indoor factory environments, however, are highly reverberant so that one ear rarely receives significantly more noise than the other.

The examiner must also be aware that there are various non-occupational noise sources that typically result in hearing asymmetry. The most common cause of asymmetric NIHL relates to the firearm user who typically demonstrates a greater hearing loss in the ear contralateral to the trigger finger. That is, right-handed hunters most often demonstrate a greater high frequency NIHL in the left ear. Of particular concern in the evaluation of asymmetric hearing loss are those conditions that reflect non-NIHL otologic pathology. Etiologies such as Meniere's disease, sudden idiopathic sensorineural hearing loss, and acoustic neuromas most often present unilaterally and require otologic evaluation. Such is also the case with allied otologic asymmetric complaints such as unilateral tinnitus, unilateral aural fullness, and vestibular symptoms.

Tinnitus

The problem of assessing injury and damages without the assistance of objective standards is particularly challenging where claims of tinnitus are included. Some compensation agencies allow a percent rating for the presence of tinnitus, in addition to the amount of hearing impairment. The lack of reliability of measurement of tinnitus and the prevalence of tinnitus in the population compounds the problem. Glorig has described a guideline used by the Veterans Administration that may be useful to experts in forming opinions as to the clinical significance of tinnitus complaints.¹⁶ These include criteria that the treatment history must include one or more attempts to alleviate the perceived disturbance by medication, prosthetic management, or psychiatric intervention, and that the complaint of tinnitus must be supported by statements from family or significant others.

Comparing a patient's tinnitus to audiometric tones or noises (tinnitus matching) may be helpful in assessing a

complaint of tinnitus. Noise-induced tinnitus is usually at or above 3000 Hz, or at least no more than an octave below the noise-affected frequencies. Its loudness is typically only 3–5 dB and very rarely more than 15 dB above audiometric threshold, and usually varies by no more than 2 dB on repeat audiometric measurements within a single session. Tinnitus loudness is not a reliable indicator of annoyance or disability, and tinnitus matching tests have potential value only in documenting the existence of tinnitus, not its severity.

Susceptibility to NIHL

The development of NIHL is dependent upon a number of factors, including the intensity of the noise, the length of time a person is exposed to the noise, and individual susceptibility. The more intense the noise, the more likely it will produce hearing loss. In addition, the longer a person is exposed to a particular noise, the greater the probability of injury to the auditory system. A long-standing observation in the field of NIHL has been that some individuals' ears are more easily damaged by noise than others. There are some persons with 'tough' ears whose hearing seems to withstand prolonged loud noise levels and others with relatively 'tender' ears that develop hearing loss greater than the norm. There is a broad range of individual differences in sensitivity to any given noise exposure and individual varying susceptibility to NIHL.

It is commonly assumed that variability in susceptibility is a manifestation of biologic factors that are unique to each individual. Some have proposed that imperfections in the physical characteristics of the cochlea and variability in cochlear structure contribute to the susceptibility. Recent research has examined the role of antioxidant status in mediating susceptibility.¹⁷ A number of potentially important variables have been examined, including age, gender, cardiovascular disease, race, previous inner ear damage, efficiency of the acoustic reflex, smoking, and pigmentation. At present, the data are inconclusive in specifying variables related to susceptibility.

A relationship between TTS and PTS has been sought for many years, since it has been hoped that the amount of TTS could be used to predict the risk of PTS. Unfortunately, the relationship between TTS and PTS is by no means clear, since no straightforward relationship between TTS and PTS has been delineated. This issue of individual susceptibility is a strong reason for annual audiometric monitoring of all employees in loud noise environments. Those persons who experience hearing deterioration require greater noise protection and possible change of work location to a less hazardous noise environment.

Audiometric surveillance for NIHL

The OSHA hearing conservation amendment mandates audiometric surveillance of workers who are exposed to noise levels equal to or exceeding 85 dBA on an 8-hour time-weighted average (TWA).¹⁸ The standard requires testing when beginning work in a noisy area, and yearly testing thereafter. While this routine audiometric testing can be performed by an audiometric technician who has completed the necessary education and training requirements, any

individual who needs to be referred for additional testing should be evaluated by an audiologist. In the US, audiometric technicians are certified by the Council of Accreditation in Occupational Hearing Conservation (CAOHC); and audiologists are certified by the American Speech-Language-Hearing Association (ASHA).

Surveillance audiograms should be performed in a sound-controlled acoustic environment. The OSHA standard provides guidelines for acceptable ambient noise levels inside a testing booth; slightly more stringent criteria are listed in the ANSI standard S3.1 1977. For the baseline audiogram, the individual should not have been exposed to loud noise for at least 16 hours prior to testing, to avoid temporary threshold shifts. Subsequent surveillance tests, however, do not require the noise-free interval. OSHA regulations require testing at the frequencies of 500, 1000, 2000, 3000, 4000 and 6000 Hz, but it is advisable to test at 8000 Hz as well to look for a 'recovery pattern' at that frequency. The results of the periodic audiogram should be compared to the baseline. If the employee's test shows a 'shift' from baseline in excess of 10 dB for the average hearing level at 2000, 3000, and 4000 Hz in either ear (a '10 dB shift' or 'standard threshold shift'), a retest may be performed within 30 days. If the shift persists, the employee must be informed in writing within 21 days, fitted with hearing protectors if not already using them, refitted and counseled if already using protectors, and referred for a clinical audiologic evaluation and/or otologic evaluation if appropriate. While OSHA requires use of the 10dB shift criteria, other shift criteria have been proposed. These include NIOSH '10 dB twice', or a shift from baseline of 15 dB at any frequency on two subsequent tests.¹⁹

Although OSHA has not recommended specific otologic referral criteria, the American Academy of Otolaryngology – Head and Neck Surgery (AAO/HNS) has previously proposed criteria for referral of individuals to an otolaryngologist.²⁰

1. Baseline audiogram
 - a. Average hearing levels at 500, 1000, 2000, and 3000 Hz greater than 25 dB in either ear.
 - b. Difference in average hearing level between the better and poorer ears of more than 15 dB at 500, 1000, and 2000 Hz, or more than 30 dB at 3000, 4000, and 6000 Hz.
2. Periodic audiograms
 - a. Change for the worse in average hearing level in either ear compared to the baseline audiogram of more than 15 dB at 500, 1000, and 2000, or more than 20 dB at 3000, 4000, and 6000 Hz.

Other criteria that may indicate a need for physician referral include ear pain, drainage, dizziness, severe persistent tinnitus, fluctuating or rapidly progressive hearing loss, or a presence of accumulated cerumen or other foreign material within the ear canal. If the employee presents with other more non-specific complaints, including aural fullness or discomfort, or if audiometric findings are inconsistent, an otolaryngology referral may also be prudent.

Age correction of the periodic audiogram may be performed under the OSHA standard to allow for the

contribution of aging to the change in hearing level. The standard provides an appendix of age correction values. The process of applying population-derived norms to an individual audiogram is a method of indirect standardization, and allows for comparison of hearing loss rates between different worker populations. Age correction, however, has been criticized as decreasing the sensitivity of medical surveillance,¹⁹ and some hearing conservation programs such as that of the US Air Force do not use an age correction.

Treatment

While conductive hearing losses are often amenable to medical or surgical treatments, hearing loss due to the effects of prolonged loud noise exposure causes a permanent and irreversible sensorineural hearing impairment, for which no specific treatment is currently available. As is the case with most types of sensorineural hearing impairments, the most common and effective remediation is hearing aid amplification. Hearing aids are simply miniature personal amplifiers, and are chosen on the basis of responses shaped to provide the necessary amplification for the frequencies affected by the hearing loss. Persons with high frequency hearing losses are fitted with hearing aids incorporating only high frequency amplification. Most hearing aids are custom made to fit within the ear and are individually programmed for the particular hearing loss.

Persons requiring hearing aids should be referred to certified dispensing audiologists, as they are the professionals who possess the necessary expertise to fit and counsel the hearing-impaired person. If a hearing loss is related to a compensation claim, hearing aid rehabilitation should be included in any settlement. Since hearing aids have a limited life expectancy (4–6 years), compensation for future hearing aids should also be considered in compensation settlements. In addition, devices such as amplified telephones, infrared TV transmitters, and other personal assistive listening devices should be considered for the hearing-impaired individual.

Accommodation of the hearing-impaired worker

If an employee is determined to have a significant hearing loss at the time of employment or subsequently, the occupational medicine clinician faces several issues regarding accommodation of a hearing-impaired employee. Considerations include risks to the individual due to inability to hear auditory warning signals, interference of hearing protection with high frequency hearing acuity, and risk of further loss due to noise or ototoxic exposures. The hearing-impaired worker who requires hearing aids presents a difficult challenge also. While hearing aids are needed by the individual to hear and understand others, the use of amplification in noise environments may cause additional hearing damage. The clinician must also consider whether the individual is sufficiently impaired to pose a risk to others if operating machinery or performing other safety sensitive jobs. The Department of Transportation has published guidelines for acceptable hearing levels for operators of commercial vehicles. In

addition to ensuring that an individual receives adequate evaluation and treatment of the hearing loss, reasonable accommodation for hearing-impaired individuals can include special warning devices relying more on visual signals, flat attenuation hearing protectors, and avoidance of safety sensitive tasks requiring auditory acuity.

Prevention

A hearing conservation program has historically consisted of at least seven identifiable elements: monitoring hearing hazards; engineering and administrative controls; audiometric evaluation; personal hearing protective devices; education and motivation; record keeping; and program evaluation. When engineering and administrative controls fail to reduce noise to an acceptable level, personal hearing protective devices (HPDs) are vital to prevent NIHL. Personal hearing protection can be an effective means of noise reduction if appropriately worn. There are a number of different types of HPDs that may be considered depending on the individual's occupation. The attenuation characteristics of the HPD must be appropriate for the characteristics of the noise environment.

HPDs are generally of two types – earplugs and earmuffs. There are many different varieties of earplugs, from custom molded to disposable types. Flanged pre-molded earplugs provide satisfactory attenuation if properly fitted. Ear discomfort may encourage a more compliant 'one size fits all' plug. An expandable foam plug is available which can be compressed and inserted; it expands in the ear canal resulting in an effective seal. These expandable earplugs are usually quite comfortable to wear and they also can provide high noise attenuation values. Custom-fitted earplugs will yield excellent sound protection if properly fitted. Retention of the plug may be a problem and a poor fit will result in discomfort. Custom plugs require cleaning and maintenance and, in fact, offer few advantages over the less expensive foam plugs. All earplugs need to fit snugly into the ear canal so that there is no sound leakage around the plug; training in correct insertion is important.

Circumaural hearing protectors or muffs fit over the outer ears to reduce acoustic levels outside the ear canal. The device must be designed to provide for a compliant fit and effective seal around the ear. The cup material should be rigid and of large volume so as to provide the best low frequency attenuation levels. Since earmuffs do not require insertion into the ear canal, they are perhaps more hygienic and less likely to cause external ear canal infections. They are also easier to remove and replace in conditions of intermittent noise exposure. The singular disadvantage to these devices is that they are cumbersome and bulky. In conditions of extremely high noise, it may be necessary to wear both earplugs and earmuffs together.

The amount of actual or real ear attenuation of HPDs depends on a number of factors including the design, material, and fit of the device. Protection is greatest in the high frequencies for most devices. In conditions of high noise exposures or when significant communication demands exist, it may be helpful to determine the frequency characteristics of the environmental noise,

along with the intensity, in order to select a HPD with the exact appropriate attenuation characteristics.

Workers' compensation and assessment of impairment

Assessment of impairment

Following the history, otologic examination, and audiologic evaluation, it must be determined if the individual's hearing status has been adversely affected, on a 'more probable than not' basis, by occupational loud noise exposure.²¹ If the audiometric configuration shows greater thresholds in the 3000–6000 Hz range with some recovery at 8000 Hz (i.e., 'notching'), the presumption of NIHL is strengthened significantly. Older persons, however, may not show this characteristic high frequency notch, due to the effects of aging (presbycusis) causing deterioration of the high frequency thresholds.²² While there is no universally accepted method to separate the effects of noise exposure from the effects of presbycusis upon auditory function, an approach using clinical data and epidemiologic models has been proposed.²³ Many compensation agencies therefore consider the two etiologies together, with the loss being appraised as if it were entirely caused or exacerbated by a confirmed history of noise exposure. While it is extremely helpful to have access to a baseline audiogram prior to the initiation of employment, as well as annual audiograms, to characterize the history of the hearing loss, such records are often not available.

The presence of conductive hearing loss, unilateral hearing loss, visible otologic abnormalities (i.e., chronic otitis media, eardrum perforations), and unusual audiometric configurations would suggest non-industrial etiologies. Of course, if an industrial accident such as an aural slag burn occurred, a conductive hearing loss could be present. Such cases are usually rather straightforward, due to the clear-cut history and physical findings. A greater challenge is to determine the contribution of non-occupational noise exposures to the development of NIHL in compensation cases, since such exposures may be difficult to quantify. The task of the examining medical provider is to form a judgment 'to a reasonable degree of medical probability' or more likely than not, whether a given noise exposure significantly contributed to the overall hearing loss.

Workers' compensation statutes

Although US workers' compensation programs were initially established in the early 1900s, it was not until the late 1940s that industrial claims for NIHL were first filed. In 1953 New York became the first state to draft proposals for provisions dealing specifically with NIHL. Today, most states treat NIHL as an occupational disease with scheduled awards based upon the degree of hearing loss, although some states still require the claimant to show 'incapacity to work', 'disablement' or some other reason for economic disability. States also vary widely on such critical compensation issues as hearing impairment formulas, waiting periods for filing, presbycusis corrections,

filing time limits, and whether willful failure to use hearing protection voids an employee's right to file for compensation.

Workers' compensation laws exist in all 50 states and for most federal workers. Unfortunately, these laws are not uniform, particularly with respect to hearing loss claims, and employ a bewildering array of schemes to determine whether compensation is appropriate and, if so, how much is due.²⁴ To make matters worse, some states apparently administer their systems in ways that are not entirely consistent with their 'governing' legislation. Before becoming involved with a workers' compensation case, the professional should obtain a copy of the appropriate state statute, and seek advice from another professional experienced with the system, as statutes are frequently amended.

Many methods have been used over the years to calculate impairment ratings for hearing loss. The majority of compensation formulas use the pure tone audiogram to determine eligibility for compensation awards, although the frequencies used to arrive at the amount of compensation may be different. Since NIHL typically first affects the frequencies in the 3000–6000 Hz range, a critical factor is whether or not frequencies above 2000 Hz are included in the averaging process. Compensation formulas include a specification of the frequencies that will be averaged, a low and a high fence (the decibel criterion threshold level at which impairment is assumed to begin, and the level at which it is assumed to be complete), and a method of averaging the better and poorer ears.

The most widely accepted formula at the present time is that proposed in 1979 by the American Academy of Otolaryngology ('AAO-79' method), and subsequently accepted by the American Medical Association.²⁵ This formula averages the frequencies of 500, 1000, 2000, and 3000 Hz. Prior to this, only the frequencies of 500, 1000, and 2000 Hz were used in the 1959 AMA formula. The low fence, or beginning of impairment, is 25 dB HL. The better ear is weighted to be five times more important than the poorer ear.

While the AAO-79 method is perhaps the most widely accepted compensation formula, some states have no recommended formula, but leave impairment ratings to the discretion of the examining physician. The Veterans Administration (VA) incorporates speech discrimination (understanding) scores into a compensation schedule. Many states include a provision that excludes a claim when the occupational noise exposure is below a specified level, such as 90 dBA TWA. The statutes of limitations for filing claims vary from jurisdiction to jurisdiction, and are as short as 30 days to as long as 5 years. Over 40 states and provinces permit some type of deduction in impairment award for presbycusis (hearing loss attributed to aging). In other jurisdictions, the use of the AAO-79 low fence of 25 dB HL is considered to account for the effects of aging on hearing. Although tinnitus typically accompanies NIHL, only about one-half of US states permit additional impairment for tinnitus. Some states deny compensation or penalize workers for failure to use protective devices. A few states reduce the compensation award if the claimant

shows improvement with the use of hearing aids. Due to these many differences in hearing impairment calculation and awards, individuals with the exact same audiograms can receive entirely different hearing loss ratings and compensation, dependent upon the jurisdiction and governmental agency responsible for NIHL claims.

Non-noise-induced hearing loss

Head trauma

Hearing loss, tinnitus, facial nerve injury, and/or dizziness can be caused by blunt or penetrating trauma to the head. Motor vehicle accidents, industrial accidents, falls, and recreational injuries can result in fractures of the temporal bone. The large majority (80%) of temporal bone fractures are classified as longitudinal and are typically caused by a direct blow to the lateral skull, usually the parietal region. Longitudinal fractures pass through the ear canal and the middle ear but bypass the inner ear structures. These fractures typically produce conductive losses by lacerating the ear canal, rupturing the tympanic membrane, causing blood accumulation behind the tympanic membrane (hemotympanum), and/or dislocating the ossicular chain. Even though the inner ear structures are not directly involved in longitudinal fractures, a high frequency sensorineural hearing loss with tinnitus may sometimes occur, with an audiometric configuration resembling NIHL. These losses are believed to be caused by 'labyrinthine concussion' and may or may not improve over subsequent months.

Transverse fractures of the temporal bone are seen in association with intense blows to either the occiput or a direct frontal blow. The fracture usually passes through the vestibule of the inner ear resulting in complete and permanent loss of cochlear and vestibular function. The hearing loss is a severe/profound sensorineural impairment; 10–20% of longitudinal and 40–50% of transverse temporal bone fractures are associated with facial nerve injury.

A history of head injury with loss of consciousness is strongly correlated with a risk for hearing loss.²⁶ Injuries too mild to cause loss of consciousness will rarely cause permanent hearing loss.

Penetrating trauma to the temporal bone can range from a simple Q-tip injury to a life-threatening emergency due to a gunshot wound to the temporal bone. Penetrating temporal bone trauma is generally more destructive than blunt trauma, as vascular and other intracranial injuries are more commonly effected in penetrating injuries. Hearing loss is related to the site of damage to the auditory system, from external canal injury up to the central auditory system. Facial nerve trauma is present approximately half of the time and tends to be severe, as the nerve may be transected and large segments of the nerve may be missing or damaged.

Most patients experience some degree of balance disturbance after temporal bone trauma. Causes of post-traumatic vertigo include postconcussive syndrome, concussive injury to the labyrinth, cupulolithiasis, massive

and disruptive injury to the labyrinth, and traumatic perilymphatic fistula.

Inner ear disorders of diving

A professional diver's hearing is at risk for multiple reasons, and studies of divers have suggested increased rates of hearing loss.²⁷ Noise-induced hearing loss is possible due to high intensity noise generated by compressed air entering the diver's helmet or decompression chambers. Divers may also be exposed to high noise levels from nearby ship engines or power tools. Additionally, sensorineural hearing loss may be due to barotrauma and decompression sickness.²⁸ Decompression sickness of the inner ear must be considered as a potential cause for sensorineural hearing loss following a dive if the diver has been close to or exceeded the safe depth and time limits of the United States Navy Dive Tables (see Chapter 36). Vertigo is a frequent concomitant symptom.

Sensorineural hearing loss following diving may also be caused by labyrinthine membrane rupture. This is usually caused by pressure disequilibrium between the inner and middle ear and may be the result of a strong Valsalva maneuver used by the diver to clear an unobstructed ear during the dive. A sudden pop may be experienced followed by hearing loss and vertigo. The membrane rupture may occur anywhere within the labyrinthine membranes or at the oval or round window membrane. The evaluation of vertigo or hearing loss following a dive should include an audiogram as soon as possible.

Decompression sickness is best treated by immediate recompression in a chamber. In some cases, hyperbaric oxygen may be helpful even though the diving profile does not suggest decompression sickness. As a temporizing measure, oxygen should be administered and a benzodiazepine will provide vestibular sedation. If decompression sickness is unlikely, sensorineural hearing loss following a dive is considered secondary to labyrinthine membrane rupture. There are no pathognomonic findings, and the fistula may only be identified at the time of surgical exploration of the middle ear. The hearing loss of many patients with suspected fistulas may improve on simple bed rest. If the hearing loss persists or is progressive, or if vertigo is present, surgical exploration of the middle ear for closure of the labyrinthine fistula at either the oval or round window, is generally required.

Prevention of labyrinthine injuries related to diving includes strict adherence to the profiles established by the United States Navy Dive Tables. Pressure disturbances in the middle ear cannot always be avoided, but are more common in cases of poor eustachian tube function. A documented sensorineural hearing loss after diving is a contraindication to further diving.

Radiation-induced hearing loss

Radiation exposures during treatment of head and neck cancers have been associated with sensorineural hearing loss. This appears to be a direct result of radiation injury to the cochlea, and should be considered in the differential of sensorineural hearing loss.^{29,30}

Other non-noise-induced trauma

The external and potentially the middle ear may be traumatized by debris and other contaminants generated in the industrial setting. Specifically, slag burns of the external canal, tympanic membrane, and even the middle ear have historically been a frequent source of permanent tympanic membrane perforations and conductive hearing loss. The frequency with which this type of injury occurs has declined as a result of the increased use of noise protection devices. The history is diagnostic. The welder will report a foreign body sensation in the ear followed by intense pain and burning sometimes accompanied by a sizzling. If the slag comes in contact with the tympanic membrane, perforations of almost any size may result in any quadrant. Large perforations are not uncommon, and at times portions of the slag will contaminate the middle ear. The amount of conductive hearing loss that results will depend on the size and location of the perforation. Infection following contamination of the middle ear may ensue and will be manifested by drainage.

Initial treatment generally includes an antibiotic to discourage infection; drops may be used if there is no tympanic membrane perforation. Unfortunately, and in contrast to burns caused by caustic agents, thermal burns of the tympanic membrane are very slow to heal and are likely to become chronic. This being the case, surgical closure is generally required, and foreign material may be removed from within the middle ear cleft at the time of tympanic membrane repair.

Prevention of slag burns may be accomplished by using appropriate protective hoods. As mentioned above, the consistent use of noise protection devices in conjunction with welding hoods has reduced the incidence of this form of industrial injury.

Hearing loss due to chemicals

In addition to well-known ototoxic drugs such as aminoglycosides and cisplatin, clinical and experimental studies indicate a potential harmful effect of chemicals, especially organic solvents, on the auditory system. The mechanism of such damage is considered to be through direct neurotoxic mechanisms. Known neurotoxins, such as the organic solvents toluene and styrene, have been shown to cause hearing loss in both animal models and human studies. Metals with neurotoxic properties such as lead, methyl mercury, and arsenic have also been reported as ototoxicants. Such toxins may affect hearing by direct cochlear damage or by retrocochlear action on the auditory nerve and auditory cortex. Carbon monoxide may predispose to hearing loss through an asphyxiant mechanism.³¹

Recent studies have suggested that certain ototoxic chemicals may damage hearing or potentiate the effect of noise on hearing. Solvents and metals are most likely to exacerbate noise-induced hearing loss, as they have well-established neurotoxic effects.³² While a direct causal relationship between sensorineural hearing loss and exposure to these substances has yet to be definitively established in humans, animal studies indicate that there may be a synergistic effect between noise and chemical exposure.³³

20.3 Upper Airway Disorders

Rebecca Bascom, Maadhava Ellaurie

Upper airway disorders are among the most common chronic conditions challenging clinicians, with diverse etiologies including allergic and non-allergic mechanisms. The range of dysfunction¹ includes impaired mucociliary clearance, nasal passage obstruction, upper airway collapse during sleep, and paradoxical vocal fold motion during the respiratory cycle. Upper airway disorders lead the differential diagnosis for patients presenting with typical symptoms of headache, nasal congestion, rhinorrhea, postnasal drip, sneezing, nasal burning, and dysphonia. Upper airway disorders may also explain cough, dyspnea, chest tightness, stridor, snoring, non-restful sleep, sleep disruption, and daytime hypersomnolence.

Allergic upper airway disorders are apparently increasing in frequency, in parallel with the worldwide increase in atopic asthma. The prevalence of rhinitis in 55,000 Swedish conscripts rose from 4.4% in 1971 to 8.4% in 1981. The attributable fraction of rhinitis caused by occupational factors is about 5% to 15%, admittedly a rough estimate. High-risk persons are those with allergy and/or hyperactivity and allergic diseases in the family. High-risk occupations are in industries involving exposure to highly active allergens, such as animal products, chemicals, latex, and flour.

The most common occupational or environmental upper respiratory condition is mucous membrane irritation. Surveys of adults in the past decade indicate 12-month cumulative prevalence rates ranging from 28% to 62%.^{2,3} Mucosal irritation occurs in domestic, industrial, and office settings; controlled human challenges show that the upper respiratory inflammatory responses differ among irritants, and collectively these are distinct from the inflammatory responses to allergens or infectious agents. Despite the clinical impression of a high prevalence of irritant rhinitis, few studies have addressed possible long-term effects by comparing the effects of medical removal versus continued symptomatic exposure. Determinants of susceptibility to chronic effects, such as squamous metaplasia, are also poorly understood, but animal studies have developed a robust chronic exposure data-set enabling new dosimetric models.

An important function of the upper airway is communication.^{4,5} Work-related hoarseness may significantly impair communication, especially by telephone or in a high-noise environment. Hoarseness, therefore, ranges from a nuisance to a distinct disability. 'Professional voice users' include singers, but also teachers, telephone operators, telemarketers, customer relations staff, and sales personnel.

The upper respiratory tract enables olfaction; vapors entrained in the nasal passages move turbulently to the superior part of the nasal cavity and bind to diverse receptors in the olfactory epithelium. Direct toxicity to olfactory epithelium clearly occurs for some, but not all, inhaled agents.⁶ Acquired olfactory impairment may be due to traumatic damage to the olfactory nerve, direct toxicity to olfactory epithelium, alterations in the surface fluid overlying the epithelium, and nasal pathology that obstructs airflow to the olfactory epithelium.⁷

Effective functioning of the upper respiratory tract directly influences job performance and worker morale. Studies have shown that the domains of physical limitation, physical functioning, pain, social functioning, emotional limitation, mental health, and general health perceptions are all significantly worse in rhinitis patients compared to controls. Upper respiratory tract symptoms often influence a worker's perception of risk. Office workers may notice work-associated mucosal irritation and mistakenly fear they are suffering from asbestos poisoning. The physician must develop an organized and effective approach to diagnosing, treating, and explaining these disorders.

PATHOPHYSIOLOGY

The upper airway serves several critical functions. It warms and humidifies inhaled air and filters large particles, including many common allergens. It is the primary adsorptive surface for water-soluble gases, such as sulfur dioxide, and removes substantial quantities of less soluble gases, such as ozone. Obstruction of the nasal passages may result in a change from nasal to oral respiration. Oral breathing bypasses the filtering functions of the nose, increasing the hazard to the lower airways and lungs. An interesting study by Lehmann in 1935 (cited by Proctor⁸) assessed the nasal filtering capacity in miners with and without advanced silicosis. Miners with the most effective nasal filters seemed to have least disease, except for those few miners who had highly effective filtration but were mouth breathers.

The epithelium of the upper airway ranges from the stratified squamous epithelium of the nasal alae, to the transitional epithelium of the antrum, to the pseudostratified columnar epithelium of the nasal passages. Additional transitional zones occur in the oropharynx and glottis. The four functional components of the nasal mucosa are venous sinusoids, postcapillary venules, glands, and the nervous system.^{9,10} The venous sinusoids swell and constrict in response to sympathetic tone and other stimuli, and thus regulate nasal airflow and patency. Postcapillary venules are present in the superficial lamina propria, where plasma extravasation and diapedesis of leukocytes occur. Their endothelial cells respond to mediators by contracting, opening gaps in the basement membrane and expressing adhesion molecules and releasing nitric oxide (NO), endothelin, and other mediators that regulate vascular tone. The seromucous glands release antimicrobial factors such as lysozyme, lactoferrin, secretory immunoglobulin (Ig) A, hyaluronic acid, and neutral mucins. Mucous cells and goblet cells release acidic mucins coated with sialic acid and sulfate groups that enable them to adsorb particulate or irritant chemicals on the mucosal surface. Innervation of these structures is by sympathetic, parasympathetic, and type C nerves. Non-myelinated type C nociceptive nerves are present in the epithelium and mediate sensations of itch and burning pain by H1 and capsaicin receptors, respectively.¹¹ Parasympathetic nerves

include cholinergic nerves that mediate glandular secretion,¹² and sympathetic fibers are responsible for vasodilation of the venous sinusoids. Sympathetic fibers contain either norepinephrine or norepinephrine and neuropeptide Y (NPY). Norepinephrine causes vasoconstriction and collapse of the sinusoids and an increase of nasal patency, while NPY reduces vascular permeability.

Cardinal nasal symptoms of congestion, pruritus, sneezing, and secretions occur through these mechanisms.¹⁰ Congestion results primarily from venous sinusoidal pooling and secondarily from subepithelial vasodilation, increased vascular permeability, and glandular secretion. Pruritus, burning, and sneezing result from sensory nerve stimulation, though these responses can be dissociated.¹³ Secretions are the result of glandular stimulation and increased vascular permeability. Some of the components of nasal secretions that have been studied are prostaglandin D₂ (PGD₂), tosyl-arginine methyl ester (TAME) esterase activity, kinins, albumin, immunoglobulins, lactoferrin, lysozyme, tryptase, and major basic protein. Asthma and rhinitis often coexist¹⁴ and basement membrane thickening, eosinophilic inflammation, and epithelial shedding are present on biopsies obtained from both sites, though typically are worse in the lower airway.

Subclasses of T-helper (TH) lymphocytes have been identified among antigen-specific T cells by measuring the profile of cytokines that they produce. TH1 cells are characterized by production of interleukin (IL)-2, interferon (IFN)-gamma, and tumor necrosis factor (TNF)-beta, and evoke cell-mediated immunity and phagocyte-dependent inflammation. TH1 responses are highly protective against infections mounted by the majority of microbes, especially the intracellular parasites. TH1 cytokines activate phagocytes and promote B lymphocytes to produce opsonization and complement-fixing antibodies. TH2 cells represent a polarized form of the T-helper cell-mediated immune response that is characterized by the production of IL-4, IL-5, IL-6, IL-9, IL-10, and IL-13 but not of IFN-gamma and TNF-beta. TH2 cells evoke strong antibody responses (including the IgE class) and eosinophil accumulation, but inhibit several functions of the phagocytic cells. The TH2 cytokines induce the differentiation, activation, and the in-situ survival of the eosinophils (through IL-5), promote the production by B lymphocytes of high amounts of antibodies including IgE (through IL-4 or IL-13), as well as promoting the growth of mast cells and basophils (through IL-4, IL-5, and IL-10). It appears that both environmental and genetic factors act in concert to determine the TH1/TH2 profile.

The allergic reaction appears to be the result of a TH2-type T-cell response to one or more common environmental allergens. Circulating IgE binds to high-affinity Fc epsilon receptor 1 on mast cells and basophils. Re-exposure to allergen leads to cross-linking of these Fc receptors and degranulation of these cells. The preformed and newly formed mediators lead to an immediate hypersensitivity reaction and a late-phase response. Histamine plays the most important role in the immediate reaction, together with TAME esterase, PGD₂, and kinins. Four to 6 hours

following the immediate phase, a late-phase response occurs with an accumulation of eosinophils, basophils, and TH2 cells together with increased levels of histamine, TAME esterase, and kinins. Nasal levels of NO, too, are elevated in patients with allergic rhinitis and appear to correlate with inflammation.^{15,16} Levels rise further during the pollen season and may be modulated by nasal steroids.

CLINICAL EVALUATION

The initial evaluation of a patient with upper respiratory symptoms consists of a careful history and physical examination (Table 20.3.1). A careful history is the single most important diagnostic tool for evaluating upper respiratory tract disease. Many centers base the initial empiric treatment of rhinitis solely on the history. This is probably reasonable for cases with mild symptoms or an evident etiology, provided that there is follow-up to verify the efficacy of treatment. Temporal patterns of irritation, congestion, rhinorrhea, or sneezing often suggest likely etiologies. As with asthma, the response to allergen exposure can occur within minutes of exposure (acute response), can occur hours later (isolated late response), can be a biphasic response, or an acute, sustained response. A symptom diary may be useful to clarify these patterns. The evaluation of asthma in the occupational setting emphasizes the importance of observation and measurement with 2-week intervals of exposure and removal from exposure (see Chapter 19.2). A similar 'longer-view' approach will clarify some complex cases of upper airway diseases.

The history should also pay particular attention to symptoms suggesting sinusitis (facial pain and pressure, fever, discolored mucus), or asthma or reactive airways (paroxysmal cough, episodic chest discomfort, exercise or nocturnal dyspnea, or wheezing). Upper chest or xyphosternal discomfort accompanying dyspnea may indicate laryngeal dysfunction instead of asthma. Hyperfunctional voice disorder can also cause dyspnea and upper chest discomfort, often with cough. Treatment of the upper airway disease can improve asthma and seems to reduce sinusitis risk. If the evaluation suggests concomitant lower respiratory tract disease, further workup should proceed, as described elsewhere in this text (see Chapter 19.1).

If the history is strongly suggestive of IgE allergies, a referral should be made directly for allergy skin testing. If an allergist is not available, radioallergosorbent tests (RAST) may be performed on sera to a panel of allergens appropriate for the region. Allergy reference laboratories exist that allow serum samples to be mailed in for analysis. A less desirable approach is to obtain a multiallergen RAST and then to refer patients for allergy skin testing if the screening multi-RAST has positive results. False-negative results limit the applicability of this approach; also, targeted environmental modification needs cannot be determined. If the physical examination indicates pharyngitis, cultures of the throat may be taken. Nasal cultures are not indicated routinely. A nasal swab test may help assess the nature of the cellular influx.

History

1. Symptoms (symptom diary)
Nature: Congestion, rhinorrhea, sneezing, itching, hoarseness, coughing, headache, postnasal drip, burning, irritation, and dryness
Timing: Seasonal, perennial, episodic, weekends, and vacations
Severity: 0–5 (absent, mild, mild-moderate, moderate, moderate-severe, or severe). Number and length of attacks, boxes of tissue used.
Precipitants: Specific environments, odors, or exposures
Past symptom patterns: Childhood respiratory symptoms
2. Environmental
Home: Age, structure, dampness, insulation type(s), heating and air-conditioning, carpets, renovations or remodeling, environmental tobacco smoke, roaches, rodents, dust, visible mold, history of leaks, or standing water. Have allergen reduction measures been taken (e.g., carpet removal or encasement of mattress and pillow)?
Pets: Dogs, cats, or birds
3. Occupational
Type of work and length at past and present jobs, materials used, and known exposures
Industrial hygiene sampling results and material safety data sheet information
Other employee problems
4. Hobbies
Materials: Solvents, finishes, pesticides, herbicides, exotic plants, prints, glues, epoxies, paints, and lubricants
Activities: Grinding, spraying, gluing, soldering, welding, or cleaning
5. Habits and medications
Habits: Tobacco smoke, cocaine, or other drugs
Medications: Prescription drugs or intranasal decongestants

Physical examination

1. Ears: Erythema, tympanic light reflex, mobility, and air–fluid levels
2. Nasal mucosa (pre- and posttopical decongestants):
Color: Red, pale, or bluish.
Exudate: Amount and nature.
Abnormal features: Swelling, polyps, septal deviation, ulcers, or pigmentation
3. Pharynx: As with nasal mucosa plus tonsils and dentition
4. Sinuses: Localized tenderness, transillumination, and osteal or posterior pharyngeal purulence
5. Neck: Thyroid, lymphadenopathy, and muscle trigger points
Vocal performance: Habitual pitch, pitch range, phonation times on /a/, /s/, and /z/
6. Lungs: Presence and quality of spontaneous cough, size and shape of rib cage, breathing pattern (inspiratory to expiratory ratio), accessory muscle use, percussion, wheezes, rales, ronchi, and e-to-a changes

Diagnostic measures

1. Nasal swab: Number of eosinophils, neutrophils, and basophils per high-power field
2. Serology/hematology: Total and allergen-specific IgE, and eosinophil count
3. Pulmonary functions: Spirometry, flow volume loops, diffusing capacity, and serial peak flows
4. Antigen skin testing
5. Environmental sampling results: Dusts, mists, fumes, and vapors

Diagnostic adjuncts

1. Computed tomography scans
2. Fiberoptic rhinoscopy and videostroboscopy
3. Rhinometry: Acoustic rhinometry, nasal rhinomanometry
4. Methacholine reactivity
5. Antigen challenge/symptom provocation
6. Special procedures: Nasal lavage, biopsy, and mucociliary transport

Further diagnostic studies that may be initiated at the initial visit include a request for information about the work environment, including material safety data sheets and air sampling information. House dust analysis may be ordered through specialized facilities to identify the presence of specific antigens. A literature search may be needed to identify laboratories capable of measuring antibodies to unusual antigens. A judgment must be made at the initial visit as to the severity of the health effects that are occurring. Any lower respiratory symptoms should prompt additional evaluation. Interim work placement recommendations should be made, and recommendations for work modification or respiratory protection should be given to the patient in writing at the time of the office visit.

A provisional diagnosis is often made at the initial visit. Medication may be prescribed as a therapeutic trial or for symptomatic relief. Allergen avoidance, nasal corticosteroids, and non-sedating antihistamines are prescribed for allergic rhinitis. Nasal cromolyn sodium (Nasalcrom) relieves symptoms in some patients. For irritant rhinitis, avoidance of irritant triggers is advisable but may be difficult. If nasal dryness or irritation is the dominant complaint, saline lavage (1/4 of a teaspoon of salt in one cup of warm water, snuffed, then expelled) or oral guaifenesin (Robitussin) may be tried. Pharmacotherapy is difficult for vasomotor rhinitis. Nasal ipratropium bromide (Atrovent) for runners and sneezers, and oral alpha-agonists demonstrate limited success. Antihistamines do not appear to help in this condition. Low-dose tricyclic antidepressants at bedtime have been suggested. If a bacterial infection is suspected, a course of antibiotics is prescribed.

Charcoal-impregnated paper masks intended for use against nuisance volatile organic compounds (VOCs) should be used only if exposures are clearly low level. The psychosocial impact of putting someone in a respirator should be considered. Local-air cleaners may provide symptomatic relief when office or home ventilation is inadequate and point sources (such as tobacco smoke) cannot be controlled. The performance characteristics of air cleaners are highly variable. A combination high-efficiency particulate air (HEPA) filter and charcoal (or other VOC-adsorbing substance) is most appropriate for most office environments. Anecdotal data suggest that portable air cleaners worn around the neck may provide symptomatic improvement for some sensitive patients.

We recommend a follow-up visit 2 to 4 weeks after the initial visit. At that time, the results of laboratory studies and the response to treatment are evaluated. Workplace data are assessed. Further recommendations after discussion with the patient may include additional treatment or testing, source reduction, respiratory protection, medical removal, or job modification.

History

The history seeks to establish the presence and nature of upper respiratory symptoms, to gauge their severity, and to

Table 20.3.1 Components of upper airway symptom evaluation

seek evidence for the major causes of rhinitis. A patient who is distraught with concern about an occupational or environmental exposure is often reassured by a thorough medical history, including an occupational and environmental history, and rational plan for longitudinal evaluation and monitoring. The initial visit is also a time to help the patient distinguish between the actual events and symptoms that occurred, and the subsequent interpretations and conflicts that may affect his or her perception of the health problem.

Environmental history

The environmental history should include a description and sketch of the home. Adjacent structures should be noted. Note the age, type of structure, and building materials in the home. Determine the type and age of insulation, the type of heating and air-conditioning systems, whether wall-to-wall carpets are present, and, if present, their age and whether they are on a concrete slab (a situation leading to high concentrations of house-dust mites). If there is a forced-air system, focus on the type of humidification system and how it is maintained. Determine whether there is a wet basement or crawl space and the history of leaks. Ask whether there have been renovations to the home. Determine the presence of pets (cats, dogs, and birds), cockroaches, and rodents. Hobby-rooms and workrooms should be identified and the specific nature of the activity and materials. Responses to these questions may alert the physician to possible causes of symptoms. Animals, roaches, or rodents are important sources of allergens. Excess dampness as well as water (basement, forced-air system, or leaks) can be a source of bioaerosols and is a strong determinant of respiratory symptoms (even in the absence of identifying a specific pathogen or allergen). VOCs arise from hobbies, cleaning, or new furnishings. New carpets can be a source of irritants; old carpets, especially those on concrete, can be a reservoir for house-dust mites or molds. If an outside dog uses a rug, the rug can be damp and can develop high mold counts.

Occupational history

In addition to a routine screening occupational history (see Chapter 3), the physician should focus on the current or most recent job. Central functions of the job that require upper airway functioning typically include speaking (specify needed volume, intelligibility, and duration) and, less likely, olfaction. The ability to wear a respiratory mask may be compromised by sinus pressure or pain. Requirements for sustained alertness are important to assess the impact of diseases such as sleep apnea and to predict the impact on job performance of medications such as antihistamines.

Allergy and symptom history

A careful allergy history also should be obtained, because the temporal pattern of symptoms will identify likely seasonal allergic causes for further diagnostic evaluation. Seasonal exacerbations can be readily shown with a retrospective diary or patient history. In general, early spring

rhinitis relates to local tree pollens, late spring rhinitis relates to grass pollen, and fall rhinitis relates to weed pollen. A local allergist can provide more specific information about regional allergens and typical patterns of pollen dispersal. Patients are less able to link perennial rhinitis symptoms with exposure to relevant antigens such as dust mites, cats, rodents, or cockroaches.

Patients should be specifically questioned about their childhood health, whether they had childhood respiratory troubles, and whether they were raised with household smokers, because adult respiratory problems are associated with childhood exposure to environmental tobacco smoke (ETS). Immunodeficiency diseases such as secretory IgA deficiency may present with childhood infections.

The examiner should question the patient about any exposures that trigger symptoms, including cold air, ETS, perfumes, cleaning materials, and other household products. In more complex cases, a daily symptom diary may provide additional clues to environmental precipitants and document particular patterns of reaction. The diary should encompass 2 weeks of usual activities and should include symptoms such as congestion, rhinorrhea, sneezing, and other sentinel symptoms. Rough quantification helps discern any patterns and can be recorded as the severity of congestion or headache on a five-point scale. Quantifying the number and length of sneezing attacks and the approximate number of tissues used during an episode of rhinorrhea may be helpful.

Physical examination

The face is inspected for periorbital or facial swelling. Sinuses are palpated by applying gentle pressures. The maxillary sinuses are palpated below the orbits, the frontal sinuses over the eyebrows, and the ethmoid sinuses over the bridge of the nose. Non-specific hyperesthesia or tenderness may be noted, but the finding of differential or localized tenderness raises the suspicion of sinusitis. Sinus transillumination is an insensitive procedure, particularly for maxillary sinus disease.

The ears are examined and tympanic membranes inspected for erythema or fluid by insufflation. The patient should blow against his or her pinched-closed nose while the physician looks for motion of the light reflex on the tympanic membrane. This maneuver provides additional information about middle ear fluid and eustachian tube function. In the absence of formal hearing tests, patients can be asked about the quality of the voices they hear (muffled voices suggest fluid in the middle ear). The physician can ask questions in a quiet voice when positioned behind the patient. Inability to hear in the simple scenario suggests a need for hearing tests and possible assistive devices (see Chapter 20.2).

Many physicians do not inspect the nasal passages. This can be done readily using the speculum from the ear examination. Landmarks to recognize include the nasal septum and turbinates. The mucosa is inspected for the presence, color, and thickness of secretions; mucosal ulcers; the color of the mucosa (pale, bluish, or red); boggy-

ness; swollen turbinates; and polyps. A stream of purulent mucus descending over the inferior turbinate confirms sinusitis. Since the nasal speculum provides only a partial view, patient referral for an otolaryngology examination is indicated if the inspection of the nasal passage does not correlate with the history, if treatment failure suggests structural disease, or if strongly unilateral symptoms raise a suspicion of neoplasm.

Otolaryngologists typically inspect the mucosa using a headlamp, and increasingly with a fiberoptic rhinoscope. The mucosa should first be inspected without the application of decongestants. A topical vasoconstrictor can then be applied (e.g., oxymetazoline [Afrin]), with repeat inspection 2 to 15 minutes later. Decongestion should not be performed in the case of poorly controlled hypertension or in the rare case of allergy to the vasoconstrictor. The main reason for visualization after decongestion is that a swollen inferior turbinate can obstruct the view of posterior polyps or of purulent discharge, which is often seen inferior to the middle meatus in early sinusitis.

The oral mucosa is visualized with particular attention to the presence and nature of secretions in the posterior pharynx, one of the most sensitive signs of draining sinuses. The salivary pool is noted, and absence of saliva under the tongue suggests a sicca syndrome.

The quality of the voice and presence of spontaneous cough are noted. Screening for hyperfunctional voice disorder can be done at the initial visit as follows. Listen to phonation at the patient's habitual pitch on /a/ (the sound 'ahhh'); a normal voice produces a single sustained tone without pitch breaks, excess tremor, or dysphonia (hoarseness). Ask the patient to repeat the /a/ on his or her lowest pitch, and then on his or her highest pitch. The habitual pitch should be just above the bottom third of the pitch range, and the pitch range should exceed one, preferably 1.5, octaves. The patient should then be instructed to phonate on /a/ for as long as he or she can. Normal values exceed 15 seconds. Patients with hyperfunctional voice disorder may phonate only 3 seconds and dissolve in a paroxysm of coughing and discomfort. These same patients can typically speak in full sentences during conversation without inducing discomfort. The abnormality is only demonstrable during the sustained phonation on a single sound. Maximal phonation times on the phonemes /s/ and /z/ will complete the screening examination. An s/z ratio of 1.4/1 is typical. Patients with hyperfunctional voice disorder will often have an increased s/z ratio, meaning that they have adequate breathing capacity but demonstrate abnormalities of the phonatory apparatus.

The neck is palpated for adenopathy, and the thyroid is palpated for tenderness, nodules, or enlargement. Lung examination is included to identify concomitant lower tract findings.

Diagnostic procedures

Direct assessment of upper respiratory function remains limited because of the lack of commonly available meas-

ures of physiologic response. Nonetheless, when directed by the history and physical examination, the tests identified may play a role in the diagnostic workup. Selectively applied, they may either clinch a particular diagnosis or can at least raise the level of confidence enough to allow a provisional diagnosis, with subsequent treatment and workplace recommendations.

Nasal swab

Samples of nasal mucosa can be obtained with a swab or a curette. The most comfortable procedure for the patient is to use a flexible, disposable plastic scoop (Rhinoprobe). The probe is inserted in the nose under direct vision and pulled gently for 0.5 cm along the middle turbinate. The contents of the probe are then spread on a slide. Alternatively, a Calge swab may be inserted approximately 3 cm and gently pulled along the septum of the nasal cavity below the inferior or medial turbinate. Once off the mucosa, the swab is rotated, and a second pull is made, for a total of five passes. This is somewhat less comfortable. One swab from each nostril is rolled onto two glass slides, air dried, and stained. Commonly available stains, such as Wright-Giemsa stain or Diff Quik, will identify neutrophils and eosinophils on one slide; alcian blue will best pick up basophils on the other. The slide is examined, and the presence and proportions of inflammatory cells (particularly neutrophils and eosinophils) are noted. Eosinophils are characteristic of allergic diseases, and a high correlation has been found between nasal eosinophils and signs and symptoms of allergy. Eosinophilic rhinitis that occurs without an identifiable allergic cause is termed non-allergic rhinitis with eosinophilia syndrome. Increased metachromatic cells (basophils or mast cells) also have been observed with in-season allergic patients. Neutrophils are more commonly seen with infections or irritant exposures. They may also be present in association with eosinophils in allergic rhinitis. Population-based epidemiologic studies have not been performed with nasal swabs; therefore, the distribution of the findings of neutrophils in a normal population is unknown. Generally, the normal nasal mucosal cytologic findings consist of numerous epithelial cells with perhaps a few neutrophils and bacteria but no eosinophilic or basophilic cells. A qualitative and quantitative grading scheme has been used for both clinical medicine and pharmaceutical studies (Table 20.3.2).¹⁷

Pulmonary function

Spirometry with flow volume loops should be performed on all individuals who are being evaluated for work-related upper respiratory disease. Attention to the entire flow volume loop (slow inspiration followed by maximal exhalation followed by maximal inspiration) enables assessment of extrathoracic airflow obstruction. A ratio of the FEF50/FIF50 of greater than 1 suggests extrathoracic airflow obstruction. Early termination of the inspiratory flow loop or marked asymmetry suggests laryngeal dysfunction.

The expiratory portion of the test establishes a critical baseline value for the patient without lower respiratory

Grade	Cytologic findings		
	Inflammatory cells	Neutrophils/eosinophils	Basophils
0	None	0–1	0–0.3
1	Few scattered cells or clumps	1–5	0.4–1.0
2	Moderate	6–15	1.1–3.0
3	Many cells or large clumps	16–20	3.1–6.0
4	Large numbers	>20	>6

Table 20.3.2 Qualitative and quantitative grading scheme for cytologic findings in rhinitis. The values represent the mean of cells per 10 high-powered fields ($\times 1000$).

symptoms and begins the diagnostic evaluation for patients with concomitant chest symptoms. In workers exposed to protein allergens, spirometry and 2 weeks of peak flow tracings are usually sufficient to exclude significant illness (see Chapter 19.2). For symptomatic exposure to irritants or low-molecular-weight sensitizers, a complete set of pulmonary function studies, including spirometry, diffusing capacity, and serial peak flow measures, is advised, given the potential for hypersensitivity pneumonitis and interstitial inflammation.

Allergy testing

Serum IgE is not a good screening test for allergic disease; although allergic disease is distinctly uncommon in the presence of a low IgE level, it may occur in the presence of a normal serum IgE concentration. Age-specific reference values should be used to evaluate the total IgE. The presence of eosinophils on a nasal swab or a history of perennial rhinitis should prompt a referral for skin testing.

If the history suggests that nasal symptoms are related to exposure to low-molecular-weight compounds, obtaining serum IgE levels against such compounds should be considered only in unusual cases. Antibodies to toluene diisocyanate are often undetectable despite clinical sensitization; antibodies to hexamethylene diisocyanate and methylene bisphenyl diisocyanate appear to be more sensitive. It is not appropriate to obtain antibodies to evaluate symptoms resulting from a single exposure. Technical factors may significantly affect the laboratory results, and caution is advised in the selection of a reference laboratory.

If a patient previously had skin tests, these results should be obtained for review. Indicators of good-quality skin tests include the explicit measurement of the response to a negative control (saline) and a positive control (histamine). If saline causes a wheal and flare, then RAST rather than skin prick testing is the test of choice. If the histamine skin test is negative, then the medication history should be reviewed for unrecognized antihistamines, or failure to stop medications far enough in advance of the skin testing. Local allergists are usually familiar with the major allergy seasons in each community. There is usually a spring season related to trees and grasses, and a late summer or fall season occurring with ragweed. The primary perennial allergens are cats, house-dust mites,

and, in some cases, mold spores. In an urban setting, cockroach and rodent allergens may be important. If skin test results were previously negative but the symptoms are strong and increase in the middle of a known allergy season, repeat skin testing may be warranted at the time of the symptoms. Fungi may cause allergic disease despite negative skin tests because such tests assess only some of the many species that exist.

Skin tests are generally accepted for IgE-mediated protein allergens. There is no established value for skin tests against chemicals, such as formaldehyde, and cigarette smoke. An etiologic role for these latter agents remains best established by a combination of clinical evaluation, symptom diary, and environmental assessment. Provocation testing is not a practical clinical tool in most cases.

Fiberoptic rhinoscopy and videostroboscopy

Fiberoptic rhinoscopy is rarely part of the initial workup, although it is increasingly used by allergists and otolaryngologists.¹⁸ For difficult cases and in consultation with experienced operators, however, it may usefully identify polyps, sinusitis (through purulence at the ostia), septal deviation, and posterior nasopharyngeal lesions, and provide excellent visualization of the vocal cords and glottis. The procedure is well tolerated by patients, and clinicians find it superior to laryngoscopy in cases of suspected unilateral vocal cord paralysis.

Fiberoptic rhinoscopy is key to diagnosing laryngeal dysfunction (also called vocal cord dysfunction or vocal fold dysfunction). The hallmark of this group of disorders is paradoxical vocal fold motion, asynchronously with the respiratory cycle. The normal pattern is vocal fold abduction during inspiration and a return to neutral position during exhalation; the abnormal pattern is adduction of the vocal folds during inspiration. A posterior chink, stippling of the epiglottis, and interarytenoid edema are often seen. With practice, the clinician can position the rhinoscope so the patient can breathe comfortably without gagging.

Videostroboscopy provides even clearer visualization of the larynx, but does not allow concomitant visualization of the nasal passages.

Radiography and computed tomography (CT)

The diagnosis of sinusitis, when accompanied by classic symptoms, presents little difficulty. The presence of fever, frontal headache or facial pain, and purulent nasal discharge, supported by opacity on transillumination, tenderness to palpation, nasal neutrophilia, and/or visible sinus drainage, dictates the presumptive diagnosis of sinusitis and a trial of antibiotics. More diffuse and puzzling symptoms, however, or upper airway symptoms recalcitrant to treatment may demand further workup. CT of the sinuses has replaced the sinus X-ray series since the latter may show maxillary or frontal sinusitis, but it typically misses ethmoid or sphenoid disease. Cost-effective imaging of the sinuses can be obtained by a limited, dry (non-contrast) CT, performed at the end of a course of antibiotics. This will

demonstrate osteomeatal disease, masses, congenital abnormalities, and refractory inflammation.

Rhinometry

Rhinometry is not widely available and it is unclear whether it will ever have the wide clinical application and utility that exists with spirometry. Nasal airway dimensions and physiology can be repeated after decongestants, helping to separate fixed lesions (e.g., deviated septum) from vascular congestion.

Acoustic rhinometry can document surgical correction of septal deviations. Acoustic rhinometry measures the cross-sectional area of each nasal passage as a function of the distance from the nasal antrum.

Nasal resistance is calculated by measuring the pressure and flow at the nose during gentle panting efforts. For anterior rhinomanometry, one side of the nasal cavity is occluded to monitor nasopharyngeal pressure by a differential pressure transducer. Airflow through the other nares is measured with a pneumotachometer.⁶ From the relationship between flow rate and pressure, one can derive nasal airway resistance. Commercially available anterior rhinomanometers measure airflow through one nares by means of a closely fitting face mask, while the other nares is sealed with a small tube to measure nasopharyngeal pressure. The technique is easy to perform, requires very little patient cooperation, and is convenient for nasal provocation. Posterior rhinomanometry is also available, but the procedure is difficult to perform for some patients. The test consists of placing a modified diving or anesthesia mask on the patient, having the patient close his or her mouth over a tube, and then having the patient perform panting maneuvers through the nose.

Nasal inspiratory peak flow meters have been used in some epidemiologic studies. These measures may provide confirmation of congestion and document the possible association with workplace exposures. They can also be used as an outcome measure during challenge studies.

Nasal reactivity by methacholine and histamine challenge

Nasal reactivity can be assessed using methacholine, histamine, or capsaicin challenge. A variety of techniques have been employed; however, this test has primarily been used in a research setting. An increase in secretions has also been demonstrated following capsaicin or methacholine challenge in subjects with vasomotor rhinitis when compared with unaffected subjects. In the experimental setting, cholinergic nasal reactivity increases following antigen challenge. A new method for methacholine challenge, utilizing impregnated paper discs, obviates the need for mist inhalation, making the procedure considerably safer, more comfortable, and more convenient. The clinical utility of the test is limited by the narrow separation of nasal reactivity between patient groups.

Challenge by specific suspected agents

Nasal challenge with antigen is used in some countries, such as Finland, to establish a diagnosis of occupational

nasal allergy. The use of provocation with other agents (e.g., cold air, ozone, or ETS) may demonstrate hyper-responsiveness in some people, but its use has been limited to a few centers. It remains primarily a tool for research settings.

Nasal lavage

Nasal lavage has been used as a research tool to define the inflammatory response to specific agents. As the inflammatory patterns with different nasal conditions are defined, a screening instrument may be feasible akin to the 'dipstick' screening of urine samples.

Nasal biopsy or cytology

Nasal biopsy is rarely performed unless the physical examination suggests granulomatous disease, such as sarcoidosis or Wegener's granulomatosis, or malignancy. Improved techniques of nasal cytologic examination are being developed and may play a role in occupational medicine. These are being used initially to study pathogenesis and may later be used to indicate dose, host response, or susceptibility. Nasal mucosal cytologic testing by scraping has been used successfully in studies of formaldehyde-exposed workers to detect squamous metaplasia as a possible precursor of dysplastic transformation.

Mucociliary transport

The mucociliary apparatus clears both soluble and insoluble materials. The sugar test quantifies the mucociliary transport of soluble substances: a small quantity of sucrose is placed on the inferior turbinate, and the subjects are instructed not to sniff or blow and to indicate when they taste sweetness. Intervals greater than 30 minutes are considered abnormal. In the research setting, insoluble radiotracers and charcoal powders have been used to assess clearance, and may show reduced clearance despite the presence of a normal sugar test.

CLASSIFICATION OF DISORDERS

This section describes specific types of upper respiratory tract disease. The individual patient may have one or more conditions simultaneously, and the physician must tailor the therapy and work recommendations accordingly. The interested reader is referred to an excellent classic textbook on the nose,⁸ a more recent clinical rhinitis text,¹⁹ and a classic nasal toxicology text.²⁰ A review by Harkema discusses the comparative pathology of the nasal mucosa in laboratory animals exposed to inhaled irritants, highlighting problems of cross-species comparisons.²¹

Rhinosinusitis

Rhinosinusitis is an inflammation of the paranasal sinuses and the nose and occurs frequently in patients with perennial rhinitis. Acute rhinosinusitis commonly follows a viral upper respiratory infection (URI) and lasts for up to 3 weeks. Chronic rhinosinusitis is inflammation of the sinuses that lasts longer than 3 months. Common

causes are infection, mechanical obstruction, allergy, and primary eosinophilic inflammation of the nasal and sinus mucosa. Other causes include fungal infections such as aspergillus or an immune response to a fungus. More than 50% of asthmatics have chronic rhinosinusitis. Local, systemic, and environmental factors all contribute to the development of rhinosinusitis. Local risk factors include URIs, allergic rhinitis, non-allergic rhinitis, deviated nasal septum, tumors, and nasal polyps. Environmental risk factors include cigarette smoke, swimming and diving, barotraumas, and overuse of topical decongestants. Systemic factors include IgG and IgA deficiency, cystic fibrosis, bronchiectasis, diabetes, Wegener's granulomatosis, immotile cilia syndrome, immunosuppressive therapy, HIV infection, and Kartagener's syndrome.

The signs and symptoms of rhinosinusitis are facial pain, pressure, or fullness, nasal obstruction, purulent nasal discharge and discolored postnasal drip, hyposmia, anosmia, cough, headache, halitosis, dental pain, fever, fatigue, and pressure, pain, and fullness in the ears. Plain sinus X-rays are not useful in the diagnosis of recurrent and chronic rhinosinusitis in adults. A coronal CT scan can identify involved sinuses, define pathologic changes, and is necessary when the diagnosis is in question, complications are suspected, and when surgical intervention is being considered. Nasal endoscopy can identify anatomic abnormalities, pinpoint the source of infection within the middle meatus, and is useful in obtaining nasal cultures from the osteomeatal complex. Allergy skin tests, mucociliary clearance measurements, and nasal airway measurements are other useful diagnostic tests.

Management of rhinosinusitis includes using appropriate medications to control infection and reduce inflammation, palliative measures, and surgery when aggressive medical management has failed. Palliative treatment consists of nasal lavage with warm salt water and inhalation of warm mist through the nose for 15 minutes three to four times a day. The choice of antibiotic therapy for rhinosinusitis depends on local sensitivity patterns, potential for resistance, suspected bacteria, and the patient's allergy history. Common bacterial pathogens in acute rhinosinusitis are *Streptococcus pneumoniae* and other streptococcal species, *Haemophilus influenzae*, and *Moraxella catarrhalis*. Treatment of acute rhinosinusitis is typically 10–14 days, but up to 3 weeks of treatment is sometimes necessary. Chronic infectious rhinosinusitis may need up to 6 weeks of antibiotic treatment, and anaerobes, staphylococcus, and gram-negative pathogens may be present in addition to pneumococcus. Antibiotics used for repeated episodes of acute or recurrent rhinosinusitis include amoxicillin/clavulanate, azithromycin, clarithromycin, levofloxacin, and loracarbef. Intranasal steroids are indicated to treat allergic and non-allergic rhinitis and nasal polyps, and are useful in the maintenance therapy for chronic rhinosinusitis. Oral and topical decongestants can alleviate symptoms and oral mucolytics may help to thin discharge and promote drainage. Surgery is considered when appropriate medical management of rhinosinusitis has failed. The goals of surgery are to reduce recurrences of

rhinosinusitis, remove obstruction to sinus drainage, and alleviate acute complications. Mucociliary clearance defects are often present in patients with persistent symptoms post sinus surgery, and bacterial testing may show clearance of infection.

Rhinitis

A simple classification of rhinitis lists four groups:

- infectious (purulent) rhinitis;
- seasonal allergic rhinitis (also called pollinosis or hay fever);
- perennial allergic rhinitis; and
- perennial non-allergic rhinitis (eosinophilic or non-eosinophilic).²²

Absent from this scheme is episodic rhinitis related to specific stimuli, rhinopathies which typically show intra-subject consistency but inter-subject variation. Irritant rhinitis, cold air-induced rhinitis, and gustatory rhinitis are examples of episodic rhinitis. The clinical history points to the link between a stimulus and the rhinitic response.

Infectious rhinitis

Respiratory tract infections result in billions of dollars of direct medical costs and indirect costs (e.g., lost time). The effect of environmental exposures on infectivity and rates of infection is therefore of interest. Oxides of nitrogen (produced as the combustion products from gas stoves, welding, and smelting operations) have been associated with increased respiratory infections in some, but not all, studies. Samet and associates reviewed the epidemiologic studies and concluded that 'evidence implies that clinically relevant effects of NO_x from gas stoves are uncommon at the concentrations found in most US homes'.²³

Energy conservation measures that reduce ventilation may increase infectious respiratory diseases that are spread through droplet nuclei. One study demonstrated consistently higher rates of febrile acute respiratory disease among army trainees occupying modern (energy-efficient design and construction) barracks compared with old barracks.²⁴ Immunization of military trainees against adenovirus has been associated with reduction in acute respiratory disease rates.

Allergic rhinitis

Epidemiology Allergic rhinitis is a common condition with prevalence estimates ranging between 5% and 25% of the population. Both seasonal and perennial antigens may cause allergic rhinitis, with dominant antigens varying by region. Recent research has focused on the home as an important source of exposure to antigens such as cats, mites, cockroaches, and rodents. The non-industrial work environment (e.g., schools or office buildings) can also be a clinically important source of these allergens. Even less is known about the entrapment of seasonal pollens into buildings. It is plausible that, as has been shown in relation to IgE-mediated asthma, upper respiratory tract exposure to irritants (e.g., ozone) will enhance the likelihood of

allergic rhinitis. Tobacco smoke is a major indoor pollutant and is strongly associated with allergic sensitization. Increased serum IgE levels and an increased prevalence of positive skin tests to aeroallergens and occupational allergens have been shown in several studies. Smokers are sensitized more easily to occupational allergens than are non-smokers exposed to allergens to the same degree.

Allergic rhinitis also appears to increase the likelihood of developing viral respiratory infections. The allergen exposure maintains a persistent inflammation that upregulates the expression of intercellular adhesion molecule (ICAM)-1 and vascular cell adhesion molecule (VCAM)-1 in the inflamed epithelium. Since ICAM-1 is the ligand for almost 90% of the rhinoviruses, the upregulation may explain the increase in viral respiratory infections.

Work-related allergic rhinitis is well documented. Common symptoms are sneezing, rhinorrhea, and nasal congestion. The prevalence of occupational rhinitis is unknown, but limited data indicate that occupational allergic rhinitis is more common than occupational allergic asthma. Symptoms may be immediate (within an hour of exposure) or delayed (late-onset symptoms 8 to 24 hours after exposure). Prolonged removal from work and re-exposure under close observation may be necessary to establish the link with the workplace. An IgE mechanism is likely for most rhinitis caused by exposure to high-molecular-weight protein allergens. The mechanism of rhinitis associated with low-molecular-weight chemicals is less certain, because skin tests and IgE antibodies may be negative in the presence of clinical sensitization. When possible, skin testing should be performed to establish the presence of a specific IgE allergy.

In Finland, nasal provocation testing is performed routinely at the Institute of Occupational Health. Of 300 to 400 annual provocation tests for rhinitis, occupational causes are diagnosed in approximately 10%, with flour dust being the primary allergen. Nasal provocation is rarely performed for occupational diagnosis in the US at present.

The prevalence of occupational allergic rhinitis is estimated to be 10% to 40% among exposed workers. It may occur alone or in conjunction with occupational asthma. Symptoms of rhinitis are less pronounced with low-molecular-weight agents, but more often appear before occupational asthma in the case of high-molecular-weight agents. In a survey of 474 laboratory animal workers, 17% had nasal symptoms repeatedly within 12 hours of contact with animals, with chest symptoms occurring in 9% and eye symptoms in 10%. Over 80% of patients with rat or mouse allergy have IgE antibodies to Rat n 1 or Mus m 1, which are lipocalin rodent urinary protein allergens. A cross-sectional study of 218 dock workers occupationally exposed to green coffee beans reported a 9% prevalence of work-related oculorhinitis, a 4% prevalence of both oculorhinitis and asthma, and a 1% prevalence of asthma.²⁵ A cross-sectional study of workers exposed to phthalic anhydride showed symptoms of rhinitis in 40% of the heavily exposed workers and 20% of the low-exposure workers.²⁶ Specific IgG antibodies were significantly elevated in the former group. Guar gum causes rhinitis.²⁷

Limited studies have focused on the pathogenesis of occupational rhinitis. Studies of rat-allergic workers showed that challenge in a rat vivarium was associated with nasal symptoms and increases in nasal lavage histamine and TAME esterase activity, indicating mast cell activation.²⁸ The allergenic agent is a protein in rat urine, and immediate skin test results were positive in sensitized individuals. The studies confirm that laboratory animal rhinitis is a classic IgE-mediated reaction. A dose-response relationship was demonstrated between the allergen concentration and the response. Cage cleaning resulted in the highest air-borne concentrations of allergen. Recently, it has been recognized that galactomannans, high polymer carbohydrates, may also trigger an IgE-mediated response.

Articles describing occupational asthma commonly allude to the presence of concomitant upper respiratory symptoms. The list of causative agents for occupational asthma (see Chapter 19.2) should be considered a list of potential agents for occupational allergic rhinitis.

Inhalation of latex from powdered gloves can cause rhinitis in latex-sensitive persons. These reactions have been described in workers in healthcare and rubber-glove manufacturing facilities. The majority of latex-allergic individuals are atopic, with seasonal allergic rhinitis and allergic asthma.

Diagnosis Diseases such as occupational allergic rhinitis are recognized by the clinical pattern and confirmed by specific skin tests. When sensitization to a workplace agent is suspected, the causative agent may be a well-established sensitizer (see Table 20.3.3). However, new sensitizers are still being reported; therefore, a clinical diagnosis of sensitization may necessitate an evaluation of a compound.

Protein allergens

Laboratory animals
Guar gum (galactomannans)
Psyllium
Coffee beans
Grain mites
Grain dust
Flour dust

Low-molecular-weight chemicals

Western red cedar (plicatic acid)
Trimellitic anhydride
Phthalic anhydride
Isocyanates

Other

Sodium isononyl oxybenzene sulfonate
Carbonless copy paper
Permanent wave solution

The list of agents causing occupational asthma (see Chapter 19.2) should be consulted for other possible causative agents. Common environmental allergens that may be present in the occupational environment include cat (brought in on the clothes of workers with domestic cats), dust mite, roach, rodents, and pollens from grasses, trees, and weeds. A local allergist should be consulted about the regional allergens and their expected seasons.

Table 20.3.3 Upper respiratory sensitizers

Companies should be notified when their products trigger specific reactions in patients. Permissible exposure limits are essentially irrelevant in evaluating cases of allergic rhinitis or other sensitization because exposure well below allowable limits may cause significant disease.

Treatment and prevention For occupational asthma, allergen avoidance is recommended because the prognosis is related to the duration of symptomatic exposure. It is plausible that a similar relationship for prognosis exists for occupational rhinitis, but this has not been established. It is our impression that, at present, medical removal for occupational allergic rhinitis occurs only sporadically. Environmental control measures can include providing adequate ventilation, enclosing open operations, automating hand operations, supplying space suits, and providing glove boxes.

The first line of treatment for allergic disease is allergen avoidance. This standard recommendation needs to be placed in the context of the realities of the workplace. Antihistamines are most helpful for the treatment of allergic symptoms and may be tried for chronic rhinitis. They are ineffective for the treatment of chronic nasal congestion unless combined with a decongestant. The sedating side effects of antihistamines may create a workplace hazard. Jobs should be reviewed to determine whether motor coordination or alertness is important. Problems with sedation can be minimized by using desloratidine (Clarinet), fexofenadine (Allegra), azatadine (Trinalin), or antihistamines from the alkylamine or ethylenediamine classes, administering a long-acting antihistamine at bedtime, or combining a decongestant with an antihistamine.

Avoidance of antihistamines can often be achieved by the use of inhaled nasal corticosteroids. The topical steroids have been shown to be safe and highly effective. They block the inflammatory cell influx that occurs in the late-phase IgE response. Intranasal antihistamines such as azelastine hydrochloride (Astelin) are effective in treating the symptoms of allergic rhinitis. Intranasal cromolyn sodium (Nasalcrom), too, is safe and effective in the management of seasonal and perennial allergic rhinitis, and is considered first-line treatment for managing allergic rhinitis during pregnancy. A trial of cromolyn sodium is merited in cases of non-allergic rhinitis with eosinophilia because there are mixed opinions as to its efficacy in this condition.

Allergen immunotherapy is effective in the treatment of seasonal allergic rhinitis caused by pollens and in perennial allergic rhinitis caused by dust mites and molds. It can affect the natural course of the disease and is indicated in allergic individuals who are inadequately controlled on medications or who experience undesirable side effects from medications. Such therapy is given for a period of 3 to 5 years.

Irritant rhinitis

Epidemiology Irritant rhinitis is defined as rhinitis symptoms induced by dusts, chemicals, or fumes that are noxious to tissues. Irritation can occur to a wide range of aerosols, gases, and vapors, including inert dusts. The

mechanisms of activation of the sensory irritant receptor are reviewed in detail by Nielsen.²⁶ Irritation can describe only a symptom, but usually it also implies a non-specific inflammatory response. A respiratory irritant that mainly affects deeper structures, such as ozone, often causes large airway and nasal inflammation characterized by plasma exudation. Very soluble gases and dusts with a diameter greater than 10 μm tend to produce sinusitis and nasal irritation.

Mixtures of chemicals may induce symptoms and/or nasal neutrophilia, although individual components of the mixture would be expected to be inert. Sick-building syndrome is a term that applies to a constellation of symptoms occurring in non-industrial worksites, for which the cause is unknown (see Chapter 50). The symptoms encountered in the sick-building syndrome include irritation of the eye, nose, and throat; dry mucous membranes and skin; erythema; mental fatigue; headache; airway infections; cough, hoarseness of the voice, and wheezing; unspecific hyper-reactivity reactions; nausea; and dizziness. Studies point to a high prevalence of work-associated upper respiratory symptoms in some office buildings. The mechanism of these symptoms is often unknown, but nasal symptoms consistent with an irritant mechanism may be a prominent part of the symptom complex.

Exposure to a common mixture, ETS, provokes symptoms of irritation in many individuals. Eye irritation is more common than nose and throat irritation, although both have been demonstrated at low concentrations of smoke (e.g., 1 ppm of carbon monoxide [CO]). Many patients also report that they are allergic to tobacco smoke. Studies of this condition have confirmed ETS-induced rhinitis in some subjects but indicate that an allergic mechanism is not responsible. A history of one or more symptoms of rhinitis (rhinorrhea or congestion) with historic ETS exposure was reported by one-third of a group of healthy young adults.²⁹ Controlled challenge studies with a brief high level of smoke confirmed the occurrence of nasal congestion in the subjects with a history of ETS sensitivity but not in historically ETS-non-sensitive individuals. Nasal lavage studies following smoke exposure did not show elevations of histamine (indicating that mast cell activation was not occurring), or of albumin (indicating that an increase in vascular permeability was not occurring), or of TAME esterase activity (indicating that glandular secretion was not occurring). These data suggest that non-allergic vascular congestion is responsible for the increased nasal resistance. Controlled challenge to tobacco smoke at moderate doses of smoke (15 ppm CO for 1 hour) caused congestion in both study groups; HEPA filtration of the smoke decreased congestion only in ETS-non-sensitive individuals. The urinary cotinine/creatinine ratio did not correlate with the magnitude of the congestive response, suggesting that host factors, not altered dose, were responsible for the differential response. It is unknown whether differential acute responsiveness relates to a differential risk of chronic exposure.

Some individuals report the onset of chronic rhinitis following an acute high-level irritant exposure. One exam-

ple was a 16-year-old youth who opened a container of large swimming-pool chlorine tablets that had been left in the sun. He had immediate nose and chest irritation with paroxysmal coughing. Since that time (2-year follow-up), he has had chronic non-allergic rhinitis without lower respiratory symptoms or methacholine hyper-reactivity. Greater than 95% of inhaled chlorine is absorbed in the upper airway. In animal studies, nasal lesions were observed following chlorine exposure.

Exposure limits for some irritants were established based on the relative potency of the chemical as determined by the animal model of Yves Alarie.^{30,31} The concentration of a chemical causing a 50% inhibition in the respiratory rate (RD50) was established in a mouse inhalation challenge model. The threshold limit value was set as 10% of that value. The rank order of chemicals by RD50 in mice has been shown to be fairly similar to the rank order of chemicals by irritant symptoms in humans. It is interesting to note that differences exist in the RD50 of different inbred strains of mice to a single chemical. Differential sensitivity to irritants in humans has also been documented. It is also worth mentioning that the Alarie RD50 mouse bio-assay does not consider the ability of the chemical to induce inflammation or long-term tissue damage. Despite these limitations, the Alarie method has provided a practical approach to ranking irritants and suggesting exposure levels.

Changes in air quality related to air-borne pollutants may be a factor contributing to the severity of upper airway disorders (see Chapter 51). Chronic alterations of the normal structure of the nasal mucociliary apparatus may have adverse effects on the nasal defense mechanisms that protect the upper respiratory tract tissues from potentially harmful levels of inhaled irritant gases, dusts, and bacteria. The nature of the lesions in toxicity studies with volatile chemicals in rodents varied with the duration of exposure.²⁰ In short-term exposures, degeneration and regeneration of the affected olfactory mucosa were frequently seen. With long-term exposure, basal cell hyperplasia and respiratory metaplasia were observed. The human nasal mucosa is susceptible to ozone toxicity. Acute inflammation is induced in the nasal airways after exposure to this highly reactive irritating gas. Long-term ozone exposure causes mucous cell metaplasia and epithelial hyperplasia in the surface nasal epithelium of rats. These changes persist for weeks and months after the end of a chronic exposure. A study in a Mexico City population showed a strong correlation between histopathologic changes in the nose and nasal symptoms.³² Residents complained of epistaxis, rhinorrhea, nasal crusting, dryness, and nasal obstruction. Nasal biopsies showed patchy shortening of cilia, basal cell hyperplasia, deciliated areas, and squamous metaplasia. Dysplastic lesions were predominantly located on antral squamous epithelium and in squamous metaplastic epithelium of the posterior inferior turbinates, and they exhibited p53 nuclear accumulation. Individuals with more than 10 hours of daily outdoor exposure for 5 years or more had the highest rate of dysplasia. Subjects with epistaxis were more likely to

have dysplasias and neovascularization. The results of this study suggest that nasal lesions in Mexico City residents are possibly related to toxic and carcinogenic pollutants such as ozone, aldehydes, and particulate matter.

Major sources of inhaled pollution in industrialized cities are diesel exhaust particles (DEPs) and their associated polyaromatic hydrocarbons (PAHs). DEPs make up 40% of the particles less than 10 μm (PM10) in a big city. In-vitro models of human airway epithelial cells have shown that DEPs undergo phagocytosis and induce a specific inflammatory response, with an increase in IL-8, granulocyte-macrophage colony-stimulating factor, and IL-1 beta. Experiments in guinea pigs have shown that DEPs significantly enhance histamine-induced vascular permeability and increase eosinophil infiltration into the nasal mucosa. Thus, DEPs may play an important role in promoting nasal hyperactivity by enhancing antigen absorption through the nasal mucosa and increasing eosinophil-induced inflammation. DEPs also upregulate histamine H1 receptor expression in human nasal epithelial cells and mucosal endothelial cells. DEPs have several effects on the human in-vivo allergic response. They enhance local mucosal IgE production, induce an inflammatory response of cells, chemokines, and cytokines, and thereby exacerbate allergic inflammation. PAHs enhance local mucosal IgE production without a measurable cellular inflammatory response. DEPs in combination with an allergen such as ragweed enhanced local antigen-specific IgE production.³³ Following the combined challenge, there was a deviation of cytokine production toward a TH2 profile with an increase in IL-4 and a decrease of IFN-gamma. Exposure to DEPs can enhance the clinical symptoms to an allergen by enhancing mast cell degranulation as well as modify the nature of the subsequent immune response. In humans with ragweed allergy, a combination of DEPs and ragweed allergen is capable of driving in-vivo isotype switching to IgE. DEPs also act as mucosal adjuvants in a de-novo IgE response in humans and increase allergic sensitization. Thus, DEPs not only play a role in exacerbating pre-existing allergic antibody responses and allergic inflammation but can also be a factor in driving primary sensitization to inhaled allergens in human subjects.

Diagnosis Work-related mucosal irritation is a diagnosis that must often be made on a clinical basis alone because there are few diagnostic tools and the symptoms are often non-specific. Clinical findings of irritant rhinitis include erythematous obstruction, rhinorrhea, and postnasal drainage. Nasal cytologic findings are unremarkable or show neutrophils.

The occupational physician should interpret the recommended or legal limits for a chemical in the context of an assessment of an individual's sensitivity. Exposure levels below the recommended exposure limits may present problems for some otherwise healthy people and may additionally aggravate patients with any pre-existing conditions.

Periodic medical screening of groups of workers for upper respiratory irritant symptoms is indicated when a

known irritant is present or a new mixture or process is being used. The presence of symptoms can focus industrial hygiene attention on areas needing additional air sampling or ventilation. Physicians are often the ones who identify and recommend air sampling for a worst-case scenario. Industrial hygienists usually have an established sampling strategy for a specific area and try to define a representative exposure. Physicians should be aware that each of these approaches has merit.

Table 20.3.4 lists selected compounds that are nasal or respiratory irritants at varying levels of exposure. The compounds are grouped according to the permissible exposure limits as a rough guide to irritant potential. Carcinogens are so noted because this designation will lower the recommended exposure level independent of the irritant potential. Material safety data sheets should be consulted for information about other compounds. In the authors' experience, almost any substance may provoke symptoms in one individual or another. The symptoms, and the risk of continued exposure, must be weighed against existing information about the irritant potential of these agents. The occurrence of symptoms with low-level irritant exposures should provoke evaluation for mucosal inflammation of other causes (e.g., IgE-mediated disease). A professor of pulmonary medicine has remarked that, 'Each spring, when my hay fever acts up, I can't stand my wife's perfume'.

Treatment Meltzer and coworkers advise the practice of 'consistent avoidance of the irritant or nonspecific factors that may trigger symptoms in patients with chronic rhinitis'.³⁴ This recommendation needs to be placed in the context of the realities of the workplace and the options for alternative work.

The physician may believe it to be in the best interests of a patient to recommend adjustments in workplace ventilation or altered work practices, even when environmental assessment finds no evidence of increased concentrations of specific chemicals above threshold limit values. Medical removal may be indicated, particularly if the irritant symptoms are linked with other symptoms, such as severe headache, visual disturbances, or neurologic symptoms. An industrial worker who is significantly intolerant of the irritants or VOCs in his or her workplace may find the best long-term success by retraining for a non-industrial position.

Removal from irritant exposure may also be necessary when mucosal inflammation is severe. Adequate respiratory protection may be temporarily productive, but it should not substitute for engineering and process controls; one patient's problems with a particular process or material may herald a widespread future problem for other workers.

In the industrial setting, a fundamental preventive strategy is to follow the motto 'The solution to pollution is dilution'. However, if the point source is being handled by the worker, general ventilation may not reduce breathing-zone exposure. Irritating materials may be replaced by less toxic ones, or process enclosure can occur. Respiratory

protection may be effective when these strategies are impractical.

The relative efficacy of strategies to avoid widespread mucosal irritation in office buildings continues to be debated. There is general agreement that ventilation should meet the new American Society of Heating, Refrigerating and Air Conditioning Engineers standards, and point sources should be minimized (see Chapter 50). Strategies to accommodate sensitive or allergic individuals in the office setting may include bans on workplace smoking, the use of low VOC-emitting products, or the provision of individual offices with high-capacity portable air cleaners.

Air cleaners should be recommended only after careful thought. Improperly chosen air cleaners result in unnecessary expenditure and divert resources from more effective treatments. Anecdotal evidence suggests that properly chosen air cleaners can produce significant symptomatic improvement for some individuals with rhinitis triggered by specific exposures, such as ETS, or in buildings where cleanup is delayed. They also may be effective against small point source VOCs. However, a wide range of so-called air cleaners are marketed, and many are ineffective because of low flow rates or inadequate removal of pollutants. The recommended commercial testing program for air cleaners determines their efficacy for removal of particulates only. This ignores the important contribution of irritating vapors to indoor air symptoms. Some commercial air cleaners actually generate ozone to purify the air and may seriously exacerbate symptoms. Portable air cleaners usually have limited utility in pollen allergy because their capacity for particle filtration is often overwhelmed by the influx of allergen from the outside.

Other standard recommendations for medical management of upper respiratory disease are outlined subsequently. Vigorous exercise is a decongestant, and 15 to 30 minutes of exercise once or twice daily has been recommended for the nasal congestion that occurs in chronic rhinitis. Elevation of the head of the bed 30 degrees may reduce the nasal congestion that occurs with recumbency.

Nasal saline is an effective treatment for irritated tissue. Two sprays of commercially available buffered saline spray may be used four times daily. A less expensive option is to have patients mix one-quarter teaspoon of table salt with one cup (8 oz) of warm tap water and to snuffle it into the nose. A bulb syringe is preferred by some patients. A third option is a longer, higher-volume saline lavage using one teaspoon of salt with 800 ml of water administered with the nasal adapter of the Water Pik. Some physicians recommend putting petroleum jelly proximal to the nasal antrum to reduce irritant symptoms; it is unclear how this affects nasal epithelial morphology and nasal airflow. It should not be used as a substitute for point source reduction.

Intranasal decongestants are not advised for chronic use because they may induce rhinitis medicamentosa, which is iatrogenic nasal vasodilation and obstruction caused by the overuse of topical sympathomimetics. Topical decongestants may be used for 3 days for an acute viral illness,

Note: This list is primarily drawn from the NIOSH Pocket Guide to Chemical Hazards⁴⁰ and includes substances listed as causing 'irritation, laryngeal, mucous membrane, pharyngeal, or respiratory'. Compounds are grouped by the exposure limits (see text for explanation). NIOSH Ca means the substance should be considered a possible carcinogen (see Acheson⁴¹ for additional discussion of upper airway carcinogens). NIOSH D indicates substances for which NIOSH has questioned whether the permissible exposure limits are adequate to protect workers from recognized health hazards (see Pocket Guide, Appendix D).

Table 20.3.4 Upper respiratory irritants

for air travel, or at the initiation of steroid or cromolyn sodium therapy. Combination oral antihistamines and oral decongestants may be useful in the treatment of allergic rhinitis, eosinophilic non-allergic rhinitis, and nasal hyper-reactivity characterized by increased secretions.

Vasomotor rhinitis

Vasomotor rhinitis is characterized by nasal symptoms of vasomotor and secretory instability occurring in the absence of any defined cause or disorder. Clear rhinorrhea is present, IgE is low, and nasal cytologic findings are unre-

markable. Some physicians use this term to describe rhinitis provoked by a range of low-level VOCs. In this case, avoidance may decrease symptoms. Oral alpha-agonist decongestants can be helpful, but they remain unsatisfactory in 50% to 70% of patients. Runners (i.e., patients with predominant rhinorrhea) benefit from nasal ipratropium bromide. Low-dose tricyclic antidepressants show a response rate on the constellation of symptoms from 60% to 80%. Nasal steroids and antihistamines are not significantly useful. Saline lavage and exercise are also recommended.

Atrophic rhinitis

Atrophic rhinitis is defined as nasal symptoms resulting from aging or as normal nasal mucosa is replaced by squamous epithelium. Studies by Broder and coworkers of people living in homes with formaldehyde insulation demonstrated an increase in squamous metaplasia among the subset of people intending to remediate their homes. These individuals had an excessive range of symptoms, although patch tests were negative and nasal resistance was similar to controls.³⁵ More information is needed on the histology of the nasal mucosa in other populations chronically exposed to irritants.

Nasal ulcers

The compounds most commonly associated with nasal ulcers and perforations are listed in Table 20.3.5. Ulcers, other sores, and leukoplakia indicate potentially serious exposures. The characteristically painless and non-necrotic, non-heaped-out punch lesions of chromium exposure may

indicate the need for hematologic and air monitoring (see Chapter 39.5). Painful exudative lesions may indicate infection requiring antibiotics. All lesions not substantially resolved in 2 weeks and persistent leukoplakia merit referral to an otolaryngologist for evaluation and possible biopsy.

Periodic medical screening for workers exposed to substances affecting the upper respiratory tract may be indicated when the experience at a worksite indicates a risk. An example would be monthly inspection of the nasal septum in workers exposed to chromium dust. Topical anti-inflammatory treatment, respiratory protection, and medical removal are options when nasal ulcers are found. Formal group evaluation also becomes an important adjunct to individual assessment when screening workers routinely exposed to known irritants.

Laryngitis and related disorders

Laryngitis and cough

Laryngitis, or inflammation of the larynx, can be caused by the same list of conditions and exposures that cause rhinitis. A similar diagnostic approach is recommended, with two modifications. Symptoms of vocal abuse or gastric reflux should be sought in the history, and patients should be referred to an otolaryngologist for adequate visualization of the vocal cords. The primary differential diagnosis of persistent paroxysmal non-infectious cough includes cough-variant asthma, postnasal drip, and gastroesophageal reflux.

Voice disorders

Occupational voice disorders among speech and voice professionals are very common and these disorders often constitute a barrier to work performance. The primary risk factor in voice and speech professions is the need for prolonged use of the voice. Males have a 50% lower total number of vibrations than females. This may explain why female teachers report significantly more voice problems than males. Vocal nodules are also almost exclusively seen in females. Air quality, dryness, dust, and allergies can cause hoarseness. Exposure to ETS may contribute to some minor changes in vocal fold structure and physiology.³⁶ Videostroboscopic evaluation revealed mild edema and erythema in passive smokers. Smoking cigarettes leads to chronic irritation and an increase in vocal fold mass. Sidestream smoke carries more free nicotine and higher values of such substances as CO, benzene, NO, and ammonia. ETS has also been linked to the development of laryngeal carcinoma. Vocal cord paralysis has also been reported following lymph node involvement by silicosis.

Upper airway obstruction

Laryngeal edema is a potentially life-threatening complication of inhalation injury caused by thermal burns, irritant chemicals, and smoke inhalation. The obstruction may develop up to 48 hours after the injury, and in-hospital observation is prudent. A case report described

Ulcers/perforated nasal septum

Arsenic
Calcium oxide
Chromic acid and chromates

Epistaxis

Warfarin
Pindone (tert-Butyl valone)

Rhinorrhea (with miosis, lacrimation, and salivation)

Carbaryl
EPN (Ethyl p-nitrophenyl benzene thionophosphonate)
Malathion
Parathion
Phosdrin
Pyrethrum
TEDP (Tetraethyl dithiopyrophosphate)
TEPP (Ethyl pyrophosphate)

Blue-gray nasal septum

Silver

Numb mucous membrane

Rotenone
DDT (Dichlorodiphenyltrichloroethane)

Edema on nasal folds

Nitramine

Stomatitis

Mercury vapor

Table 20.3.5 Miscellaneous occupational upper respiratory effects

reversible obstructive sleep apnea caused by occupational exposure to guar gum dust, presumably related to pharyngeal edema.³⁷

A case report by Sales and Kennedy details epiglottic obstruction related to diisocyanate exposure.³⁸ A 34-year-old non-atopic, non-smoker began making award plaques with 65% methylene diisocyanate (MDI). One week later, he was treated for fever, diaphoresis, chest pain, and nasal congestion. Subsequent evaluation showed persistent asthmatic symptoms and marked epiglottic dysfunction with aspiration demonstrated by barium contrast cineradiography. Total epiglottectomy resolved the upper airway symptoms without altering asthmatic symptoms. Histologic examination of the excised epiglottis showed marked chronic submucosal inflammatory changes with focal fibrosis, edema, and reactive changes.

Extrathoracic airflow obstruction and chronic laryngo-tracheitis have been described in some Persian Gulf War veterans.³⁹ Veterans complained of cough, shortness of breath on exertion, and sleep disturbances. Histologic examination of the upper airways showed chronic inflammation with mononuclear cells and thickening of the basement membrane; sampling data indicated exposure to PM10 (fine particulate) levels seven- to eightfold higher than the Environmental Protection Agency standards.

Biologic weapons such as anthrax can also affect the airways, and physicians should be aware of that potential.

Chapter 21

Disorders of the Blood and Blood-Forming Organs

Ben Hur P Mobo Jr, Mark R Cullen

The vulnerability to exogenous poisons of the circulating blood cells and the stem cells from which they evolve has been well established for over a century. Heavy metals, solvents, ionizing radiation, pesticides, and a wide range of reactive organic chemicals have all been implicated in the cause of primary hematologic disturbances. Although not all of the major hematologic diseases have established environmental or occupational causes, many do.^{1,2} The most important of these are summarized in Table 21.1, along with a list of agents known to cause them.

Although the mechanisms of injury for most of the diseases remain incompletely understood, the basis for prevalent and well-recognized effects on this target organ is apparent. First, although circulating cells and the bone marrow are not intimately connected to a portal of entry for toxins like lung or skin, all agents that enter the systemic circulation have at least brief contact with blood and marrow at concentrations reflecting systemic absorption, which are considerably higher than those that reach other targets such as the nervous system or other visceral organs. Second, because all cell lines except for some lymphocytes are extremely short lived and turn over rapidly, even mild effects on cell survival or production are likely to result in measurable abnormalities. Finally, because blood is so readily and frequently subject to evaluation, and because normal values are so tightly controlled under physiologic conditions, subclinical effects are more readily detected than for virtually any other organ system.

Many of the toxins that have an impact on hematologic function also have effects on other target organs, as is evident from Table 21.1. However, circulating blood cells or bone marrow often represent the first and/or most severely affected tissues, even in systemic poisonings. Appropriate evaluation of hematologic disturbances, however apparently mild or inconsequential, merits consideration of occupational or environmental causes. Moreover, identification of a cause, such as an abnormal hemoglobin or congenital enzymatic defect, should not discourage a thorough examination of environmental factors. As will be seen, individuals with such underlying host factors are potentially more susceptible to exogenous insult that may at once be life threatening and readily amenable to amelioration by environmental control or avoidance.

CLINICAL EVALUATION

History

Hematologic disorders may have protean clinical presentations, ranging from asymptomatic to the conspicuous and life-threatening consequences of markedly depressed levels or function of one or more cell lines. Although classic symptoms of anemia (fatigue, pallor, dyspnea), neutropenia (infection, fever, sore throat), and thrombocytopenia (ecchymoses, bleeding) may be evident in severe cases, other manifestations also must be considered, including skin discoloration (jaundice, acrocyanosis), change in urine color (hemoglobinuria), or abdominal pain associated with hemolysis or enlargement of the liver and spleen. Often, the history alone is inadequate to target hematologic dysfunction, which becomes apparent based on physical and laboratory findings.

The search for environmental etiologies depends on the nature of the disturbance identified or suspected. Clues should always be sought to effects on other organs such as the nervous system, gastrointestinal (GI) tract, and skin, that might turn suspicion toward heavy metals, solvents, or pesticides. Another important issue is the timing of possible exposures of interest. Acute or subacute disturbances of circulating cells, such as hemolysis, usually can be traced to very recent exposures if the environment is responsible. Recent changes in job or activity, the introduction of a new chemical into the environment, or the occurrence of an accidental overexposure or spill should be actively sought in the history and pursued if the sequence of events suggests a cause-and-effect relationship. Because the circulating cells have half-lives that are measurable in hours (for neutrophils), days (for platelets), and months (for red cells), historic or more chronic exposures are unlikely to be the cause unless some change in dose or form of exposure has occurred. However, with the exception of massive or accidental overexposures, the temporal association between exposure to agents with potent effects on circulating cells and consequent clinical manifestations is rarely so obvious – unlike the case with some occupational lung or skin disorders – that it will occur to the patient. For example, a worker newly hired in a lead-exposed job may not develop hemolysis until enough lead has accumulated to cause acute poisoning, typically after several weeks or months. Similarly, a glucose-6-phosphate dehydrogenase (G6PD)-deficient

Disorder	Representative causes
Methemoglobinemia	Aniline, nitrites
Hemolytic anemia	Arsine, lead, trinitrotoluene
Hypoproliferative anemia	Lead, trimellitic anhydride
Secondary polycythemia	Cobalt, carbon monoxide
Thrombocytopenia	Turpentine, chlordane, polyurethane
Aplastic anemia	Benzene, ionizing radiation
Myelodysplastic syndrome	Benzene, nitrogen mustard
Myelofibrosis	Ionizing radiation

Table 21.1 Hematologic disorders caused by environmental agents

person beginning employment in a pharmaceutical house may work for months before having contact with a potent oxidant that precipitates an acute hemolytic crisis. In general, therefore, the task of connecting the environment to the disturbance, however acute, requires thoughtful reconstruction by the treating physician.

At the other end of the disease spectrum, effects on the bone marrow itself, such as hypoproliferative, dysplastic, or neoplastic processes, are more consistent with a long-standing exposure to a culprit known or suspected to be causal, such as benzene or ionizing radiation. It also must be remembered that unlike the circulating cells, the response of bone marrow to injury at one point in time may result in later consequences that follow a prolonged period of apparently normal hematologic function. Thus, it is well described that individuals who have worked in the past with potent leukemogens such as benzene may appear well by all parameters for many years, only to develop subsequently a myeloproliferative process or leukemia.

For such chronic conditions, questions such as 'Have you *ever* been exposed to. . .?' are appropriate, and a thorough lifetime review is in order when evaluating those conditions that have well-established environmental causes. Whenever possible, additional historical clues to possible dose of exposure should be sought as well. For example, if someone had been exposed to benzene, it would be valuable to know whether or not he or she had experienced any of the typical acute solvent effects on the central nervous system (CNS). The early occurrence of GI or dermal effects likewise is a clue to an excessive dose of arsenicals in the appropriate settings. Most often, unfortunately, such historical exposures can only be indirectly inferred from the nature of the patient's contact, its duration, and the physician's knowledge of the particular industry or environmental setting.

Physical examination

The physical examination may offer valuable clues to both the presence of a hematologic disorder and its etiology. Pallor, jaundice, or signs of high-output congestive heart failure suggest the possibility of severe anemia. Disorders of platelets usually result in petechiae or ecchymoses when the absolute count drops below 20,000/mm³ or when platelets are functionally impaired. Splenic enlargement, with or without coincident hepatic enlargement, is a hallmark of many myeloproliferative disorders

and also is evident in certain chronic hemolytic anemias. Acrocyanosis is the major clue to the presence of methemoglobinemia that might elude detection if this sign is overlooked.

Because the agents that most predictably cause hematologic disturbances may affect other organs as well, a careful search for signs of these effects may be rewarding. Examples include the dermal effects of arsenicals (hyperkeratoses, pigmentary changes) and organochlorine pesticides (chloracne, porphyria cutanea tarda), or the neurologic effects of arsenic or lead (peripheral neuropathy). On the other hand, the sensitivity of most such signs in the setting of hematologic disorders is low, so the absence of such signs should not discourage careful history taking and the appropriate use of laboratory tests to identify causal agents or markers of their effects.

Laboratory evaluation

As noted earlier, hematologic function is highly amenable to laboratory investigation because of its constancy over time (i.e., the timing of samples is generally unimportant), and, because of the uniformity of most parameters in the healthy population, the ranges of normal generally are narrow. For these reasons, one rarely needs multiple specimens or access to a previous specimen from the same individual to interpret a complete blood count (CBC), differential count, or peripheral blood smear. On the other hand, rarely does this basic test battery provide strong evidence of an environmental basis for disease. Although such findings as basophilic stippling (due to lead) or Heinz bodies (due to oxidant stresses) may point toward a toxic etiology, these findings are non-specific.

Beyond the CBC, a wide range of tests are readily available that may allow precise definition of a disease process if not its cause. Evaluation of reticulocyte count, serum and urine hemoglobin, haptoglobin, and direct and indirect bilirubin generally allows classification of anemias into those that are hemolytic and those that result from inadequate marrow production. Various immunologic tests such as the direct Coombs' test may allow differentiation of peripheral destructive processes into immune versus non-immune bases; similar tests now exist for evaluating rapid platelet turnover. The effects of nutritional deficiencies and chronic disease states, such as chronic inflammatory processes or renal, endocrine, and liver disease, generally can be excluded by simple blood tests as well. Bone marrow aspiration discriminates major causes at that site, where the production and maturation of myeloid and megakaryocyte precursors to neutrophils and platelets occur. The addition of a biopsy and cytogenetic study may provide highly accurate pathophysiologic classification and prognostication. Unfortunately, environmental effects on blood are so similar to the effects caused by infection, systemic disease, and idiopathic disorders that none of these more sophisticated tests provides direct evidence of a toxic etiology. Rather, the role of such testing is to establish the basis of the lesion physiologically and to exclude non-environmental causes, if possible. The

laboratory must be used in a different way if etiologic clues to an environmental factor on the history or the physical examination are to be confirmed. For many agents of interest, such as heavy metals or pesticides, the most valuable approach is direct assessment of the toxin or its metabolites in blood or other body fluids. Indirect evidence may be obtainable by examination of metabolic consequences associated with the agent, for example, the inhibition of various enzymes of porphyrin synthesis caused by lead or organochlorine compounds.

Although these approaches to confirmation of an etiologic agent are useful for culprits that are either long lived in the body (e.g., organochlorine pesticides, heavy metals) or produce their effects very shortly after exposure occurs (e.g., aromatic amines), the laboratory is less useful for pinpointing historical causes of chronic diseases, such as the myeloproliferative states caused by benzene or ionizing radiation. At the present time, there are no specific markers for these important etiologies and evaluation ultimately hinges on recognition of the appropriate disease state combined with knowledge of exposure parameters, including intensity, duration, and latency.

CLASSIFICATION

A classification of non-malignant hematologic disorders follows.

DISORDERS OF SINGLE CELL LINES

Red cells

Methemoglobinemia

Anemias

Hemolytic anemias

Intravascular hemolysis

Extravascular hemolysis

Hypoproliferative anemia

Polycythemia

Platelets

Thrombocytopenia

Peripheral destruction

Hypoproliferation

Other platelet disorders

Disorders of white blood cells

Neutrophils

Eosinophils

Lymphocytes

DISORDERS OF STEM CELLS AND MICROENVIRONMENT

Hypoplastic and aplastic anemia

Myelodysplastic syndromes

These disorders are discussed in detail throughout the rest of this chapter.

DISORDERS OF SINGLE CELL LINES

The most frequently encountered environmental effects on blood are those that affect circulating cells. Injury may occur at any stage in the lifespan, ranging from maturation within the bone marrow through premature senescence within the vasculature or in the reticuloendothelial system. Because all the major cell lines turn over rapidly, these disorders almost invariably reflect the recent effects of toxins or other injurious agents; often, the culprit is still detectable in body tissue, which may aid the examining physician considerably in the differential diagnosis.

Disorders of red blood cells

Methemoglobinemia

Oxidation of the iron in hemoglobin without oxygen binding results in an altered hemoglobin molecule that is almost black in color and functionally limited. A wide range of organic chemicals, mostly of the aromatic nitro and amino groups, are capable of causing the formation of methemoglobin in clinically significant quantities.³ Although the condition has been best described in workers making dyestuffs and explosives, a wide range of chemicals have been implicated, including phenylpropanolamine.⁴ More common causes of chemical-induced methemoglobinemia are listed in Table 21.2.

Pathogenesis The iron in hemoglobin is normally maintained in the reduced state, as ferrous or Fe⁺² iron. Although iron in hemoglobin has the remarkable property

Agent	Setting of exposure
Aromatic nitro and amine compounds	
Aminophenol	Fur making
Aniline	Dyes, pharmaceuticals
Chloroaniline	Plastics
Dinitrobenzene	Dyes, explosives
Dinitrotoluene	Dyes, explosives
Naphthalamine	Dyes, explosives
Nitroaniline	Dyes
Nitrobenzene	Dyes, explosives
Nitrotoluene	Dyes, explosives
Phenylpropanolamine	Pharmaceuticals
Trinitrotoluene	Explosives
Toluidine	Dyes, chemicals
Aliphatic nitro compounds, nitrates, nitrites	
Ethylene glycol dinitrate	Explosives
Nitroglycerin	Explosives, pharmaceuticals
Nitropropane	Chemicals, coating
Organic and inorganic nitrites	Pharmaceuticals, chemicals
Miscellaneous	
Antimalarials	Pharmaceuticals
Chloramphenicol	Pharmaceuticals
Sulfa drugs	Pharmaceuticals
Naphthalene	Moth balls
Nitrofurantoin	Pharmaceuticals

Table 21.2 Environmental causes of methemoglobinemia and/or oxidant-induced hemolysis

of being able to combine directly with oxygen while maintaining this reduced form, other oxidants (see Table 21.2) may directly oxidize the iron to the ferric or Fe^{+3} state without binding of oxygen. Unopposed, this alteration leads to two important functional changes:

- a sharp leftward shift in the oxygen dissociation curve of neighboring normal hemoglobin molecules (limiting delivery of oxygen to tissues); and
- denaturation of hemoglobin altogether, leading to development of inclusions called Heinz bodies, which can destabilize the red cell membrane and lead to hemolysis (see the section on Hemolytic Anemias).

Obviously, if the proportion of hemoglobin in the Fe^{+3} state rises, the total oxygen-carrying capacity of blood also is directly decreased, because methemoglobin is unable to carry oxygen.

In the normal person, there are no fewer than four separate enzyme systems that may oppose the oxidation of hemoglobin to methemoglobin.⁵ The most important system is rate-limited by the enzyme nicotinamide-adenine dinucleotide (NADH) methemoglobin reductase, or cytochrome *b5* reductase. Under normal circumstances, this system scavenges almost all of the methemoglobin formed by physiologic oxidants or low-level chemical exposures. Rare individuals with congenital methemoglobinemia have deficiencies in this system and are somewhat blue in color.

When the NADH methemoglobin reductase system is overwhelmed, NADPH generated by the alternative glucose-metabolizing pathway (Emden-Meyerhof pathway or hexose monophosphate shunt) may reduce methemoglobin. However, to be quantitatively effective, an additional redox transfer factor is necessary. Methylene blue is the usual therapeutic choice (see later) to serve this role. The shunt must be intact to work, however, because once methylene blue is oxidized, it can serve as a further oxidant stress itself unless it is quickly reduced by NADPH. The rate-limiting enzyme in this pathway is G6PD, which is, unfortunately, congenitally deficient in a high proportion of black and Middle Eastern populations.

Two other pathways exist to reduce methemoglobin back to the ferrous form. One involves reduced glutathione, and the other involves ascorbic acid. These pathways are probably of limited physiologic importance and as yet have not been found to have any therapeutic applications.

Clinical manifestations and diagnosis The major effects of methemoglobin in increased concentrations are acrocyanosis and asphyxiation. The onset often is insidious because exposure may result transdermally or through gradual accumulation over several days. Fatigue, dyspnea, palpitations, headache, or abdominal distress may precede recognition of cyanosis.⁶

The hallmark for diagnosis is recognition of cyanosis, which begins in acral areas. Blood obtained from an artery or a vein is very dark and *does not turn red on exposure to the air*, a distinguishing feature of cyanosis due to hypoxemia. Arterial blood gases may reveal a normal PO_2 even when

the amount of methemoglobin starts to exceed 30% of total hemoglobin, the level at which major organ damage becomes likely in otherwise healthy individuals. Usual tests such as blood chemistries and an electrocardiogram generally do not help distinguish between hypoxemia and methemoglobinemia. The most important test is direct measurement of methemoglobin – a test that is fast, easy, and cheap, but it is not routine and must be ordered. Another important diagnostic test is a CBC and reticulocyte smear, which is used to search for evidence of hemolysis that often is caused by the same oxidants, as indicated by Heinz body formation (see the section on Hemolytic Anemias).

Having confirmed the diagnosis, there is generally little reason to identify the causal agent in body fluids, although the agent usually still is present. When there is no clear history of exposure or when multiple possible agents are present in the environment, samples of blood and urine and a gastric aspirate may be helpful. The gastric aspirate is particularly useful for the detection of covert or accidental ingestion, which is well described.

Management The principles of management are straightforward. First, 100% oxygen should be delivered while results of tests are pending. Next, the patient should undergo skin decontamination by thoroughly washing the entire body because dermal contact is an important route of exposure in the industrial setting. If there is suspicion of ingestion, gastric lavage, followed by the administration of charcoal and cathartics, is appropriate.

If the methemoglobin level exceeds 20% or the patient is markedly symptomatic, methylene blue should be administered in 1% intravenous solution, over about 10 to 15 minutes, to a dose of 1 to 2 mg/kg. The medication must be given with some caution, especially in patients who may be G6PD deficient, in whom it could cause the formation of more methemoglobin or precipitate further hemolysis.⁷ The effect is rapid, peaking within 1 hour, at which point the dose may be repeated orally or intravenously. Patients should be monitored closely until the methemoglobin levels are well below 20% and to ensure that no rebound effect has occurred after stopping the methylene blue.

Finally, evidence of coincident hemolysis must be searched for and managed, as discussed later. The key is maintenance of adequate hemoglobin and good renal function. When methemoglobinemia and hemolysis coexist in major degrees, consideration should be given to exchange transfusion as a lifesaving means to establish adequate tissue oxygenation.

Prevention The key to prevention is the use of primary strategies – strict control of air levels and scrupulous measures to avoid skin contact because many of these agents, such as aniline, are rapidly absorbed through intact skin. As a backup strategy, it is appropriate to measure CBC, reticulocyte counts, and methemoglobin levels periodically and even more frequently in new workers whose sensitivity to the effect is not characterized and whose

experience with these toxins may not be adequate. There is debate in the literature regarding the efficacy of excluding individuals from exposure altogether based on baseline or pre-placement levels of the enzyme G6PD. Many, if not most, with mild-to-moderate deficiencies, as are common in the black population, have worked around these chemicals without any adverse or disproportional effect, probably owing to the complexity of the heme reduction mechanism. On the other hand, it is probably reasonable to exclude from further exposure any G6PD-deficient individual who has developed a significant degree of methemoglobinemia under routine working circumstances (i.e., levels > 5% to 10%). In such cases, the worker has provided biologic evidence of sensitivity and further exposure presents an unacceptable level of risk.

Anemias

Hemolytic anemias Hemolysis, or shortened red cell lifespan, is a common effect of a diverse range of environmental and occupational exposures. Following the usual clinical convention, we classify them here based on their clinical presentations.

Intravascular hemolysis Premature destruction of red blood cells within the vasculature has been described in three important environmental or occupational exposure settings:

- as a consequence of overexposure to the gases *arsine* (AsH_3) and *stibine* (SbH_3) (Chapter 39.2);
- in association with other clinical consequences of *acute lead poisoning* (Chapter 39.7); and
- as a consequence of *repetitive trauma of the hands or feet against a hard surface*, so-called march hemoglobinuria.

Because the mechanisms and presentations differ markedly, these conditions are discussed separately. Intravascular hemolysis also has been reported in association with *angiosarcoma of the liver*, a rare tumor usually associated with an environmental cause such as vinyl chloride monomer, arsenicals, and thorium (see Chapter 30.6).

HEMOLYSIS DUE TO ARSINE AND STIBINE

Pathogenesis These gaseous metal compounds (AsH_3 , SbH_3) are highly reactive and bind to multiple sites in the red cell, including the membrane, oxyhemoglobin, and virtually all free sulfhydryl groups.⁸ The integrity of the membrane is impaired by disruption of sodium-potassium pump channels, as well as by depletion of glutathione. The net effect is loss of osmotic balance of the cells, swelling, and intravascular lysis. Although some portion of these compounds is oxidized to the highly toxic metals arsenic and antimony, the role that these metals play in the acute hemolytic reactions is unclear but is probably of secondary importance.⁹ In most cases, the acute hemolytic effects and their consequences, such as reduction in effective oxygen transport, sludging of red cell debris in the circulation, and the outpouring of free hemoglobin into plasma, dominate the clinical picture, which bears little resemblance to acute poisonings with these metals in other forms (see Chapter 39.2).

Clinical manifestations and diagnosis Because these gases are not particularly irritating, there may be no evidence of an acute reaction for several hours after an accidental exposure. The onset of hemolysis is heralded by non-specific GI and neurologic symptoms such as headache, dizziness, nausea, and abdominal or flank pain. Shortly thereafter, the evidence of darkened urine and a jaundiced appearance to the skin marks the classic clinical presentation of acute intravascular hemolysis.¹⁰ There is no clinical history or physical examination findings that distinguish the picture from acute hemolysis of other causes, such as transfusion reaction.

Initial laboratory evaluation is consistent with intravascular hemolysis: low hematocrit, low or absent haptoglobin, free hemoglobin in plasma and urine, and dramatic elevation of lactate dehydrogenase (LDH). The peripheral smear initially may show fragmentation of cells, as well as anisocytosis and poikilocytosis. There may not be striking reticulocytosis early in the course of the disease in view of the rapidity of onset of the reaction and possibly also the myelosuppressive effects of arsenic itself; leukocytosis is commonly seen, but platelet count may be low, suggesting disseminated intravascular coagulopathy or hemolytic-uremic syndrome. Diagnostic tests such as direct Coombs' or tests for fibrinolytic factors (e.g., fibrin split products) are negative.

The most striking and clinically important extra-hematologic signs and laboratory findings are related to renal function, which is generally affected early by hemoglobin in plasma. Evidence of early acute tubular necrosis may be seen by rising blood urea nitrogen (BUN) or serum creatinine and failure to conserve sodium appropriately; oliguria or even anuria is usually evident within a day. There are no pathognomonic findings for a toxic etiology unless a sample of urine is sent to the laboratory for measurement of levels of the base metals, which may be elevated if determined before renal failure is profound.

In addition to renal injury, other findings may include hepatomegaly with slightly elevated enzymes and diffuse CNS dysfunction, including alterations of mental status. Occasionally, evidence of acute myopathy is seen with muscle tenderness and elevations of creatine phosphokinase (CPK). Whether these additional findings are related to the toxicity of the base metals or to the acute hemolytic reaction itself is unclear.

In addition to the acute hemolytic syndrome described earlier, a more chronic variant of hemolysis has been described in an outbreak among workers with repeated low-level exposures to arsine. These individuals had anemia with reticulocytosis and basophilic stippling similar to that seen in subacute lead intoxication (see later). The occurrence of this syndrome has not been reported for over 50 years.

Course and management The mainstay of treatment includes steps to ensure an adequate hematocrit and to preserve renal function. Oxygen and alkaline diuresis are appropriate immediately. If oliguric renal failure ensues,

exchange transfusion is considered the treatment of choice because the hemolytic reaction itself may persist for up to 4 days after a single acute exposure. There is no role in acute management for chelating agents such as British Anti-Lewisite because it cannot bind arsine or stibine to any appreciable degree.

After these steps are taken, treatment depends on the clinical course. If renal failure is profound, hemodialysis is generally indicated for as long as necessary; chronic dialysis may be needed in severe cases in which renal function fails to recover. Late manifestations of arsine poisoning may include evidence of bone marrow depression, peripheral or central neuropathy, and GI manifestations typical of arsenic poisoning. In such cases, there may be a role for chelating agents (see Chapter 39.2) although the literature has not established their utility in this setting.

Prevention Because the major risk of arsine and stibine gas is accidental overexposure, the thrust of prevention must be primary: real-time, continuous monitoring for leaks wherever the gases are used and intense education in industrial operations in which arsine or stibine may be generated by faulty work practices such as the addition of acids to tanks in which traces of the metals may be found. The routine use of surveillance, including CBCs and reticulocyte counts in workers who have regular opportunities for exposure, may be of some value in detecting early or chronic low-level failures of primary prevention, but it is a meager substitute.

HEMOLYSIS IN ACUTE LEAD POISONING Individuals who rapidly accumulate lead over a period of days to months may develop the insidious syndrome called acute lead poisoning. This syndrome is classically characterized by abdominal pain or colic, intravascular hemolysis, and peripheral or central neurologic symptoms and signs.^{11,12} Although it is called acute, the designation has been applied to distinguish the picture from the more indolent picture of chronic lead intoxication, which occurs in individuals with regular, longstanding exposures (see Chapter 39.7). In no sense is acute lead poisoning truly acute like the syndrome caused by arsine (above); it is virtually impossible to absorb enough lead fast enough to cause such an immediate reaction.

Pathogenesis Lead causes many alterations in red cell function, most classically by interference with enzymes in the cascade of porphyrin and heme synthesis (see the section on Hypoproliferative Anemia). However, the effect of lead that leads to hemolysis is unrelated to porphyrins and is probably due to the inhibition of the enzyme pyrimidine 5' nucleotidase, leading to destabilization of membrane function with the formation of basophilic inclusions within the cells (stippling) and premature destruction within the vasculature.¹³ The role of other lead–red cell interactions in the pathogenesis of the hemolysis is unclear, as is the marked variability in host responses to lead, such as why some individuals can have

prolonged intense exposures sufficient to cause chronic lead poisoning without ever manifesting the acute syndrome.

Clinical presentation and diagnosis Rarely is hemolysis the major presenting sign of acute lead poisoning. Typically, patients seek attention for GI or neurologic complaints and the usually mild-to-moderate anemia is discovered as part of the workup. Basophilic stippling usually is seen, although it is non-specific for lead, and the reticulocyte count is elevated. Contrary to the information contained in the old literature on this subject, the average red cell size (mean corpuscular volume [MCV]) is normal or even elevated if reticulocytosis is pronounced; microcytosis should suggest either another diagnosis or the coexistence of a second problem such as iron deficiency or thalassemia trait.¹¹ In children, for example, both iron deficiency and thalassemia trait are common in the population at risk for acute lead poisoning. Haptoglobin may be low but rarely is nil, and free hemoglobin in plasma or urine is not seen. Tests for other causes of hemolysis, such as Coombs' and G6PD tests, are negative. The diagnosis of acute lead poisoning is made by measurement of the whole blood lead level, which is generally very high in this setting, usually over 70 µg/dl. The zinc or free erythrocyte protoporphyrin (ZPP or FEP) levels also are usually very high because of concomitant inhibition of heme synthetase, leading to an accumulation in the red cell of heme's precursor. Because only iron deficiency also is known to cause such elevations of red cell protoporphyrins (with the exception of the rare hereditary condition erythropoerythroid porphyria), the combination of high protoporphyrin levels and hemolysis is almost pathognomonic for lead poisoning.

Because the rate of hemolysis is low even in severe cases compared with that induced by intense exposures to arsine, for example, renal injury due to free pigment is not a problem. However, acute accumulation of lead may itself affect renal function, with development of Fanconi's syndrome, which includes proximal tubular injury with renal tubular acidosis, aminoaciduria, phosphaturia, uricosuria, and glycosuria.

Management and course The presence of significant hemolysis in acute lead poisoning is a compelling reason to initiate aggressive chelation therapy, which might otherwise be a judgment call. This therapy is described in Chapter 39.7. Usually, the hemolysis responds rapidly, with decrements in reticulocyte count and a rise in hematocrit occurring within days. There is no need to take additional steps such as transfusion or diuresis unless the level of hematocrit presents a threat to the patient's immediate health, such as in the presence of ischemic heart disease. As a caution, because blood lead levels generally rise again after completion of a course of chelation with CaEDTA or BAL, it can be expected that hemolysis also may return in a milder form and the patient must be watched carefully. Avoidance of any lead exposure in this setting is crucial to successful management.

Prevention Regular blood lead levels, ZPPs, and CBCs are an essential part of surveillance for anyone, either adult or child, who may have had significant lead exposure.

HEMOLYSIS DUE TO COPPER Copper has been implicated in rare cases of acute hemolysis in the setting of Wilson's disease, suicide attempts, and dialysates contaminated with copper from copper pipes.¹⁴ In 1995, a case of acute hemolysis complicated by acute renal failure was reported in a Nigerian man living in the US.¹⁵ The patient had ingested a green-colored 'spiritual drink' containing copper as part of a cleansing ritual practiced by some Nigerians. He underwent hemodialysis and subsequently stabilized with improvement in hematocrit, indirect bilirubin, and lactate dehydrogenase (LDH) levels.

The mechanism of copper-induced hemolysis is thought to be due to inhibitions of glycolysis, NADPH, and G6PD systems.¹⁶ Treatment is generally supportive care.

TRAUMATIC HEMOLYSIS (MARCH HEMOGLOBINURIA, SPORTS ANEMIA) An appreciable fraction of individuals participating in activities that bring body surfaces repeatedly and forcefully against hard external objects will lyse red cells.¹⁷ In a small fraction of the population, this lysing of red cells may be sufficient to lead to mild anemia, hemoglobinuria, or both. In addition, plasma volume expansion contributes to 'pseudoanemia'.¹⁸ Either condition usually is transient. Rarely are there any clinical signs or symptoms other than the pigmentary change in urine.

The major importance of this disorder is its exclusion from more serious causes of hemolysis or intrinsic renal disease. Exclusion of intrinsic renal disease is effectively accomplished by demonstrating that red cells are absent in urine – the pigment arises from hemoglobin, which occasionally is mixed with small amounts of myoglobin from the same trauma. Exclusion of more serious forms of hemolysis, such as paroxysmal cold or nocturnal hemoglobinurias or that induced by toxins or drugs, relies on the fact that almost all abnormal laboratory tests – reduced haptoglobin, increased free hemoglobin, and mild elevations of muscle enzymes – return to normal within a day or two after an episode. Reticulocytosis is demonstrable only with frequent, repeated bouts. The peripheral blood smear may be normal or may show macrocytosis.¹⁹ Physical examination may be normal as well. The history of long runs, military activities, karate, conga drumming, or other physical contact with hard surfaces is essential to the diagnosis.

Treatment consists largely of reassurance. Whenever possible, further episodes should be controlled by efforts to reduce the degree of trauma between the body surface and external objects to the greatest extent possible, often by using appropriate protective equipment.

Extravascular hemolysis Certain environmental exposures may lead to alterations of the red cell that decrease its survival because of enhanced splenic destruction. In almost every case, the cause is a combination of an exter-

nal environmental factor and a host factor. The first important group includes those caused by potent *oxidants*. For these conditions, host deficiencies of enzymes such as G6PD are important co-factors in disease. The second group is *immune mediated*; presumably, affected subjects carry some predisposition for development of an immunologic response to an external agent that directly or indirectly disturbs red cell membrane integrity. Finally, certain exposures have been demonstrated to accelerate or *exacerbate the hemolytic process due to abnormal hemoglobin structure*. Individuals with hereditary variants may be at risk for environmental exposures that are unimportant to hosts with typical AA hemoglobin patterns.

OXIDANT HEMOLYSIS

Pathogenesis A large and somewhat eclectic group of chemical agents, including pharmaceuticals and reactive compounds used in plastics, explosives, and dyes, are potent chemical oxidants. Important environmental agents have been listed previously in Table 21.2. As noted in the earlier discussion on methemoglobinemia, these compounds may directly oxidize heme iron to form methemoglobin, or they may bind to the protein moiety of hemoglobin, generally at a sulfhydryl group. If this binding is not reversed by reduced glutathione, hemoglobin may precipitate, forming hyperpigmented vesicular structures in the red cells called Heinz bodies. Unfortunately, the presence of Heinz bodies, in turn, makes these cells less distensible as they traverse the sinusoids of the spleen, and premature destruction results.

The natural defenses of the red cell are complex. It remains unclear why one single oxidant compound may induce clinically significant methemoglobinemia in one individual, with minimal hemolysis, while causing the reverse in another person. Based on clinical reports, it seems likely that individuals with hereditary deficiencies of the enzyme G6PD are at increased risk for hemolysis, as are some individuals with congenital variants of this and other enzymes in the hexose monophosphate shunt.²⁰ In some individuals, both reactions may occur and some investigators believe that methemoglobin formation may be the precursor of the denatured hemoglobin, which leads to hemolysis.

Clinical manifestations and diagnosis Irrespective of underlying enzyme status, subjects who develop acute hemolytic crises after exposure to oxidants are clinically normal and well prior to the offending exposure. The onset of illness usually is abrupt and may occur hours to several days after initial contact with the offending agent. Because the host may be unusually susceptible, the exposure need not entail unusual circumstances such as a spill, ingestion, or the like; others similarly exposed may be fine. The onset usually is marked by fever, systemic complaints, and, often, pigmenturia; infection is likely to be the first diagnostic consideration.

Physical examination typically reveals pallor, tachycardia, fever, and, sometimes, mild jaundice. The spleen, liver, or both may be tender and somewhat enlarged. The

primary clue to acute hemolytic crisis and its possible underlying cause comes from the laboratory. Low hematocrit with reticulocytosis is the rule. The smear may reveal Heinz bodies, but schistocytes, spherocytes, or nucleated red cells typically are not seen. The white count and platelets generally are unremarkable. Liver and muscle enzymes are normal. Urinalysis is most remarkable for occult blood without red cells. Tests for specific causes of extravascular hemolysis, such as Coombs' or hemoglobin electrophoresis, are normal.

There are several clues to the roles of oxidants and underlying enzyme abnormalities. Measurement of methemoglobin may yield evidence of a more generalized oxidant effect. Heinz bodies, if present, are strongly suggestive of this diagnostic consideration. Confirmation ultimately may require measurement of red cell levels of enzymes such as G6PD or others in the Embden-Meyerhof pathway. However, these measurements must be interpreted with caution because:

- the most deficient cells (generally older cells) are the first to be hemolyzed, hence the measured levels during or immediately after a crisis are falsely high;
- there is marked populational heterogeneity, making establishment of normal levels for an individual subject precarious; and
- the defect may be in any of several enzymes, at least in theory.

For these reasons, the most important diagnostic feature in the usual case of oxidant hemolysis is the history of new or very recent onset of exposure to a potential oxidizing agent. In the occupational setting, a careful history of recent work, including changes in job or activity, is most likely to be revealing. It is especially important to remember, however, that the intensity of the exposure of concern may be unremarkable in and of itself because the crisis may involve a susceptible host, not necessarily overexposure per se.

Management, course, and prevention Because oxidants are rapidly bound or metabolized and because the levels of protective enzymes are higher in newly made cells, hemolytic crises from oxidants are generally self-limited. Although in severe cases there may be need for exchange transfusion to support oxygen transport and to minimize the resultant acute renal failure from pigmenturia, these measures are rarely necessary. No steps other than supportive care and observation generally are required or beneficial.

Obviously, it is imprudent to return an individual to a potentially similar exposure situation after recovery from an episode of hemolytic crisis; if exposure cannot be reduced sharply, permanent transfer or job change is indicated. Less clear are the roles for:

- pre-placement screening of workers likely to be exposed to oxidants; and
- routine surveillance with examinations and blood testing for those who are exposed.

Unfortunately, there are insufficient data on which to make strong judgments.²¹ Although pre-placement blood studies are likely to prevent exposure of most of those at the high-

est risk for hemolytic crisis, they do not exclude all and they undoubtedly exclude many who could work with perfect safety in the environment. There is no credible reason to exclude individuals based on any less specific characteristic than a documented low level of G6PD or related enzymes, such as all members of an ethnic or racial group known to have high carrier rates of enzyme variants, or all those with any other hematologic disturbance. Whether or not pre-placement studies are chosen, periodic CBCs with methemoglobin levels and reticulocyte counts are probably advisable because they may help detect excessive exposures or overly susceptible individuals.

In any event, it should never be forgotten, however relevant host factors may be, that the oxidant class of chemicals includes extremely potent and reactive agents, and many are capable of causing devastating effects in any host at sufficiently high levels of exposure. Primary control of exposure, therefore, remains the *sine qua non* of prevention of disease from these compounds.

IMMUNE-MEDIATED HEMOLYSIS Although there is a long list of drugs that can cause immune-mediated hemolysis (e.g., by serving as haptens on red cell membranes, by forming immune complexes that, in turn, bind red cells, or by inducing autoantibodies), environmental exposures that cause similar effects have not been clearly identified. Hemolysis is a prominent component of the hemorrhagic pneumonitis and anemia syndrome described in workers exposed to the plastic component *trimellitic anhydride*, or TMA (see Chapter 41). Workers with this syndrome typically have gamma G immunoglobulin (IgG) antibodies directed against TMA-red cell adducts but are not predictably Coombs' positive on direct testing.^{22,23} Whether this is a variant of the innocent bystander mechanism of hemolytic anemia described with quinidine and other drugs remains to be elucidated. In any event, the hemolysis behaves much like quinidine-induced cases and responds to removal of the individual from exposure. The therapeutic role of steroids in this setting is unclear, but all patients should be evaluated for iron deficiency because they generally have had significant hemoptysis, the usual presenting and predominating complaint.

A case of Coombs-positive anemia related to exposure to the pesticide *dieldrin* was reported in 1978.²⁴ An IgG anti-dieldrin antibody was identified. The patient required splenectomy for cure.

The only other well-documented setting in which an environmental exposure may lead to immune-mediated hemolysis is in association with malignant mesothelioma due to asbestos exposure. Study of case reports suggests that tumor antigens cause the relevant immunologic reaction, not antigens associated with asbestos per se. Treatment with corticosteroids is supportive during management of the otherwise lethal tumor.

HEMOGLOBINOPATHIES AND ENVIRONMENTAL EXPOSURES

Sickle cell anemia and trait For reasons familiar to victims of SS disease, many aspects of the work and ambi-

ent environment represent potential threats for sickle cell crises. These include exertional stresses, with attendant dehydration and hemoconcentration; exposures to oxygen-deficient atmospheres, leading to hypoxemia; and exposure to chemicals that could impair oxygen transport, such as asphyxiants. Unfortunately, much has been written but little proved regarding substantive risks to the much larger population of individuals who carry the sickle cell trait (hemoglobin AS). Although historically excluded from exertional sports, aviation, diving, and other activities because of theoretic effects on renal and other target tissues, there are no credible data to support the view that sickle cell trait substantially alters an individual's responses to any environmental stress of relevance.²⁵ In fact, recent studies suggest that such individuals handle barometric changes, hypoxia, and exertion no less well than age- and sex-matched counterparts. Any occupational exclusion, including aviation, sports, or diving, that is not based on physiologic demonstrable abnormalities in such individuals is inappropriate.

Other hemoglobinopathies There are no reliable data on special risks of carriers of thalassemia traits or other major hemoglobin variants. These factors should not be used for the purpose of job placement or risk determinations. Their only importance at present is in the differential diagnosis of environmental effects, a reason why baseline CBCs are of value in surveillance for any suspected agent that affects the peripheral blood.

Hypoproliferative anemias Anemias caused by inadequate production of red cells are of two broad types. First are those due to alterations in the bone marrow stem cells, which ultimately differentiate into the red cell series, or in the microenvironment of the marrow, which supports the growth and normal differentiation of the bone marrow stem cells. These disorders include aplastic anemia, myelodysplastic syndromes (MDS, refractory anemias), myeloproliferative diseases, and diseases associated with infiltration of bone marrow by infection, granuloma, or tumor. Although anemia often dominates in clinical presentation, in general, such disorders affect multiple cell lines, which becomes apparent on examination of the peripheral smear or, if necessary, the marrow itself. For this reason, and because this group of diseases are of special importance in occupational and environmental medicine practice, the subject is considered in detail separately later in this chapter.

On the other hand, inadequate production of red cells also may occur because of more specific lesions that affect the development of red cells. These may include inadequate stimulation by the hormonal mediator erythropoietin, as in chronic renal insufficiency; inability to respond to stimulation, as in chronic inflammatory or malignant disease states; or inability to synthesize hemoglobin or one of its constituents because of nutritional deficiency or metabolic blockade, either acquired or congenital.

Outside the context of another disease of occupational or environmental origin, such as renal insufficiency due to

solvents or lung cancer due to asbestos, the environmental causes of this group of disorders are relatively few. Iron deficiency with microcytic anemia may be an integral part of the pulmonary hemorrhage-anemia syndrome seen in some individuals exposed to TMA; however, as noted earlier, immune-mediated hemolysis is probably more important clinically when patients are first seen.^{22,23}

A single case of megaloblastic anemia with normal levels of folate and B₁₂ has been described following exposure to the pesticide *chlordane*.²⁶ The clinical picture was identical to that seen in pernicious anemia, and all manifestations reversed on removal of the individual from exposure. Complicating acceptance of a causal relationship, however, was the occurrence in this case of cholestatic hepatitis, likely due to the exposure. Because malabsorption was documented, the role of chlordane as a primary cause of megaloblastic change in the erythron must be questioned despite the measured nutrient levels.

Pernicious anemia also has been linked to longstanding *work in textile mills* by epidemiologic studies of mortality.²⁷ No obvious biologic basis for this link is known, so it is unclear whether it relates to the well-characterized immune-mediated gastric injury leading to vitamin B₁₂ deficiency or whether there may be some environmental factor in this work setting that causes a similar clinical picture of megaloblastic anemia.

Macrocytosis without anemia has been described recently in *organic solvent*-exposed workers believed not to have been exposed to benzene or other myelotoxic compounds, but the significance of this observation remains obscure.²⁸

The best-described cause of hypoproliferative anemia due to an environmental factor is the effect of *lead* on heme synthesis.

Anemia of chronic lead intoxication The mechanism and presentation of hemolysis that occurs when individuals are heavily exposed to lead above their accustomed burden has been described earlier in this chapter. Accumulated body lead also has a subtle but measurable effect on the proliferation of red cells from the marrow irrespective of the rate of accumulation and unrelated to any of the acute manifestations of lead poisoning. Although clinically far less important than the hemolytic episodes or other organ system effects of lead, the inhibition of heme synthesis has been long understood and forms the basis for much of our knowledge of the mechanisms of lead poisoning at the cellular level, as well as the development of an important biomarker to assess lead burden, the whole blood ZPP or FEP level.¹¹

PATHOGENESIS The pathway by which glycine, succinyl coenzyme A (CoA), and iron are converted into heme for incorporation into hemoglobin is illustrated in Figure 21.1. Two enzymes in this pathway are markedly lead-sensitive in readily demonstrable fashion. d-Aminolevulinic acid (ALA) dehydratase, which synthesizes the first porphyrin ring, is exquisitely sensitive, with decreases in the bioactivity of the enzyme measurable once

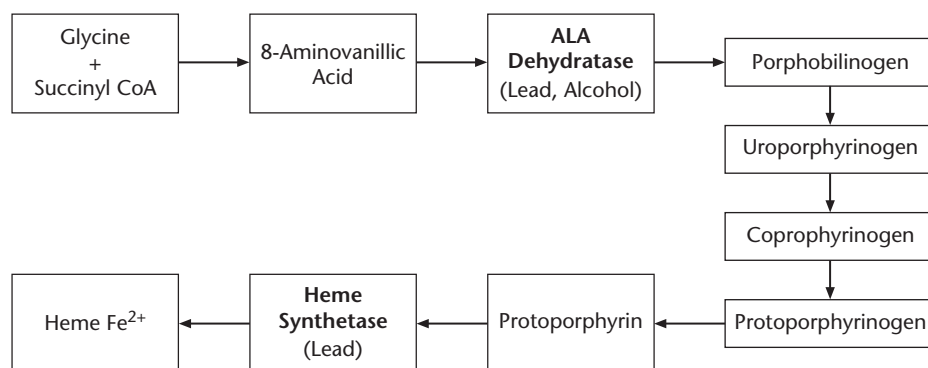

Figure 21.1: The heme synthesis pathway in red cell precursors. Lead inhibits the enzyme ALA dehydratase, as does alcohol. Lead also inhibits the rate-limiting enzyme heme synthetase.

whole blood level exceeds about 10 µg/dl; similar inhibition is conferred by low levels of alcohol, but there is no evidence of synergy between the two. This enzyme is not rate limiting, however, and even marked depression, as may be seen with low levels of lead, is rarely associated with any other measurable biochemical change. At somewhat higher body burdens, usually when the whole blood level approaches 35 or 40 µg/dl, there is inhibition of the more important enzyme ferrochelatase, or heme synthetase, which incorporates iron into the protoporphyrin ring to form heme. This blockade leads to the accumulation of protoporphyrin in the red cells, the basis for the ZPP or FEP blood screen. With progressive inhibition of heme synthetase, there is a gradual inhibition of the proliferative process, with small incremental decreases in hemoglobin production. The marrow, in turn, compensates with an increased stimulation of red cell production, causing compensatory erythroid hyperplasia, as would be seen in iron deficiency.

DIAGNOSIS AND CLINICAL MANIFESTATIONS The hematologic picture associated with elevated lead burden is unimpressive unless accompanied by acute hemolysis, as described previously. Although slightly lower than may be predicted, the hematocrit and hemoglobin are usually well within the normal range. The MCV and red cell morphology usually are normal, although a few basophilic stippled cells may be identified. The only relevant abnormal laboratory tests are the whole blood lead level and the protoporphyrins, ZPP or FEP, assuming that they have been ordered.

Because the hematologic disturbance associated with chronic lead poisoning tends to be very mild, the most important clinical issue is recognition of the underlying cause, which may be associated with far more important renal, neuropsychiatric, reproductive, or other manifestations of lead poisoning. For this reason, lead poisoning should remain in the differential diagnosis of normochromic, normocytic anemias in both children and adults who may have had significant exposures. Perhaps more important, because peripheral blood findings in lead poisoning are so frequently normal, a CBC and smear should never be used as a screening test for lead poisoning,

nor should a normal CBC ever be used to exclude the diagnosis, which may be suggested by other clinical features or by virtue of known exposure.

Polycythemia

As with the hypoproliferative anemias discussed earlier, polycythemia may be primary, a myeloproliferative disorder of stem cells, or secondary to other factors. Consideration of environmental causes of primary polycythemia or polycythemia vera is discussed in Chapter 30.3. Here, we shall consider two causes of secondary increases in blood hemoglobin:

- the metal *cobalt*; and
- chronic exposure to asphyxiants, especially carbon monoxide.

Although secondary polycythemia also may be seen with lung diseases due to environmental factors, this form is no different from that seen with chronic obstructive pulmonary disease.

Cobalt-induced polycythemia

It has long been recognized that cobalt is a potent stimulus for red cell production, even beyond its important role as a co-factor for vitamin B₁₂. Years ago, cobalt salts were used therapeutically in the treatment of sickle cell and other congenital anemias. The mechanism for erythrocytosis appears to be inhibition of oxidative metabolism, with induction of tissue hypoxia resulting in stimulation of erythropoietin.

From a clinical point of view, the only environmental demonstration of this effect of cobalt occurred in association with consumption of cobalt-contaminated beer in Canada several decades ago.²⁹ The major clinical manifestation was the development of a congestive cardiomyopathy, but many of those affected also had evidence of an increased red cell mass. Both problems ameliorated when cobalt was removed as a foaming agent from the beer. Similar effects on the blood and the heart have not been seen in the major occupational settings where cobalt is used and where the serious respiratory effects are seen, namely in hard metal manufacture and grinding and in diamond cutting (see Chapter 39.3). To date, no case of an

exposed individual with significant polycythemia in these settings has been reported. Increased hemoglobin is not part of the clinical picture of cobalt-induced asthma or parenchymal lung disease.

Polycythemia secondary to asphyxiants

The occurrence of increased red cell mass in response to tissue hypoxia is appropriate, probably regulated in the kidney, where erythropoietin is produced. Not surprisingly, regular exposure to oxidative uncouplers such as cyanide or significant levels of carbon monoxide has, as a consequence, elevated erythropoietin levels and, therefore, elevated hemoglobin levels. Rarely is this manifestation serious in itself compared with the life-threatening risk of the exposure on cardiovascular function. For this reason, the main importance of the association is as an indirect sign that leads to suspicion of regular overexposure to a lethal compound rather than to its hematologic consequences, which are slight, rarely much exceeding that seen, for example, in very heavy smokers.

Disorders of platelets

Thrombocytopenia

Far less is known about environmental causes of thrombocytopenia than anemia, at least in part for reasons related to detection: the normal number of cells varies far more than the normal hematocrit, counts are less frequently obtained, and profound derangement of function or counts is necessary before clinical symptoms or signs of bleeding ensue. It may, of course, also be true that platelets are less susceptible to environmental alteration or damage, but this seems unlikely in view of the sensitivity of platelets to the effects of drugs, infectious agents, and other physiologic disturbances.

As with anemia, there are two broad possibilities for a decrease in platelet count: decreased production and increased destruction. Isolated decreases in platelet production have been described after intense exposure to a number of the complex *organochlorine pesticides*.³⁰ More diffuse damage to stem cells in marrow or the marrow microenvironment also may affect platelets along with other cell lines, the subject of a subsequent section. Decreased survival of platelets may be on an immune or a non-immune basis. Immune destruction has been described in association with *isocyanates* and *turpentine*. Non-immune destruction has been described in workers who have developed advanced hepatic dysfunction from *vinyl chloride monomer* exposure; the mechanism of vinyl chloride monomer exposure that dominates the clinical picture is presumably hypersplenism associated with portal hypertension (see Chapter 26.1).

Megakaryocyte hypoplasia due to organochlorine pesticides Sporadic reports have appeared over the years associating these suspect myelotoxic compounds with selective thrombocytopenia. Vacuolated megakaryocytes have been reported in two individuals with otherwise normal bone

marrow, suggesting an effect specific to production of platelets. However, the natural history of these lesions is not clear, nor is the relationship to the more diffuse effects of these compounds on bone marrow function, which is more frequently described (see later).

Immune thrombocytopenic purpura due to organic chemicals Two cases of an idiopathic thrombocytopenic purpura (ITP)-like illness were reported in 1963 from a single polyurethane insulation process.³¹ Each person had developed a sudden onset of asthma, presumably due to toluene diisocyanate (TDI) exposure, which was uncontrolled. One patient responded promptly to removal from exposure, whereas the other required prolonged medical treatment, including steroids and, ultimately, splenectomy. However, despite extensive subsequent experience with TDI asthma, no further cases of thrombocytopenia have been documented, suggesting that the cause was a factor unique to this work environment. In 1991, a case of recurrent polyurethane-induced thrombocytopenia was reported in a young girl who was re-exposed during home renovation.³² In both instances, thrombocytopenia responded to cessation of exposure and systemic steroid.

Two cases of self-limited thrombocytopenia also have been described after intense exposure to turpentine; both cases occurred in children.³³ In each child, platelet counts rebounded promptly once the exposure was discontinued.

Other platelet disorders

Functional disturbances of platelets, as seen with various drugs and metabolic disturbances, have not been described in relation to specific environmental agents or exposures. Similarly, no agent is known to cause thrombocytosis or a hypercoagulable state except in the setting of a primary marrow disorder (see later) or an injury to another organ system, such as in lung cancer.

Disorders of white blood cells

Neutrophils

Although transient neutrophilia is common in a host of acute occupational and environmental illnesses, such as metal fume fever or alveolitis caused by irritant gases, it is neither specific nor important as a feature in differential diagnosis. Persistent neutrophilia or evidence of early forms in the periphery should suggest a chronic inflammatory disorder or a myeloproliferative disease; environmental agents are not known to cause such changes directly. Neutropenia may be seen in the setting of injury to the bone marrow due to ionizing radiation, arsenic, benzene, or other agents affecting stem cells or the marrow microenvironment. However, the isolated neutropenia seen in response to various drugs and infections has not been described in the occupational or environmental setting unrelated to more diffuse marrow effects, which can readily be demonstrated either on peripheral smear or, if necessary, by examination of the bone marrow itself.

Eosinophils

Mild eosinophilia may be seen in the range of environmental allergic disorders that are gamma E immunoglobulin (IgE) mediated, including rhinitis and conjunctivitis and asthma, especially when caused by large antigenic molecules such as proteins. Importantly, eosinophilia is not always present in asthma due to small molecules such as isocyanates or Western red cedar, but mild elevations, especially in atopic individuals, should not be used as strong evidence against these considerations either. Eosinophilia also may be seen in association with delayed-type hypersensitivity immune disorders, including contact dermatitis and hypersensitivity pneumonitis. In hypersensitivity pneumonitis, eosinophils may be seen variably in peripheral blood and bronchoalveolar lavage fluid.

An outbreak of eosinophilia associated with acute respiratory illness was reported in 1986 among rubber workers.³⁴ A careful hazard evaluation revealed that cases were largely limited to employees associated with the thermoinjection process, but a specific causal agent could not be isolated in the neoprene rubber plant. Both eosinophilia and respiratory symptoms responded to removal of individuals from exposure but recurred in some on re-exposure; long-term follow-up has not been published.

The most notable environmental disease associated with more striking eosinophilia (i.e., >1000 cells/mm³) is the toxic oil syndrome (see Chapters 23.5 and 44). In this disease, the early manifestations include fever, pneumonitis, and eosinophilia, sometimes as high as 50% of the total white count. Eosinophilia also was very prominent in the closely related disorder eosinophilia-myalgia syndrome, caused by ingestion of contaminated L-tryptophan preparations. Neurologic, dermal, and musculoskeletal sequelae of the two disorders also are indistinguishable, suggesting a related or possibly common causal agent.

Exogenous agents have not been implicated in the hypereosinophilic syndrome, nor is persistent eosinophilia an important sign in any other toxicologic illnesses. Its presence should suggest parasitic, autoimmune, or malignant disease.

Lymphocytes

Benzene causes mild depressions of total lymphocyte counts, usually in a dose-related fashion. Depression of lymphocyte counts is an early peripheral finding and portends depression of the bone marrow, which is more serious. Occasionally, a paradoxical absolute lymphocytosis is seen in this setting. Beyond this, environmental agents, including other marrow toxins such as arsenicals, do not have significant effects on lymphocyte numbers. Even the several lymphoproliferative diseases that have been most strongly associated with environmental or occupational exposures, such as multiple myeloma or non-Hodgkin's lymphoma (see Chapter 30.3), generally are not associated with major changes in lymphocyte counts or changes in their appearance on peripheral smear.

On the other hand, changes in technology have led to considerable interest in the lymphocyte family as a target for toxic injury. Two groups of effects are worthy of

mention. The first are immunologic. It is now clear that in several environmental diseases of importance, delayed-type hypersensitivity is of central pathogenic importance. Disorders include allergic contact dermatitis (Chapter 29.1), extrinsic allergic alveolitis of all causes (Chapter 19.6), and chronic beryllium disease (Chapter 19.7). For the respiratory diseases, the most specific test for diagnosis is based on identification of a subgroup of sensitized lymphocytes in peripheral blood or bronchoalveolar lavage, which reacts in vitro to stimulation by the causal agent. Further, in chronic beryllium disease, at least, this specific reactivity is associated with depression of function of lymphocytes globally, which is clinically recognizable by anergy.

At present, possible roles for lymphocytes in the pathogenesis of many other occupational and environmental diseases are being explored, including asthma, pneumoconioses, malignancies, and multiple chemical sensitivities. In the attempt to study these conditions, various populations and individuals are having a variety of sophisticated studies performed on lymphocytes from peripheral blood and other internal sites. Tests may include in-vitro responses to various antigens, subtyping by measurement of receptors on cell surfaces, and others. In general, these tests are research tools that at present have virtually no direct clinical application in medicine except when gross alterations are seen, as with various infections like the human immunodeficiency virus (HIV). For now, it is premature to attempt to interpret more subtle changes as either indicative of an effect of an environmental agent in an individual or predictive of risk for later health effects.

A second important area of focus on lymphocytes has been on the integrity of their genome. Because lymphocytes have very long lives in the body and are very accessible to study, evolving technologies have begun to look at aberrations of chromosomes in lymphocytes as a function of environmental exposures. This approach may be accomplished either by direct staining of the cells (banding) and performance of routine cytogenetic analysis or by co-culture with DNA base-pair analogs, which allows detection of more subtle sister chromatid exchanges. At present, the state of the art is such that several established human carcinogenic agents, including ionizing radiation, chemotherapeutic alkylating agents, cigarette smoke, and benzene, have been proved to increase the background rates of these chromosomal changes. Several other exposures also have been shown consistently to enhance the rate of such changes, such as ethylene oxide and some pesticides. What has not been demonstrated is any causal connection between increased rates of chromosomal alterations in these long-lived cells and any direct health effect, malignant or otherwise. Therefore, at the present time, these effects on lymphocytes, while interesting and possibly helpful in determining the range of biologic effects of an agent, cannot be equated with early effects themselves or even act as clear markers of early effects. Furthermore, the level of such alterations measured in a subject who may have been exposed to one or more agents of interest

cannot be equated with a risk for any outcome of importance or interest at this time.

DISORDERS OF BONE MARROW STEM CELLS AND MICROENVIRONMENT

Disorders of the blood-forming organ in bone marrow are typically recognized when signs or symptoms develop that are referable to a deficiency of one or more cell lines or when a CBC demonstrates such deficiencies of multiple lines in an asymptomatic person. Examination of bone marrow may reveal that the marrow is impaired secondary to an external or systemic disease, such as infiltration with granulomas and tumor or blood-borne infection, or the marrow itself may be the problem. Secondary involvement of the marrow can be distinguished by examination of a bone marrow aspirate and a biopsy, combined with a culture for viral, mycobacterial, fungal, or bacterial organisms. The following section considers the primary disturbances of the marrow that may be produced by environmental toxicity. As will be apparent, these disorders range over a spectrum from those that are clearly benign (i.e., they are not associated with the presence of a malignant clone of cells) to those that are obviously neoplastic (i.e., myeloproliferative diseases and leukemias). Between these two extremes are a collection of conditions that share features of both. We consider here all of those conditions that are not frankly neoplastic. Hematopoietic malignancies are considered separately in Chapter 30.3.

Aplastic anemia (bone marrow hypoplasia)

Aplastic anemia is an imprecise but time-honored term that refers to the primary depression of the precursors of multiple cell lines, usually all of them. When the defect is limited to erythropoietic cells only, with normal cellularity in other lines, the term pure red cell aplasia is used; similar isolated defects of the other cell lines also have occasionally been described.³⁵ The hallmark of aplastic anemia is decreased cellularity of the bone marrow, in which the cellular material (if any can be found) generally is normal morphologically and the remainder of the marrow space is occupied by fat.³⁶

Although aplastic anemia is rare (affecting about three persons per 100,000 per year), a substantial fraction of all cases appear to occur as a result of an identifiable event or exposure, including certain infections, drugs, and environmental agents. Established and suspect environmental agents are listed in Table 21.3. A small fraction of cases occur in young individuals with apparent chromosomal instability syndromes such as Fanconi's anemia.

Pathogenesis

Aplastic anemia may be induced by injury to the marrow in one of three ways. First, the primitive stem cells, which differentiate into all cell lines, may be directly destroyed or

Known causes

Trinitrotoluene
Dinitrotoluene
Benzene
Lindane (gamma-benzene hexachloride)
Ionizing radiation
Arsenic/arsenicals
Alkylating agents

Suspect causes

2,3,7,8 TCDD (Dioxin)
Chlordane
DDT
Ethylene glycol ethers
Paradichlorobenzene
Pentachlorophenol

Reported causes

Diclorvos
Organophosphate insecticides
Stoddard solvent
Methoxychlor
Chlorophenothane
Toxaphene

Table 21.3 Environmental causes of aplastic anemia

inhibited. Second, an immunologic reaction may be initiated, which secondarily leads to cell-mediated or antibody-mediated attack on these primitive stem cells. Third, the mesenchymal stromal cells, which appear necessary to support the growth and differentiation of stem cells, may be injured. Although many of the functions of these slowly replicating cells remain to be elucidated, it is known that they secrete many of the cytokines and other factors, such as interleukins, that are obligate growth factors for stem cells.

The sites and mechanisms of injury are not completely understood for any of the agents known or suspected to cause aplastic anemia, which are listed in Table 21.3. Using available in-vitro culture techniques to grow marrow stem cells in their own or autologous environments, it appears likely that direct injury to stem cells is a major dose-related consequence of ionizing radiation and radiomimetic chemotherapeutic drugs. By interaction of radical metabolites with stem cell chromosomes, benzene probably also disrupts the function of stem cells directly. The apparent reversibility of the effects of many of the toxins in animal experiments and human experience suggests a primary role for the rapid turnover of stem cells, which return to normal or apparently normal kinetics after removal of the toxin from the marrow. One could infer that failure of the condition to reverse in more severe cases or with higher experimental doses may be related to total or near-total eradication of the vital stem cell line.

Substantial experimental evidence is mounting, however, to support the view that stromal injury may be as important or even more important than injury to stem cells themselves. Stem cells from irradiated animals do not replicate normally in the environment of irradiated marrow despite their return to normal numbers and full growth and differentiation potential when transplanted into non-irradiated animals. Similar results also have been found with alkylating agents, distinguishing them from various antimetabolites, which depress stem cells only transiently. This factor is extremely important because it

may explain the long delay in recovery from even sublethal marrow injuries. Further, damage to the microenvironment of the marrow may explain the emergence of late consequences of aplastic anemia that occur up to many years after apparently normal recovery.

However, aplastic anemia does not appear to occur unless there is injury to the stem cell, either directly or via immunologic attack. Further, damaged stromal cells themselves do not appear capable of causing this type of injury *de novo*, although they may participate in the occurrence or unmasking of malignant clones (see later). Thus, aplastic anemia itself is not a late consequence of environmental damage to the bone marrow, unlike the myelodysplastic and myeloproliferative syndromes, which do occur later. Excess cases of aplastic anemia have not been seen in populations that have been subjected to ionizing radiation after the initial period, nor do cases spontaneously occur long after exposure to chemotherapy, benzene, or other primary causes, such as drugs or viruses.

Presentation and diagnosis

The diagnosis of aplastic anemia is suggested by the finding of depressed counts of two or more cell lines on the peripheral smear of an individual, with or without clinical symptoms. Generally, the physical examination is normal except for the effects of low cell counts, such as fever, pallor, and petechiae. In particular, lymphadenopathy and splenomegaly usually are absent; their presence should raise alternative considerations. However, because a bone marrow examination is necessary in any event, the differential diagnosis usually revolves around the result of this examination.

Even when the typical findings of aplastic anemia are present on evaluation of the marrow – hypocellularity with normal or near-normal cell morphology and absence of infiltrating cells or fibrosis – there remain two important tasks in the differential diagnosis. First, the diagnosis of aplastic anemia must be confirmed. Second, a detailed search for the cause must be undertaken. Confirmation of the diagnosis of aplastic anemia requires exclusion of diseases that may closely mimic it, including certain infections (typical and atypical tuberculosis, HIV, cytomegalovirus [CMV] infection) and leukemia occurring without blasts, so-called aleukemic leukemia, now generally called myelodysplastic syndrome (MDS). Rarely, carcinoma may be missed on a single biopsy. Exclusion of these possibilities with obviously different indications for treatment generally requires careful culture of the marrow and other specimens, performance of stem cell cytogenetic tests, and examination of multiple specimens if suspicion lingers. Once the diagnosis is secure, the search may begin for a causal agent. In addition to the environmental agents listed in Table 21.3, two other categories are important – viral infection and drugs. The viruses include infectious mononucleosis and hepatitis, especially non-A, non-B (the role specifically for hepatitis C in aplastic anemia has not yet been confirmed). The drug list is lengthy and includes antibiotics, anti-inflammatory drugs, and a host of others. For each of these possibilities, it must be kept clearly in

mind that there generally is not a significant latency period between exposure to a causal agent for aplastic anemia and the resultant syndrome. For this reason, the search should be confined largely to events and environments to which the patient has been exposed over the previous 6 months.

Given the severity of the disorder, the public health implications if others have been exposed, and the danger of continued exposure during treatment if the cause is not found, a full evaluation of the individual's home and workplace environment is warranted in every case in which the cause is not obvious, such as the administration of a drug with high potential for this effect. When appropriate, clinical evaluation of coworkers or co-inhabitants may provide valuable clues. Unfortunately, although recent exposures are sought, there is rarely any diagnostic utility to blind testing of biologic specimens for toxic agents unless the history itself is suspicious. The unanticipated presence of inorganic arsenic in urine may be the single exception to this rule (see Chapter 39.2).

Clinical course and treatment

The natural history of aplastic anemia follows one of four pathways.

1. Some cases reverse spontaneously, usually after the discovery of a causal agent that can be removed, such as a drug.
2. Most cases persist and require long-term support or a trial of curative bone marrow transplantation.
3. Some cases evolve directly into a myeloproliferative syndrome or acute leukemia within months to years.
4. Among those who appear to recover, late consequences such as the development of a myelodysplastic or myeloproliferative syndrome may occur.

The treatment for all but very mild cases of aplastic anemia is independent of the specific cause; all patients should avoid exposure to myelotoxic agents. Among patients who recover spontaneously or after transplant, it is not clear whether continued surveillance of blood counts or even bone marrow examinations are of any value in preventing late complications.

Prevention

Because it seems very likely that subacute injury with marrow toxins carries a far better prognosis than more profound injury, workers with even a slight risk of exposure to myelotoxic substances should be under very careful hematologic surveillance. This surveillance should include a pre-placement evaluation of CBC, platelet count, differential counts, and reticulocyte counts. These tests should be repeated at least yearly and each individual should serve as his or her own control, which permits a search to be performed for subtle changes in cell size or count that may long precede frank abnormalities. Individuals with unanticipated variations during exposure should have a full diagnostic evaluation and assessment to determine whether excessive exposure is occurring before they are returned to the same environment.

At present, there is no rational basis for the exclusion of anyone from jobs involving possible risk of marrow toxin

exposure except individuals who have had prior marrow injuries or reactions to the agent in question.

Myelodysplastic syndromes

In the early 1980s, the term MDS came into vogue to describe a group of apparently related disorders of the bone marrow with the following characteristics:

- anemia, usually with macrocytosis on peripheral smear;
- abnormal numbers (increased or decreased) of platelets and leukocytes with morphologic abnormalities, but not frank blasts;
- a hypercellular bone marrow with sideroblastic or megaloblastic morphology in the red cell line and often abnormalities of myelocytic cells and megakaryocytes;
- absence of metabolic disturbances or nutritional deficiencies, such as folate, B₁₂, and iron; and
- frequent abnormalities on marrow cytogenetic studies suggesting the presence of a malignant clone.³⁷

Because many patients with MDS are asymptomatic, many are elderly, and the nomenclature and International Classification of Disease (ICD) coding of the disorder have been inconsistent, our knowledge of MDS has been largely derived from well-described case series. From these studies, we can infer that MDS is not rare and probably precedes leukemia in a substantial proportion of all cases. There has been enough careful follow-up of patients who have been exposed to ionizing radiation and chemotherapy to know that these agents strongly predispose individuals to the delayed occurrence of MDS, usually 3 to 10 years after treatment with apparently normal intervening marrow recovery.³⁸ Further, the occurrence of fairly unique patterns of cytogenetic abnormalities in such cases, as opposed to those that occur *de novo*, has facilitated the search for other environmental causes.^{39,40} From this viewpoint, it appears that organic solvent exposure may be an important risk for MDS. This impression is strongly reinforced by a review of well-described cases of benzene-related disease, over half of which now appear to be most consistent with MDS as opposed to aplastic anemia.^{41,42} It is likely, therefore, that agents that may cause aplastic anemia during exposure can cause MDS later, but full epidemiologic and experimental confirmation of these relationships is still needed.

Pathogenesis

The careful prospective observation of cancer patients treated with radiation and chemotherapy has generated knowledge of the sequence of events in MDS. The primary lesion appears to lie in the stromal cells, which support stem cell growth and differentiation. Later, a malignant clone or clones emerge. Whether the primary occurrence of a transformed cell line, independent of the damage to stromal cells, is necessary for the development of MDS is uncertain. Also, it remains possible that the primary lesion is, in fact, a malignant transformation with the secretion of paracrine factors that secondarily impede the function of the stroma, but serial marrow studies suggest that the stromal injury is the underlying lesion and not a reaction to abnormal stem cells.

Over time, the malignant clone or clones appear to grow, with progressive deterioration of marrow function and evolution of progressively more transformed cells. Leukemia develops in 10% to 20% of cases studied.

Clinical presentation and differential diagnosis

About half of the affected patients are discovered by routine CBC, whereas the rest present with signs and symptoms referable to a deficiency of a blood cell line, as with aplastic anemia. Some patients have enlargement of the spleen and liver. Bone marrow examination and cytogenetic studies, combined with routine exclusion of other causes of hematologic disease, are generally diagnostic, although classification may be difficult if malignant features are already apparent.

Attribution of cause requires proof of substantial exposure to a myelotoxic agent at some time prior to onset, generally with a latent interval of 3 to 10 years but longer periods are well recognized. Evidence that the prior exposure was sufficient to cause even transient bone marrow injury, as would be seen with chemotherapy or high-dose benzene exposure, provides very strong support for an etiologic relationship, but this evidence frequently is not available. Further, it must be remembered that between the time of putative injury and the later development of MDS, all peripheral blood studies and bone marrow examinations may be normal. In other words, the availability of a normal CBC between the time of an exposure of interest and the occurrence of MDS does not exclude a causal relationship.

It appears that the presence of abnormalities on chromosome 5 or 7 or both also suggests previous exposure to a marrow toxin as causal. Most of the cases of MDS that have occurred after exposure to radiation or chemotherapy have had such changes while few others do. Further, in some case series, those individuals who have been previously exposed to myelotoxic agents have a far higher prevalence of such cytogenetic abnormalities than those without. Although over-reliance on cytogenetics would be premature at present, the data are very useful, especially for focusing the search for a causal factor in cases in which chromosome 5 or 7 or both are affected when otherwise none might be apparent.

Clinical course and management

MDS either smolders for a long time or evolves into frank leukemia. There is no evidence that the disease is reversible, so spontaneous remission should raise questions about the diagnosis itself. Further, no form of therapy other than support appears to offer any change in the natural history of the disease. More disturbingly, when acute leukemias do emerge, they tend to be very poorly responsive to any modality of treatment. This appears especially true for those patients who have evidence of prior mutagenic exposure.

Prevention

At this point, only reduction in exposure to myelotoxic agents appears at all likely to reduce the occurrence rate of

MDS. There is no evidence that close follow-up of individuals who have had marrow injuries offers any long-term advantage other than reassurance and early detection of MDS so that supportive care can be initiated before a life-threatening complication occurs.

Chapter 22

Occupational Infectious Diseases

Adelisa L Panlilio, Julie Louise Gerberding

Infections acquired in the work setting represent an eclectic group that is seldom, if ever, considered together as a single category. Occupational infections involve several organ systems, respiratory, enteric, and skin infections being particularly common. Transmission involves not only casual person-to-person contact, but also a variety of other routes in special work environments. It is thus important to consider what unique features characterize the infectious diseases that can be considered occupational.

Perhaps one useful way of thinking about these diseases is that, as a group, they tend to be transmitted during work schedules or practices that are systematized. Therefore, they can be anticipated, and to the extent that unsafe infection-prone practices can be identified and modified, they can be systematically prevented. Another common feature is that many of the occupational infectious diseases can be regarded as behavioral. To the extent that unsafe practices have been defined, and practice policies modified to reduce infection risk, continued transmission often represents failure to follow accepted standards. Although certain occupational infections can be prevented by vaccines (e.g., hepatitis B), prevention often depends on simple behavioral changes, such as hand hygiene, use of gloves, and not working while ill. Finally, the anthrax cases during the fall of 2001 in the United States demonstrate the possibility of intentional (and criminal) exposure to infectious agents in the workplace, in this instance among those handling mail.¹ These intentional exposures, fortunately, are rare events, but should be considered in assessing sources of exposure for unexpected illnesses.

Prevention depends primarily on defining risky occupational practices or environments, clearly articulating policies for preventing communicable disease acquisition; removing structural barriers to compliance with policies (e.g., providing soap, hand cleansers, and gloves; allowing time away from work during periods of illness); and promoting healthy practices through behavioral change. Because infectious diseases may represent the most common cause of time lost from work, it is important for the clinician concerned with occupational medicine to understand the relationship of specific infections to specific work environments and practices, and to give at least as much attention to prevention as to diagnosis and treatment.

INFECTIOUS DISEASES TRANSMITTED IN THE WORKPLACE

Occupationally acquired infections have historically been associated with animal exposures and unsanitary work environments. Modernization of agrarian techniques and improvement in sanitation have markedly decreased the incidence of these infections in the developed world, though they remain problematic in developing countries. While nearly all infectious diseases could conceivably be transmitted in the workplace, the emphasis here is on those that can be transmitted by casual contact or by specific work-related exposures, with emphasis on diseases that are most common, most serious, or most readily prevented. Healthcare settings pose a unique challenge because of the proximity of infectious patients, susceptible patients, and healthcare personnel. Infections transmitted from personnel may have devastating effects on certain groups of patients, particularly the immunosuppressed. Likewise, certain infections transmitted to personnel, such as multidrug-resistant tuberculosis, may have serious or even fatal, consequences. Table 22.1 summarizes the microbial etiology, sources, routes of infection, categories of workers at risk, and clinical manifestations of selected infectious diseases that have occupational predilections. A detailed discussion of waterborne microbial diseases is also provided in Chapter 54. Because the treatment of occupationally acquired infections does not differ from that of infections acquired non-occupationally,² the emphasis of this chapter is on the recognition and prevention of these infections.

Air-borne/droplet infections

The common cold

Epidemiology The common cold is the most frequent illness causing absenteeism from work. Rhinoviruses cause up to 30% of cases, coronaviruses approximately 10%, and other pathogens – including influenza virus, parainfluenza virus, respiratory syncytial virus, and adenoviruses – 15–20% of cases. In about 40% of cases, the cause cannot be determined. The large number of viral subtypes within each

Condition	Organism	Source	Route	Workers at risk	Clinical manifestations
Anthrax	<i>Bacillus anthracis</i> (gram-positive rod)	Herbivores (goats, sheep), hides, wool, bones	Inhalation	Veterinarians, wool sorters, weavers	Lung: Biphasic upper respiratory infection, pneumonia Cutaneous: Papules (painless) Ulcer (large) Necrotic eschar
Blastomycosis	<i>Blastocystis dermatitidis</i> (yeast with broad-based buds)	Soil, dogs	Inhalation, cutaneous inoculation, bite	Outdoorsmen exposed to soil	Lung: Acute and chronic pneumonia Skin: verrucous lesions ulcers, subcutaneous nodules Bone: osteolytic with draining sinuses
Brucellosis	<i>Brucella abortus</i> , <i>B.</i> <i>melitensis</i> , <i>B. suis</i> , <i>B. canis</i> (gram-negative coccobacilli)	Contaminated milk products, swine, cattle, goats	Ingestion, cutaneous inoculation, inhalation	Abattoir workers, farmers, dairy workers, veterinarians	Lymphadenopathy, chronic hepatitis
Cat-scratch fever	<i>Alipta</i> spp. (bacilli on Warthin-Starry stain)	Cats, dogs	Bite, scratch	Animal handlers	Skin: Papules, pustules, regional inflammation, lymphadenopathy Ulceroglandular syndrome Lung nodule or cavity, disseminated disease
Coccidioidomycosis	<i>Coccidioides immitis</i>	Soil, fruit, cotton, landfill	Inhalation	Visitors to endemic areas, healthcare personnel exposed to infective spores (e.g., inside moist casts), archeologists	
Colorado tick fever	Orbivirus	Small rodents	Tick bite (<i>D. andersoni</i>)	Travelers to mountains in the United States	Biphasic fever, rash, pain, vomiting, leukopenia
Dengue	<i>Aedes aegyptii</i> flavivirus	Primates	Mosquito bite	Travelers to tropics, military personnel	Fever, severe muscle and bone pain, hemorrhagic signs (petechiae, purpura, gastrointestinal bleeding), lymphadenopathy, rash
Encephalitis La Crosse	<i>Bunyaviridae</i> , California serogroup	Chipmunks, squirrels	Mosquito bite	Animal handlers, campers	Encephalitis
Equine (eastern and western) Erysipelothrix	<i>Alphaviridae</i> <i>Erysipelothrix rhusiopathiae</i>	Wild swamp-associated birds, horses Animals, birds, fish, decaying matter	Mosquito bite Direct inoculation	Animal handlers, campers Fishermen, poultry workers, farmers, abattoir workers, housewives	Encephalitis Local inflammation with pruritus, suppuration not present, sepsis with endocarditis
Histoplasmosis	<i>Histoplasma capsulatum</i>	Soil in areas with avian and bat excrement	Inhalation	Soil movers, construction workers, spelunkers, pigeon and chicken handlers	Asymptomatic pneumonitis, acute pneumonitis, mediastinal lymphadenopathy, mediastinal collagenosis, histoplasma, disseminated disease

Table 22.1 Infectious diseases transmitted occupationally to selected workers

Condition	Organism	Source	Route	Workers at risk	Clinical manifestations
Leptospirosis	<i>Leptospira</i> spp. (motile spirochete)	Domestic and wild animals	Inoculation of infected urine, direct mucocutaneous inoculation	Abattoir workers, veterinarians, farmers	Icteric fever: hepatitis renal failure, uveitis, meningitis
Lyme disease	<i>Borrelia burgdorferi</i>	Ixodes tick from deer, other mammals	Bite	Outdoorsmen	Anicteric fever Early: erythema chronicum migrans Delayed: meningitis and encephalitis, myocarditis, arthritis Acute: localized nodule Latent: asymptomatic (years) Acute pneumonitis, sepsis, chronic suppurative Rash, fever, chills, sore throat, lymphadenopathy Mycetoma, pneumonia with cavity and empyema, brain abscesses, skin and visceral abscesses Local lesion (hyperplastic mass) Skin: focal soft tissue with serosanguineous discharge, rapidly progressive cellulitis Lung: pneumonia Sepsis Bubonic: regional lymphadenopathy Pneumonic: pneumonia, disseminated intravascular coagulation Septicemic: pneumonia DIC Pneumonitis, fever, headache, myalgia, arthralgia, hepatosplenomegaly Prodrome: fever, URI symptoms, local paresthesias Acute neuro: altered mental status, seizure, hyperactivity, laryngospasm, fasciculations, coma Fever, rash, arthralgia, arthritis Relapsing fever, rash, hemorrhagic complications Asymptomatic to severe respiratory illness with fever, headache, dry non-productive cough, malaise, dyspnea, progressing to pneumonia
Melioidosis	<i>Pseudomonas pseudomallei</i>	Soil	Direct inoculation	Military troops, travelers in Southeast Asia	
Monkeypox	Monkeypox virus	Infected animals or humans	Direct inoculation, bite	Animal handlers, veterinarians	
Nocardiosis	<i>Nocardia</i> spp.	Soil	Direct inoculation, inhalation	Outdoor workers	
Orf	Orf virus	Sheep	Direct inoculation	Sheep raisers	
Pasteurella	<i>Pasteurella multocida</i> , <i>P. haemolytica</i> , <i>P. pneumotropica</i> (gram-negative coccobacilli)	Domestic and wild animals	Bite, cutaneous inoculation, inhalation	Children, animal handlers	
Plague	<i>Yersinia pestis</i> (gram-negative rod)	Mammals (deer, mice, rodents, squirrels, chipmunks), carnivores, pets	Flea bite, direct inoculation, inhalation	Animal handlers	
Psittacosis	<i>Chlamydia psittaci</i>	Psittacine birds, fowl, ducks, sparrows, canaries, pigeons	Inhalation of bird feces, mouth-to-beak, direct inoculation of infected tissues	Bird handlers, turkey processors	
Rabies	Rabies virus	Wild animals, dogs, cats, livestock, some rodents	Direct inoculation	Animal handlers, veterinarians, children	
Rat-bite fever	<i>Streptobacillus moniliformis</i> , <i>Spirillum minus</i>	Rats, laboratory mice, turkeys	Direct inoculation, bites, ingestion	Animal handlers	
Relapsing fever	<i>Borrelia hermsii</i> and <i>Borrelia recurrentis</i>	Lice from humans, ticks from rodents	Bites	Campers, travelers	
Severe acute respiratory syndrome (SARS)	SARS coronavirus	Humans, animals?	Droplet, direct contact with respiratory secretions, air-borne?	Healthcare personnel	

Table 22.1 (Cont'd) Infectious diseases transmitted occupationally to selected workers

Condition	Organism	Source	Route	Workers at risk	Clinical manifestations
Sporotrichosis	<i>Sporothrix shenckii</i>	Soil, plants	Direct inoculation	Plant handlers, miners, lumber workers	Ulcer, lymphatic nodules
Spotted fever	<i>Rickettsia</i> spp.	Rodents, dogs	Tick bite, mite bite	Campers, travelers	Fever, headache, rash
Tetanus	<i>Clostridium tetani</i> (gram-positive rod)	Soil	Direct inoculation	Unimmunized travelers to endemic areas, laborers, drug addicts	Tetanus (local, cephalic, generalized)
Tularemia	<i>Francisella tularensis</i> (gram-negative coccobacilli)	Wild mammals (rabbits, muskrats), domestic animals, ticks, mosquitoes	Bites, direct inoculation, inhalation, rarely ingestion	Hunters, trappers, laborers, farmers	Depends on route of entry. Ulceroglandular, glandular, oculoglandular, oropharyngeal, pneumonic, typhoidal, and septic forms
Typhus	<i>Rickettsia</i> spp.	Humans, flying squirrels, rodents	Louse and flea or mite bites, direct inoculation, inhalation in laboratories	Outdoors workers, granary workers, laboratory technicians, soldiers	Fever, headache, rash, central nervous system
Whitlow	Herpes simplex virus type 1 (HSV-1)	Humans	Direct contact with infected secretions	Contact sports, healthcare personnel	Localized vesicles, regional lymphadenopathy (may recur)
Yellow fever	Flavivirus	Primates	Mosquito bite	Travelers to endemic areas	Biphasic fever, jaundice, hemorrhagic complications, vascular collapse
Yersiniosis	<i>Yersinia enterocolitica</i> , <i>Y. pseudotuberculosis</i> (gram-negative rod)	Rodents, lagomorphs, domestic animals, fowl	Direct inoculation ingestion via water/food	Animal handlers, campers	Gastrointestinal: enterocolitis mesenteric adenitis Skin: erythema nodosum Exudative pharyngitis Sepsis

Table 22.1 (Cont'd) Infectious diseases transmitted occupationally to selected workers

etiologic category, as well as the potential for recurrences, account for the high incidence of the common cold, even among healthy adults. Colds are more common in the fall, winter, and early spring, perhaps because of increased crowding among children during the colder seasons.

Workers are most apt to acquire colds from exposure to young children in the home. Secondary cases among coworkers may then develop. Adults experience two to four colds each year, although the incidence among adult women exceeds that of men by a small margin, and smokers have a substantially increased risk.

The modes of transmission of cold viruses are not entirely elucidated. For rhinoviruses, transmission among experimental subjects occurs most readily by direct hand-to-hand contact, with a case followed by autoinoculation of the mucous membranes of the eye or nose. Such finger-to-mucous membrane contact is ubiquitous and unavoidable. Other viruses are transmissible by aerosolized droplets. The importance of fomites (such as drinking glasses, telephone receivers, and shared office equipment) as vectors of transmission has not been determined.

Clinical manifestations Typical cold symptoms include nasal congestion, coryza, non-productive cough, sneezing, pharyngitis, and laryngeal irritation. Fever is often low grade, or may be absent. Viral upper respiratory infections usually resolve within 7–10 days, but longer durations are not uncommon.

Treatment, prevention, and control Treatment for uncomplicated infections is symptomatic. Decongestants are more useful in relieving symptoms than are antihistamines. Expectorants, saline gargles, and other non-prescription remedies are useful in some cases. Antibiotics should not be prescribed for the treatment of colds.

Colds are difficult to prevent. A policy of work restriction until symptoms improve may prevent the spread of colds but is likely to be impractical (Table 22.2). The cost-benefit analysis of such an approach could be useful, especially in childcare and healthcare settings. Hand washing after contact with nasal secretions may be helpful. Care should be taken to use tissues when coughing or sneezing and to dispose of soiled tissues after use.

Influenza

Epidemiology Influenza is a self-limited respiratory illness caused by types A and B influenza virus. Epidemics of influenza occur annually in the winter months. Adults remain susceptible to the illness despite prior episodes of infection because the antigenic structure of influenza viruses changes frequently, leading to new epidemics.

Influenza is spread from person to person, primarily by the coughing and sneezing of infected persons or sometimes by direct contact, either with infected persons or a contaminated surface. The disease is easily transmitted, and a single index case may transmit to a large number of susceptible persons in a short period of time. Adults and children typically are infectious from 1–2 days before through 5–6 days after the onset of symptoms.

Clinical syndromes An attack of influenza starts abruptly with fever, malaise, myalgia, and headache. Respiratory symptoms mimicking those of the common cold and lower respiratory symptoms including dry cough also are frequent. Fever resolves in uncomplicated cases in 48–72 hours, but other symptoms may persist for days to weeks. Influenza pneumonia, associated with hypoxemia, cough, and interstitial infiltrates, is not common in healthy adults. Elderly patients and those with underlying immunodeficiencies and chronic pulmonary diseases are at high risk for secondary bacterial pneumonias, often caused by *Streptococcus pneumoniae* and less often by *Haemophilus influenzae* and *Staphylococcus aureus*.

The diagnosis of influenza frequently is made on the basis of clinical symptoms and signs. However, influenza is very difficult to differentiate from respiratory illnesses caused by other pathogens on the basis of clinical symptoms alone. Other pathogens that can cause similar symptoms include, but are not limited to, *Mycoplasma pneumoniae*, adenovirus, respiratory syncytial virus (RSV), rhinovirus, parainfluenza viruses, and Legionella species. Many pathogens, including influenza, RSV, and parainfluenza, cause outbreaks in a seasonal pattern. Laboratory confirmatory tests can be performed to differentiate influenza from other illnesses. Appropriate patient samples to collect for laboratory testing can include a nasopharyngeal or throat swab from adults, or nasal wash or nasal aspirates, depending on which rapid test is used. Samples should be collected within the first 4 days of illness. Rapid influenza tests provide results within 24 hours; viral culture provides results in 3–10 days. Most of the rapid tests are more than 70% sensitive for detecting influenza and more than 90% specific. Because as many as 30% of samples that would be positive for influenza by viral culture may give a negative rapid test result, negative rapid tests should be followed by viral culture in a sample of the swabs collected. Viral culture can also identify other causes of influenza-like illness when influenza is not the cause.

Serum samples can be tested for influenza antibody to diagnose acute infections. Two samples should be collected per person: one sample within the first week of illness and a second sample 2–4 weeks later. If antibody levels increase from the first to the second sample, influenza infection likely occurred. Because of the length of time needed for a diagnosis of influenza by serologic testing, other diagnostic testing should be used for rapid detection of possible outbreaks. During community outbreaks, specific virologic or serologic diagnosis is not necessary once the type(s) of influenza virus causing the outbreak have been identified.

Treatment, prevention, and control Persons at high risk for serious morbidity (persons aged 65 and older, persons with chronic underlying diseases) should receive influenza vaccine annually. Immunization also is recommended for healthcare personnel and others at risk for transmitting influenza to high-risk patients (Table 22.3). While annual immunization of healthcare personnel is recommended, the National Health Interview Survey indicated vaccination rates of only 34% and 37% in the 1997 and 2000 surveys, respectively.³ Vaccination of healthcare personnel

Disease/problem	Work restriction	Duration
Conjunctivitis	Restrict from patient contact	Until discharge ceases
Cytomegalovirus infections	No restriction	
Diarrheal diseases		
Acute stage (diarrhea with other symptoms)	Restrict from patient contact, contact with the patient's environment, or food handling	Until symptoms resolve
Convalescent stage, <i>Salmonella</i> spp.	Restrict from care of high-risk patients	Until symptoms resolve; consult with local and state health authorities regarding need for negative stool cultures
Hepatitis A		Until 7 days after onset of jaundice
Hepatitis A	Restrict from patient contact, contact with patient's environment, and food handling	Until lesions heal
Herpes simplex		
Hands (herpetic whitlow)	Restrict from patient contact and contact with the patient's environment	
Measles		
Active	Exclude from duty	Until 7 days after the rash appears
Postexposure (susceptible personnel)	Exclude from duty	From the 5th day after the 1st exposure through the 21st day after last exposure
Meningococcal infections		Until 24 hours after start of effective therapy
Mumps		
Active	Exclude from duty	Until 9 days after onset of parotitis
Postexposure (susceptible personnel)	Exclude from duty	From 12th day after 1st exposure through 26th day after last exposure or until 9 days after onset of parotitis
Pertussis		
Active	Exclude from duty	From beginning of catarrhal stage through 3rd week after onset of paroxysms or until 5 days after start of effective antimicrobial therapy
Postexposure (asymptomatic personnel)		
Postexposure (symptomatic personnel)	No restriction, prophylaxis recommended	Until 5 days after start of effective antimicrobial therapy
Rubella		
Active	Exclude from duty	Until 5 days after rash appears
Postexposure (susceptible personnel)	Exclude from duty	From 7th day after 1st exposure through 21st day after last exposure
<i>Staphylococcus aureus</i> infection		
Active, draining skin lesions	Restrict from contact with patients and patient's environment or food handling	Until lesions have resolved
Tuberculosis		
Active disease	Exclude from duty	Until proved non-infectious
TST converter	No restriction	
Varicella		
Active	Exclude from duty	Until all lesions dry and crust
Postexposure (susceptible personnel)	Exclude from duty	From 10th day after 1st exposure through 21st day (28th day if VZIG given) after last exposure
Viral respiratory infections, acute febrile	Consider excluding from the care of high-risk patients or contact with their environment during community outbreak of RSV and influenza	Until acute symptoms resolve
Zoster		
Localized, in healthy person	Cover lesions; restrict from care of high-risk patients	Until all lesions dry and crust
Generalized or localized in immunosuppressed person	Restrict from patient contact	Until all lesions dry and crust
Postexposure (susceptible personnel)	Restrict from patient contact	From 10th day after 1st exposure through 21st day (28th day if VZIG given) after last exposure or, if varicella occurs, until all lesions dry and crust

Modified from Bolyard et al. 1998¹⁹**Table 22.2** Summary of suggested work restrictions for healthcare personnel exposed to or infected with infectious diseases of importance in healthcare settings, in the absence of state and local regulations

Immunogen	Indications	Schedule	Major precautions and contraindications	Special considerations
Anthrax vaccine adsorbed (AVA)	US military personnel; selected laboratory personnel	Primary vaccination, three SQ doses at 0, 2, and 4 weeks, followed by doses at 6, 12, and 18 months. Annual boosters recommended by manufacturer	Severe allergic (anaphylactic) reaction following a previous dose of AVA or a vaccine component	No studies of vaccine use during pregnancy Vaccine not recommended during pregnancy Vaccinate during pregnancy only if the potential benefits of vaccination outweigh the potential risks to the fetus
<i>Haemophilus influenzae</i> type b vaccine Hepatitis A vaccine	Consider for adults at high risk (HIV infection, asplenia) Persons who work with HAV-infected primates or with HAV in a laboratory setting; persons at increased risk for HAV infection, or who are at increased risk of complications of HAV infection; travelers to countries where hepatitis A is endemic; not routinely indicated for US healthcare personnel Adults at increased risk of occupational, social, environmental, or family exposure	Dose not established Two doses of vaccine IM, either (HAVRIX) 6–12 mos apart or (VAQTA) 6 mos apart	History of anaphylactic reaction to alum or preservative 2-phenoxy ethanol Vaccine safety during pregnancy not evaluated. Risk to fetus is likely low and should be weighed against the risk of hepatitis A in women at high risk	
Hepatitis B recombinant vaccine	Adults with increased risk of occupational, social, environmental, or family exposure	IM injections at 0, 1, and 6 months; indications for boosting are not established	No apparent adverse effects to fetus; not contraindicated in pregnancy. History of anaphylactic reactions to common baker's yeast History of anaphylactic hypersensitivity after eating eggs	Test persons with ongoing risk of exposure 1–2 months after completing the primary series to assess serologic response No evidence of maternal or fetal risk when given during pregnancy; recommended after 1st trimester
Influenza vaccine	Adults with cardiopulmonary disease, chronic care facility residence, medical care provider, older than 65 years	Annual immunization		
Measles vaccine	All born after 1956 unless: 1. MD diagnosed measles 2. live vaccine on or after first birthday 3. laboratory evidence of immunity	1 SQ dose; second dose at least 1 month later, at entry to college, on employment in healthcare setting, or before travel	Pregnancy; immunocompromised state (including HIV-infected persons with severe immunosuppression); history of anaphylactic reactions after eating gelatin or receipt of neomycin; recent receipt of immune globulin	MMR is vaccine of choice if recipients likely to be susceptible to rubella and/or mumps Persons vaccinated between 1963 and 1967 with killed measles vaccine alone or a vaccine of unknown type should be revaccinated with two doses of live measles vaccine May be useful in some outbreak situations
Meningococcal vaccine (tetraivalent A, C, W135, Y)	Travelers to areas where disease is epidemic, consider for laboratorians working with aerosolizable solutions with <i>N. meningitidis</i> All susceptible adults; if person was born before 1957, assume immunity	One dose; need for boosting not established	Vaccine safety in pregnant women not evaluated; vaccine should not be given during pregnancy unless risk of infection high	MMR is vaccine of choice if recipients likely to be susceptible to rubella and/or measles
Mumps live vaccine		One SQ dose	Pregnancy; immunocompromised state; history of anaphylactic reaction after gelatin ingestion or receipt of neomycin	
Pneumococcal vaccine (23 valent)	Adults with underlying disease or immunodeficiency predisposing to pneumococcal infection; adults older than 65 years	One dose IM or SQ; repeat after 6 years for high-risk patients	Serious allergic reaction to a dose of pneumococcal vaccine or a vaccine component is a contraindication to further doses of vaccine	The safety of vaccine in pregnancy not studied. Women at high risk of pneumococcal disease and who are candidates for pneumococcal vaccine should be vaccinated before pregnancy, if possible Use only IPV for immunosuppressed persons or personnel who care for immunosuppressed patients. Use OPV if immediate protection against polio needed
Polio vaccine inactivated (IPV) live oral (OPV)H	Not routinely recommended for unimmunized adults over 18 years unless traveling to endemic area or in healthcare occupation	IPV preferred (2 doses 4–8 weeks apart, and then 3rd dose 6–12 months later); use OPV if exposure is possible within next 4 weeks (single oral dose). Booster doses may be IPV or OPV	History of anaphylactic reaction after receipt of streptomycin or neomycin. Safety of vaccine during pregnancy not evaluated; do not give during pregnancy	

Table 22.3 Recommended adult immunizations against selected infections

Immunogen	Indications	Schedule	Major precautions and contraindications	Special considerations
Rabies human diploid cell vaccine (HDCV), rabies vaccine adsorbed (RVA), purified chick embryo cell (PCEC) vaccine	Personnel who work with rabies virus or infected animals in diagnostic or research activities	Primary, HDCV, RVA, PCEC IM, 1 ml (deltoid), one each on days 0, 7, and 21 or 28, or HDCV, ID 1 ml, one each on days 0, 7, and 21, or 28. Booster HDCV or RVA, IM, 0.1 ml (deltoid) day 0 only, or HDCV ID 0.1 ml day 0 only	Corticosteroids, other immunosuppressive agents, antimalarials, and immunosuppressive illnesses can interfere with the development of active immunity after vaccination Immunosuppressed persons who are at risk for rabies should be vaccinated by the IM route and their antibody titers checked Pregnancy; immunocompromised state; history of anaphylactic reaction after receipt of neomycin	The frequency of booster doses should be based on frequency of exposure. Vaccine may be given during pregnancy if risk of exposure warrants vaccination
Rubella vaccine (live)	All adults lacking prior live vaccine or laboratory evidence of immunity	One SQ dose		Women pregnant when vaccinated or who become pregnant within 3 mos of vaccination should be counseled on the theoretic risks to the fetus; the risk of rubella vaccine-associated malformations is negligible. MMR is vaccine of choice if recipients likely to be susceptible to mumps and/or measles
Tetanus and diphtheria toxoid (Td)	All adults, prophylaxis for wound management	Two IM doses 4 weeks apart, third dose 6–12 months later, booster every 10 years	First trimester of pregnancy; history of neurologic reaction or immediate hypersensitivity reaction; persons with severe local (Arthus-type) reaction after previous dose of Td vaccine should not be given further routine or emergency doses of Td for 10 years	
Typhoid vaccine, SQ, oral	Personnel in laboratories who frequently work with <i>Salmonella typhi</i> Travelers to areas where exposure risk is present	Two 0.5 ml doses SQ > 4 weeks apart; booster every 3 years; or four oral doses on alternate days; repeat every 5 years	History of severe local or systemic reaction to a previous dose of typhoid vaccine; Ty21a should not be given to immunocompromised persons	Vaccination should not substitute for proper procedures when handling specimens and cultures in the laboratory
Vaccinia (smallpox)	Laboratory workers who directly handle cultures or animals contaminated or infected with non-highly attenuated vaccinia virus, recombinant vaccinia viruses derived from non-highly attenuated vaccinia strains, or other orthopoxviruses that infect humans (e.g., monkeypox, cowpox, vaccinia, and variola), workers investigating or caring for animal or human monkeypox cases	One dose administered with a bifurcated needle; boosters every 10 years	Vaccinia vaccine should not be administered for routine non-emergency indications if these conditions are present among either recipients or their household contacts: eczema, pregnancy, immunosuppression, anaphylactic reactions to neomycin, polymyxin, streptomycin, and chlortetracycline	Recently vaccinated healthcare personnel should avoid contact with unvaccinated patients, particularly those with immunodeficiencies, until the scab has separated from the skin at the vaccination site
Varicella	Healthcare personnel without reliable history of varicella or laboratory evidence of immunity	Two 0.5 ml doses SQ, 4–8 weeks apart if ≥ 13 years of age	Pregnancy, immunocompromised state, history of anaphylactic reaction after receipt of neomycin or gelatin; salicylate use should be avoided for 6 weeks after vaccination	Serologic testing before vaccination may be cost-effective because up to 93% of persons with history of varicella are immune

Adapted from Bolyard et al. 1998¹⁹ and CDCP 1997.⁵⁴**Table 22.3 (Cont'd)** Recommended adult immunizations against selected infections

had been associated with reduced work absenteeism and fewer deaths among nursing home patients.^{3,4} Most employers do not provide influenza prevention programs for workers outside the healthcare field.³

Amantadine and rimantadine can reduce the duration of uncomplicated influenza A illness when administered within 2 days of onset of illness in otherwise healthy adults. Zanamavir and oseltamivir can reduce the duration of uncomplicated influenza A and B illness by approximately 1 day compared with placebo. None of these antiviral agents has been shown to be effective in preventing serious influenza-related complications. To reduce the emergence of antiviral drug-resistant viruses, the duration of therapy should typically be no longer than 5 days.

Both amantadine and rimantadine are indicated as prophylaxis for influenza A, but not for influenza B infection. Oseltamivir has been approved as prophylaxis for influenza A and B. Zanamivir has not been approved for prophylaxis, but has been shown to be as effective as oseltamivir in preventing febrile, laboratory-confirmed influenza illness. They are approximately 70–90% effective in preventing illness from influenza A. Chemoprophylaxis can be a component of influenza outbreak control programs.³

Measles

Epidemiology The incidence of measles (rubeola) has steadily declined in the United States during the last decade and is no longer considered endemic. Measles is a major cause of morbidity and mortality worldwide. The majority of cases in the United States in recent years have been imported or secondary cases epidemiologically linked to imported cases.⁵

Infected persons are highly contagious by the air-borne route during the viral prodrome, and when cough and coryza are prominent, until about 2 days after the rash appears. Infection confers lifelong immunity. Although most adults born prior to 1957 experienced childhood infection and are no longer susceptible, up to 10% may lack natural immunity. In recent epidemics, cases occurred among unimmunized children, as well as children and young adults who had received a single vaccination with live virus, and among older adults.⁵

Clinical syndromes Measles progresses in several phases. Initial virus replication occurs in the respiratory tract and leads to a primary viremic phase, which usually is asymptomatic. Release of virus from infected reticuloendothelial cells produces secondary viremia and infection of the entire respiratory system, accompanied by symptoms of coryza, cough, and in some, bronchiolitis or pneumonia. Koplik's spots, a bluish-gray enanthem most prominent on the buccal mucosa, precede development of the rash. In a typical case of measles, the rash begins on the face, then progresses to the trunk and distal extremities, and disappears in the same sequence after 5–6 days.

Treatment, prevention, and control Live-attenuated vaccine for prevention of measles became available in the early 1960s. All healthy children should receive the vaccine

at age 15 months. Because 10% do not respond to a single dose of vaccine, a second dose is now recommended to improve vaccine efficacy.⁷

All healthy adults born after 1957 who have not received two doses of live virus vaccine or have not experienced measles also are advised to receive vaccine (Table 22.3). Persons who received killed vaccine have a risk of developing atypical measles, and require re-immunization with live virus vaccine. Live virus vaccine is contraindicated in infants, pregnant women, and immunosuppressed persons. Passive immunization with γ globulin is available for unimmunized persons exposed to infected individuals, but is not routinely recommended for adults. Measles rarely can exacerbate tuberculosis and cause a temporary inhibition of delayed hypersensitivity. Vaccine administration should be delayed for 1 month after tuberculin testing, and until treatment is under way in persons with active tuberculosis.

Mumps

Epidemiology Mumps is a viral illness transmitted by the oral or respiratory route during contact with contaminated fomites or aerosolized droplet secretions. Mumps is less contagious than measles or rubella but produces significant morbidity, especially among adults. The incubation period ranges from 2 to 3 weeks. Virus is detectable for 6 days prior to and 9 days after the appearance of symptoms. Most adults are immune to mumps, but 10–20% of unimmunized adults have no serologic evidence of prior infection and are considered susceptible. Mumps incidence is now very low in all areas of the United States. The substantial reduction in mumps incidence during the past few years likely reflects the change in the recommendations for use of measles mumps rubella (MMR*) vaccine.⁶

Clinical syndromes Parotitis typically is bilateral, but unilateral disease and involvement of other salivary glands occurs in some persons. Localized parotid tenderness and swelling, fever, and painful swallowing suggest the diagnosis. Aseptic meningitis is common but benign. Encephalitis is a rare but serious manifestation. About 25% of affected postpubescent men develop orchitis, epididymitis, or both, which is bilateral in 15% of cases and may be the sole manifestation of mumps infection. About 50% of cases of mumps orchitis result in testicular atrophy, but neither sterility nor impotence are common sequelae. Oophoritis occurs in about 5% of women with mumps.

Treatment, prevention, and control Two doses of MMR vaccine separated by at least 1 month (i.e., a minimum of 28 days), and administered on or after the first birthday, are recommended for all children and for certain high-risk groups of adolescents and adults.⁶ Adult men and healthcare personnel with no history of mumps or mumps immunization should be screened for immunity and

* The use of trade names and commercial sources is for identification only and does not imply endorsement by the Public Health Service or the US Department of Health and Human Services.

vaccinated if they are susceptible. Immunization is contraindicated in persons with immunosuppression and in pregnant women (Table 22.3). Passive immunization with mumps immune globulin decreases the incidence of orchitis and is recommended for mumps in adult men with a single testis. Individuals with active mumps should be excluded from work until 9 days after the onset of parotitis to avoid transmission to others in the workplace (Table 22.2).

Parvovirus (fifth disease)

Epidemiology Fifth disease, also called erythema infectiosum or 'slapped cheek disease', is an infection caused by parvovirus B19. It is a common rash illness that is usually acquired in childhood, but can be an occupational risk for school and childcare personnel. It has been transmitted to personnel in healthcare settings.

Clinical syndromes Symptoms begin with mild fever and symptoms of fatigue. After a few days, the cheeks take on a flushed 'slapped' appearance. There may also be a lacy rash on the trunk, arms, and legs. Not all infected persons develop a rash. The child is usually not very ill, and the rash resolves in 7–10 days. Most persons who get fifth disease are not very ill and recover without any serious consequences. An adult who is not immune can be infected with parvovirus B19 and either have no symptoms or develop the typical rash of fifth disease, joint pain or swelling, or both. Usually, joints on both sides of the body are affected. The joints most frequently affected are the hands, wrists, and knees. The joint pain and swelling usually resolve in a week or two, but they may last several months. About 50% of adults, however, have been previously infected with parvovirus B19, have developed immunity to the virus, and cannot get fifth disease. Fifth disease is believed to be spread through direct contact, fomites, or large droplets. The period of infectivity is before the onset of the rash. Once the rash appears, a person is no longer contagious. The incubation period is 4–14 days but may be as long as 20 days.

Treatment, prevention, and control Symptomatic treatment for fever, pain, or itching is usually all that is needed for fifth disease. Adults with joint pain and swelling may need to rest, restrict their activities, and take anti-inflammatory medications to relieve symptoms. Transmission can be prevented by careful attention to hygiene, especially hand washing. No special precautions are necessary. Excluding persons with fifth disease from work, childcare centers, or schools is not likely to prevent the spread of the virus, since people are contagious before they develop the rash.

Pertussis

Epidemiology Pertussis, or whooping cough, is an acute infectious disease caused by the bacterium *Bordetella pertussis*. Pertussis continues to be an important cause of mortality in the United States. A dramatic decline in the incidence followed the widespread use of whole-cell pertussis

vaccines in the mid-1940s. However, since the early 1980s, the reported pertussis incidence has increased cyclically with peaks occurring every 3–4 years.^{7,8} Contributing to this increase in incidence is the waning of immunity over time following vaccination, particularly in older age groups. Transmission most commonly occurs by contact with respiratory secretions or large aerosol droplets from the respiratory tracts of infected persons and less frequently by contact with freshly contaminated articles of an infected person. Analysis of national surveillance data for pertussis during 1997–2000 indicates that pertussis incidence continues to increase in infants too young to receive three doses of pertussis-containing vaccine and in adolescents and adults.⁷

Clinical syndromes The incubation period of pertussis is commonly 7–10 days. Pertussis begins insidiously with non-specific upper respiratory symptoms including coryza, sneezing, low-grade fever, and a mild, occasional cough, similar to the common cold. The cough gradually becomes more severe, and after 1–2 weeks, the second, or paroxysmal stage, begins. Characteristically, the patient has paroxysms of numerous, rapid coughs generally with a characteristic high-pitched whoop, commonly followed by vomiting and exhaustion. The patient usually appears normal between attacks. Older persons (i.e., adolescents and adults), and those partially protected by the vaccine may become infected with *B. pertussis*, but usually have milder atypical disease. Pertussis in these persons may present as a more persistent cough of greater than 7 days duration, and may be indistinguishable from other upper respiratory infections. Inspiratory whoop is uncommon. *B. pertussis* is estimated to account for up to 7% of cough illnesses per year in older persons. Even though the disease may be milder in older persons, these infected persons may transmit the disease to other susceptible persons, including unimmunized or underimmunized infants.

Treatment, prevention, and control The medical management of pertussis cases is primarily supportive, although antibiotics are of some value, with erythromycin being the drug of choice. This therapy eradicates the organism from secretions, thereby decreasing communicability and, if initiated early, may modify the course of the illness. There is no pertussis-containing vaccine (including DTaP) currently licensed for persons 7 years of age or older, and vaccination with DTaP currently is not recommended after the 7th birthday. Vaccine reactions are thought to be more frequent in older age groups, and pertussis-associated morbidity and mortality decrease with increasing age. Studies are currently under way to determine if a booster dose of acellular pertussis vaccine administered to older children or adults may reduce the risk of infection with *B. pertussis*. This may in turn reduce the risk of transmission of *B. pertussis* to infants and young children who may be incompletely vaccinated. Studies among older children, adolescents, and adults examining pertussis disease burden and transmission of disease to infants might guide future policy decisions on the use of acellular pertussis vaccines

among persons more than seven years of age. Currently, vaccination of children more than 7 years of age, adolescents, and adults is not recommended either routinely or as an outbreak control measure. In the future, licensure of pertussis vaccines for adolescents or adults may lead to new recommendations for the use of vaccines in outbreaks.⁹

Pneumonias

Epidemiology Most epidemics of bacterial pneumonia in the workforce are due to community-acquired infections. However, legionellosis is one type of pneumonia which can be transmitted in the workplace. *Legionella pneumophila* is an important cause of both epidemic and endemic adult pneumonia, and it can be associated with outbreaks in the workplace. This organism colonizes aquatic ecosystems and potable water, and it is transmitted to humans by the air-borne route. Contaminated air conditioners, humidifiers, and shower heads have been implicated in outbreaks among workers and hospital patients. Outbreaks of legionellosis have occurred after persons have breathed mists that come from a water source (e.g., air conditioning cooling towers, whirlpool spas, showers) contaminated with *Legionella* bacteria. Persons may be exposed to these mists in homes, workplaces, hospitals, or public places. Legionellosis is not passed from person to person.

A careful occupational history should be obtained from all adults who present with pneumonia, because occupational exposures cause many otherwise rare pneumonias. Public health authorities should be notified if an occupational source is suspected so that an epidemiologic investigation to identify transmission routes and other susceptible individuals may commence.

Clinical pneumonia syndromes Community-acquired bacterial pneumonia usually is exhibited acutely, with fever, chills, productive cough, and often, pleurisy. Chest examination demonstrates signs of consolidation that may be confirmed radiologically. Sputum examination may aid implementation of empiric therapy by suggesting the etiologic pathogen. Blood cultures should be obtained when invasive disease is suspected, and lumbar puncture to evaluate meningeal fluid is indicated when symptoms or signs of meningitis are present.

Patients with legionnaire's disease usually have fever, chills, and a cough, which may be dry or productive. Some patients also have muscle aches, headache, tiredness, loss of appetite, and, occasionally, diarrhea. Chest x-rays often show pneumonia but are not pathognomonic. It is difficult to distinguish legionnaire's disease from other types of pneumonia by symptoms alone; other tests are required for diagnosis. The definitive test is culture isolation of the organism in sputum, bronchoalveolar fluid, or pleural fluid.

Other useful diagnostic tests detect the bacteria in sputum by specialized stains, identify *Legionella* antigens in urine samples, or compare antibody levels to *Legionella* in two blood samples obtained 3–6 weeks apart. The time between the patient's exposure to the bacterium and the onset of illness for legionnaire's disease is 2–10 days.

Treatment, prevention, and control Empiric ambulatory therapy of acute community-acquired bacterial pneumonia, not requiring hospitalization, should include coverage for pneumococcus and *H. influenzae*, if the patient has a history of chronic obstructive lung disease. Amoxicillin, trimethoprim-sulfamethoxazole and cefixime are reasonable choices, unless atypical pneumonia caused by *M. pneumoniae* or *C. pneumoniae* is suspected, in which case erythromycin is preferred. Erythromycin is the antibiotic currently recommended for treating persons with legionnaire's disease. In severe cases, a second drug, rifampin, may be added.

Preventing bacterial pneumonia is a difficult challenge. Workers at risk for pneumococcal and *Haemophilus* infections should be immunized, although the efficacy of this approach among patients at highest risk is debated (Table 22.3). Influenza immunization could eliminate a major risk factor for both primary and secondary bacterial pneumonias. Occupational exposures to potential pathogens should be minimized with proper ventilation. Prevention of legionellosis is achieved by maintaining an environment that is not conducive to survival or multiplication of *Legionella*. The necessary preventive measures may involve water treatment or modification of air conditioning and ventilation systems.¹⁰ These preventive steps, which may be costly, should be directed at healthcare facilities, and occupational settings where cases have been identified.¹¹

Rubella

Epidemiology Rubella (German measles) virus is transmitted person to person by mucosal exposure to infected droplets of respiratory secretions. Since 1969, children in the United States have been routinely immunized against rubella at age 15 months, so that the majority of recognized cases today occur in adults and unimmunized children. Since 1992, reported indigenous rubella has continued to occur at a low but relatively constant endemic level with an annual average of less than 200 rubella cases.⁷ Recent data indicate that the rate of rubella susceptibility and risk for rubella infection are highest among young adults. No large epidemics have occurred since the vaccine was licensed for use in 1969. However, outbreaks continue to occur among groups of susceptible persons who congregate in locations that increase their exposure, and among persons with religious and philosophic beliefs against vaccination. Several recent outbreaks have occurred in workplaces where most employees are foreign born, particularly from Latin America.⁶ Reinfection can occur following natural or acquired immunity, but it is usually asymptomatic and only rarely accompanied by viremia.

Rubella virus is shed from the respiratory tract of infected persons beginning 10 days before the development of rash and for several days after the rash appears. The onset of the rash coincides with the period of maximal contagiousness, and infected persons are not considered infectious for more than 7 days after the rash appears. Infected infants shed virus for several months despite the presence of antibody.

Clinical syndromes Adult rubella is often asymptomatic. Symptoms occur 12–23 days after exposure. Following a prodrome of fever and malaise, adults exhibit a maculopapular rash that begins on the face and extends downward, persists for 3–5 days, and often is accompanied by regional lymphadenopathy of the head and neck, which persists for days to weeks. One-third of adult women may develop arthritis in the fingers, knees, and wrists during the exanthematous phase of illness. Children develop hemorrhagic complications more often than adults. In contrast, encephalitis, albeit rare, is more common in adults and is fatal in 20–50% of cases.

Maternal rubella infection acquired in the first 20 weeks of gestation frequently results in congenital rubella. The earlier in pregnancy rubella occurs, the more severe the fetal consequences. Infection in the first trimester results in deafness, congenital heart disease, cataracts or glaucoma, endocrine abnormalities, and mental retardation in up to 60% of newborns. Spontaneous abortion also occurs commonly.

Treatment, prevention, and control Immunization of children and susceptible adults with live attenuated rubella virus effectively prevents rubella and accounts for the dramatic decline in the incidence of this disease in the United States. However, many adult women of childbearing age remain susceptible to rubella and require immunization prior to conception to prevent congenital rubella. The hemagglutination-inhibition serologic assay detects natural or acquired immunity. The Advisory Committee on Immunization Practices (ACIP) recommends screening of healthcare personnel who have not been vaccinated, and immunization of susceptible individuals.⁷ Complications of rubella vaccine occur among adults and include low-grade fever, symmetric polyarthralgias, distal paresthesias, lymphadenopathy, and rash. Vaccine is contraindicated in immunosuppressed persons and pregnant women. Pregnancy should be avoided for 3 months after vaccination (Table 22.3).

Susceptible household contacts of infected adults and children pose a transmission risk in the workplace during the period of virus shedding, beginning about 10 days before the development of rash (about 1 week after exposure) until 7 days after rash appears. Therefore, susceptible individuals should not report to work during this time interval (Table 22.2).

Tuberculosis

Epidemiology Tuberculosis (TB) is caused by *Mycobacterium tuberculosis* and, rarely today, by *M. bovis*. The incidence of tuberculosis (TB) in the United States declined steadily until the mid-1980s, but then sharply increased, especially in urban areas. The resurgence of TB in the United States in the late 1980s and early 1990s was associated with the emergence of multidrug-resistant TB (MDR-TB) and the HIV/AIDS epidemic. With this resurgence of TB in the United States came several high-profile nosocomial outbreaks associated with lapses in infection control practices and delays in diagnosis and treatment of persons with infectious TB, as well as

the appearance and transmission of MDR-TB strains. Since 1992, the declines in the overall number of reported TB cases, including the level of MDR-TB, appear to reflect successful efforts to strengthen TB control following the resurgence of TB and the emergence of MDR-TB.¹²

Activities emphasizing the first priority of TB control (i.e., promptly identifying persons with TB, initiating appropriate therapy, and ensuring completion of therapy) have been the most important factors in achieving this improvement. Such activities reduced community transmission of *M. tuberculosis*, particularly in areas with a high incidence of AIDS. Improvements in implementation of infection control measures in healthcare settings, concurrent with mobilization of the nation's TB control programs, succeeded in reversing the upsurge in reported cases of TB, and case rates have declined to their lowest levels to date. The threat of MDR-TB is decreasing, and the transmission of TB in healthcare facilities continues to abate due to implementation of infection controls and reductions in community rates of TB.

Nevertheless, some healthcare personnel are at risk for acquiring TB. Pulmonary TB is most commonly transmitted in healthcare settings by inhalation of aerosolized droplet nuclei derived from the respiratory secretions of patients with active respiratory TB. Close contact usually is required. Most other categories of workers generally are not at risk without close and sustained workplace contact with a person who has active untreated disease. Ingestion of unpasteurized milk from cows infected with *M. bovis* is no longer an important source of TB in most industrialized countries.

Clinical syndromes Primary infection usually is asymptomatic in adults. Teenagers and young adults are at higher risk for rapid progression to active disease, usually characterized by apical cavitory disease, than are older adults. Primary infection in the elderly usually is exhibited as lower lobe consolidation with hilar adenopathy. Primary tuberculosis in persons with advanced HIV infection is commonly symptomatic and progressive.

Once infection occurs, the organism may disseminate from the lungs to other sites, including the gastrointestinal and genitourinary tracts, and bone. Normally, the infection is contained by the host's immune response at this stage. The risk for reactivation is highest in the first year after exposure and declines thereafter. However, aging and stressors such as immunosuppression, intercurrent illness, and chronic malnutrition may increase the risk for reactivation or dissemination of the disease later in life. Clinically, reactivation tuberculosis usually is exhibited as upper lobe pulmonary cavitory disease, but virtually any organ system may be involved.

Treatment, prevention, and control Tuberculin skin testing allows determination of prior exposure to TB in immunologically healthy adults, by assessing delayed hypersensitivity to tuberculin antigens using purified protein derivative. The tuberculin skin test (TST) is the only proven method for identifying infection with *M. tuberculosis*

in persons who do not have TB disease. Although the available TST antigens are neither 100% sensitive nor specific for detection of infection with *M. tuberculosis*, no better diagnostic methods have yet been devised.

The preferred skin test for diagnosing *M. tuberculosis* infection is the Mantoux test. It is administered by injecting 0.1 ml of 5 tuberculin units (TU) PPD intradermally into the dorsal or volar surface of the forearm. Tests should be read 48–72 h after test administration, and the transverse diameter of induration should be recorded in millimeters. There are three cut-off levels recommended for interpretation of the TST results.¹⁴ In HIV-infected persons, any reaction resulting in an induration larger than 5 mm is read as positive. Among others, the presence of 15 mm or more of induration always indicates a positive test, 5–10 mm indicates a positive result in persons at risk for TB, and less than 5 mm is negative.

A positive TST means an individual has been exposed to TB in the past and is at risk for reactivation. A baseline chest radiogram should be performed on all persons with newly diagnosed TST positivity. If the x-ray study suggests active disease, sputum samples should be obtained, stained for acid-fast bacilli, and cultured for mycobacteria. Treatment should be implemented immediately if the index of suspicion is high. Public health officials should be notified to institute case management and evaluation of contacts in the home and work environment. If the x-ray study is negative, treatment with isoniazid to suppress or eradicate latent organisms may be recommended, especially in persons younger than age 35 and for those who have recently converted to positive TSTs.¹³

Although BCG vaccine is the most widely administered of all vaccines in the world, and has the highest coverage of any vaccine in the WHO Expanded Programme on Immunization, it appears to have had little epidemiologic impact on TB. Despite its shortcomings, and because of its beneficial effect in children and against leprosy, BCG vaccine likely will remain a component of childhood vaccination strategies in developing countries. However, because of questions about the vaccine's efficacy, and because it induces dermal hypersensitivity to purified protein derivative (PPD) tuberculin in most recipients, BCG has never been recommended for programmatic use in the United States.¹⁴

Healthcare providers should follow appropriate infection control procedures, including use of isolation rooms and respiratory protection, when caring for patients with active tuberculosis.^{15,16}

Varicella/zoster

Epidemiology Varicella virus, the causative agent of chickenpox and zoster, is a highly contagious herpes virus spread by the respiratory route from person to person. The incubation period is about 14 days, and the period of infectivity begins a few days prior to the onset of the rash to about 6 days after the first crop of vesicles appears. Immunosuppression usually prolongs the period of infectivity, especially if varicella zoster immune globulin (VZIG) has been administered. Zoster represents reactivation of

varicella virus that is latent in sensory nerve ganglia, and it is not a manifestation of primary infection except in newborns infected in utero. The incidence of zoster increases with age and immunosuppression. Susceptible persons in direct contact with zoster lesions risk developing primary varicella.

In the prevaccine era, varicella was endemic in the United States, and virtually all persons acquired varicella by adulthood. As a result, the number of cases occurring annually was estimated to approximate the birth cohort, or approximately 4 million per year. This incidence has likely decreased since licensure of the vaccine in 1995. Varicella is not a nationally notifiable disease, and surveillance data are limited.¹⁷

Clinical syndromes Varicella in otherwise healthy children usually is a benign, self-limited disease characterized by low-grade fever and vesicular rash, often preceded by a viral prodrome. Varicella vesicles of primary infection appear first on the scalp and trunk and disseminate in crops showing various stages of development over the next 3–4 days. Healing results in crusting accompanied by intense pruritus. Manifestations of varicella are more severe in adults than in children. About 15% of adults with varicella show radiographic evidence of pulmonary involvement, but this is rarely clinically significant. However, cough, tachypnea, and impaired gas exchange can occur and persist for months after infection. Varicella during pregnancy can produce congenital varicella. In its most severe form, this infection can result in mental retardation, blindness, growth retardation, deafness, chorioretinitis, and a peculiar dermatomal lesion of the upper or lower extremity associated with limb atrophy.

Zoster, the most common manifestation of varicella infection among adults, characteristically produces unilateral vesicular eruptions preceded by pain in one to three dermatomes. Disseminated zoster, which is more likely in immunosuppressed patients, probably poses the same risk of infection transmission as primary varicella infection. The major complication of zoster is postherpetic neuralgia, which is especially common in the elderly and may be extremely debilitating. Zoster frequently produces cerebrospinal fluid pleocytosis and occasionally encephalitis. Immunologically healthy persons may experience recurrences of zoster, usually in the same dermatome as the initial outbreak. Zoster is a marker of deteriorating cell-mediated immunity among HIV-infected patients, and it may disseminate.

Treatment, prevention, and control Passive immunization with VZIG is recommended for immunosuppressed susceptible persons, children with leukemia and other malignancies, and neonates exposed in utero within 5 days before delivery.¹⁸

Several antiviral drugs are active against varicella zoster virus, including acyclovir, valacyclovir, famciclovir, and foscarnet.¹⁸ Famciclovir and valacyclovir are approved for use only in adults. Clinical studies indicate that these drugs may be beneficial if given within 24 hours of onset

of rash, resulting in a reduction in the number of days new lesions appeared, in the duration of fever, and in the severity of cutaneous and systemic signs and symptoms. Antiviral drugs have not been shown to decrease transmission of varicella, reduce the duration of absence from school, or reduce complications. Oral acyclovir can be considered in otherwise healthy adolescents and adults or secondary cases in the household, because of the increased risk of severe illness in these groups. Antiviral therapy may also be considered for persons with chronic cutaneous or pulmonary disorders, persons receiving long-term salicylate therapy, and for children receiving short, intermittent or aerosolized courses of corticosteroids. Antiviral drugs are not recommended for routine postexposure prophylaxis. Systemic steroids in older adults (more than 60 years old) may reduce the incidence and severity of postherpetic neuropathy if started early (within 5 days of skin manifestations).

Varicella has been difficult to prevent because of the high degree of contagion in households, schools, and healthcare settings. Live attenuated virus vaccines have demonstrated efficacy in preventing primary infection, and one was licensed for use in the United States in 1995. Routine immunization is now recommended for children less than 18 months of age.¹⁷ Varicella vaccination should be given to susceptible adolescents and adults who are at high risk of exposure to varicella. This group includes persons who live or work in environments in which there is a high likelihood of transmission of varicella, such as teachers of young children, residents and staff in institutional settings, and military personnel. Varicella vaccination is also recommended for susceptible adolescents and adults who will have close contact with persons at high risk for serious complications of acquired varicella, including healthcare personnel and susceptible family contacts of immunocompromised individuals. The ACIP recommends that all healthcare personnel be immune to varicella, either from a reliable history of prior varicella infection or vaccination, to reduce the risk of infection and its complications, and to decrease the possibility of transmission of varicella zoster virus to patients (Table 22.3).

Susceptible adults exposed to children with varicella or with disseminated zoster pose a risk of transmitting varicella to non-immune coworkers, and they should not work until the incubation period is over or, if they become ill, until all lesions are crusted (Table 22.2). Dermatomal zoster is not spread efficiently by the air-borne route and otherwise healthy adults afflicted with this illness may be allowed to work if they can avoid touching the lesions and contaminating the work environment. The role of vaccine in the postexposure management of susceptible employees needs to be elucidated. Data from the United States and Japan in a variety of settings indicate that varicella vaccine is effective in preventing illness or modifying the severity of illness if used within 3 days, and possibly up to 5 days, of exposure. ACIP recommends vaccine be used in susceptible persons following exposure to varicella.¹⁷ Personnel should be excluded from work who have onset of varicella until all lesions have dried and crusted (Table 22.2).

Following exposure to varicella, personnel who are not known to be immune to varicella (by history or serology) should be excluded from duty beginning on the 10th day after the first exposure until the 21st day after the last exposure (28th day if VZIG was given).

Enteric infections

Acute gastrointestinal infection

Epidemiology Acute gastrointestinal infection follows upper respiratory illness as the next leading category of infectious diseases causing absenteeism among adult workers. A wide array of pathogens, including viruses, bacteria, and protozoa, can result in acute infections of the stomach, small bowel, or colon. A comprehensive discussion of enteric pathogens is provided in Chapter 54 (Waterborne Microbial Diseases). Most of the etiologic agents are acquired by the fecal-oral route; produce mild, self-limited diseases; and resolve without specific therapy. Agents of dysentery (e.g., *Shigella* spp.) often are highly transmissible through low-inoculum exposures. Occupational transmission of food-borne or water-borne illnesses occurs; person-to-person transmission has propagated outbreaks of many of these illnesses in healthcare settings, daycare and nursery schools, and institutions where sanitation is poor. Instances of such transmission have generally involved food handlers, who are often poorly trained and short-term employees, serving as sources of transmission to others. Occupations requiring travel to countries with poor sanitation present a major risk for gastrointestinal infections. Poultry workers are frequently exposed to salmonella infections.

Avoidance of oral contact with sources of fecal contamination is the most important strategy for preventing transmission of pathogens associated with intestinal infections. Maintaining good personal hygiene, including careful hand hygiene after using restrooms and before food preparation; proper cooking and storage of foods; and avoidance of contaminated foods and water when traveling are essential prevention strategies. Food handlers with diarrheal illnesses should not work until symptoms have resolved, and cure of bacterial infections should be documented by obtaining negative stool cultures more than 48 hours after antimicrobial therapy is completed (Table 22.2). The only vaccines for any of the etiologic agents for acute enteric infections are for typhoid and hepatitis A, which are recommended for personnel in laboratories who frequently work with *Salmonella typhi* or hepatitis A virus (Table 22.3).

Blood-borne infections

Cytomegalovirus

Epidemiology Cytomegalovirus (CMV) is a ubiquitous herpes virus transmitted by direct inoculation with infected body fluids (including blood, blood products, respiratory secretions, saliva, and urine) and through sexual contact with infected partners. At least 40% of

healthy adults have serologic evidence of prior CMV infection. Infection can be acquired perinatally, in utero during maternal primary infection, during birth by passage through infected vaginal secretions, or through ingestion of infected breast milk. CMV is known to be highly transmissible in daycare centers and nursery schools. Sexually active adults and recipients of blood products are also at high risk for infection.

Infants and young children excrete CMV in their urine, saliva, and respiratory secretions for several months after infection. Virus is much less readily detected in healthy adults, but intermittent shedding has been documented. Like all herpes viruses, CMV remains latent in the host after initial infection. Previously infected persons may be reinfected with new strains of CMV.

Occupational transmission of CMV has been documented in childcare settings, where person-to-person spread through exposure to infected secretions and urine is believed to provide an efficient mode of transmission. Up to 50% of seronegative workers in preschool daycare centers have acquired CMV infection in some studies, indicating a potentially serious risk to women of child-bearing age, because of the adverse effects of primary maternal CMV infection on the fetus. At one time, employment in healthcare settings also was believed to pose a high risk for CMV acquisition. However, epidemiologic investigations suggest that most infections in healthcare personnel are acquired sexually, or from exposure to young children in the home, and not from work-related contact.

Clinical syndromes Initial infection with CMV usually is asymptomatic in healthy persons. A self-limited mononucleosis-like illness occurs in a minority, which may be complicated by hepatitis, pneumonitis, hematologic abnormalities, and myocarditis.

Immunosuppressed children and adults with primary CMV infection, reactivation, or reinfection may develop severe sequelae. Organ transplant recipients, HIV-infected patients, and persons with malignancies have a risk of developing CMV viremia, pneumonia, hepatitis, pancreatitis, enteritis, and retinitis.

Primary CMV infection at any stage of pregnancy carries a greater risk to the fetus than does recurrent CMV infection during pregnancy. Symptoms of congenital CMV infection may be present at birth, and are due to the consequences of active virus replication and resultant end-organ damage. Congenital cytomegalic inclusion disease, the most severe form of this entity, includes central nervous system disease, respiratory distress, hepatitis, hepatosplenomegaly, rash, and multi-system failure. Infection acquired from exposure to cervical CMV during birth usually is asymptomatic and detected by the onset of virus shedding 4–8 weeks postpartum.

Treatment, prevention, and control Antiviral therapy with ganciclovir or foscarnet for CMV infection is reserved for immunosuppressed persons at high risk for severe complications. The safety and effectiveness of these agents in preventing congenital CMV have not been established.

Avoidance of mucosal contact with infected body fluids is the best strategy for preventing CMV transmission. Hand washing after contact with secretions and fomites is essential, especially in nurseries and daycare settings.

The presence of persons at risk for CMV shedding in the workplace does not pose a hazard to other employees unless direct contact with infected secretions is anticipated. Isolation of infected neonates or children is not essential if hand washing is performed after contact with secretions, blood, and urine. Pregnant healthcare providers compliant with hand washing protocols can generally safely care for patients with CMV infection.^{19–21} No work restriction is necessary for individuals with CMV infection (Table 22.2).

Hepatitis B

Epidemiology Hepatitis B virus (HBV) is transmitted by direct exposure to blood and other infected body fluids. Children born to infected mothers are at high risk for HBV infection. Persons parenterally exposed to blood, including multi-transfused patients, hemophiliacs, dialysis patients, and injection drug users, also are at significant risk. Sexual contact with infected partners is another efficient mode of HBV spread. In most industrialized countries, adult infections usually are acquired sexually or by injection drug use.

HBV is a relatively hardy virus capable of surviving on environmental surfaces and fomites. Transmission in households is well documented and may, in part, be attributable to mucosal contact with fomites contaminated with secretions or blood from infected persons.

Healthcare personnel and others at risk for occupational blood exposure through percutaneous, mucosal, or dermal routes can acquire HBV infection. The risk associated with accidental needle-stick inoculation of infected blood to susceptible healthcare personnel varies between 5% to 35%, depending on the hepatitis B e antigen (HBeAg) status, and hence the viral titer of the source. In up to 50% of occupational infections, a discrete exposure cannot be identified.

Hepatitis B has an incubation period of 40–180 days. The period of infectivity precedes the development of jaundice by 2–7 weeks and correlates with the presence of hepatitis B surface antigen (HBsAg) in the serum; 5–10% of persons with acute (but often clinically silent) infection develop chronic antigenemia. In the United States, up to 1% of adults are carriers of HBV, and provide a reservoir for maintenance of the disease in the population.

Clinical syndromes HBV infection results in clinically apparent hepatitis in about one-third of acutely infected adults. Clinical hepatitis may be preceded by a prodrome of fever, malaise, urticarial or maculopapular rash, and arthralgias for several days. Fever usually resolves before the onset of jaundice. Jaundice, dark urine, and scleral icterus usually are present by the time patients seek medical attention. Right upper quadrant tenderness, mild hepatic enlargement, and occasionally, splenomegaly are signs that should suggest the diagnosis. The most striking laboratory abnormality is the finding of extreme elevations

in the aminotransferase enzymes. Alanine aminotransferase (ALT) and aspartate aminotransferase (AST) may be elevated to more than 10 times the normal levels, whereas the bilirubin and alkaline phosphatase levels are increased to a much lesser extent.

Fulminant liver involvement occurs in about 1% of adults and may be complicated by more serious abnormalities, including hypoglycemia, coagulopathy, and hypoalbuminemia. Hepatic encephalopathy, hepatorenal syndrome, and bleeding diatheses are life-threatening complications seen in these patients. About 10% of adults with clinically apparent acute HBV infection proceed to chronic HBs-antigenemia, and are at risk for chronic hepatitis, postnecrotic cirrhosis, and primary hepatocellular carcinoma.

Patients with asymptomatic primary HBV infection are at higher risk for chronic infection than those with symptomatic infection. While chronic persistent hepatitis, a benign illness of little clinical consequence except for the potential for HBV transmission to susceptible individuals, may occur, the major health concern is chronic active hepatitis, which eventually may produce cirrhosis, liver failure, and hepatoma.

Hepatitis B is differentiated from other causes of hepatitis by serologic assays.²³ A positive hepatitis B surface antigen (HBsAg) test identifies patients with current infection and correlates with infectivity during acute and chronic infection. Titers of HBsAg in the chronic phase of illness may wax and wane and occasionally fall below the limits of laboratory detection, so sequential testing should be performed if chronic HBV is suspected. The presence of HBeAg correlates with active virus replication and is a marker of high infectivity and high titer of HBV in the liver and blood. Antibody to hepatitis B surface antigen (HBsAb) appears when HBsAg is cleared and is positive in individuals with immunity after recent or prior infection or immunization. Persons with HBsAb are not susceptible to acute infection or chronic hepatitis B, except in the very rare case in which reinfection occurs with a strain of hepatitis B against which the normal antibody response does not provide cross-protection. Hepatitis B core antibody (HBcAb) appears before HBsAb and just after HBsAg is cleared from the serum, and this is a useful test for diagnosing acute hepatitis B in the window period before HBsAb appears. High titers of HBcAb persist in chronically infected persons and obviously do not predict immunity from further liver disease.

Treatment, prevention, and control There currently is no treatment for acute hepatitis B. Alpha interferon and lamivudine have been licensed for the treatment of persons with chronic hepatitis B. These drugs are effective in up to 40% of cases.

HBV infection is largely preventable. Inoculation with recombinant vaccines containing HBsAg components is safe and highly immunogenic, and appears to confer protection from infection for at least 12 years (Table 22.2). Postvaccination testing should be done 1–2 months after completion of the three-dose series to document an appropriate response (i.e., > 10 mIU/ml).²³ More than 90% of

persons immunized with three properly timed doses (e.g., 0, 1, and 6 months) of vaccine administered intramuscularly in the deltoid region develop protective HBsAb levels. Factors associated with a lack of response include improper vaccination (improperly stored vaccine, gluteal inoculation, subcutaneous injection), obesity, older age, and smoking. Persons who do not respond to the primary vaccine series should receive a second three-dose series or be evaluated for HBsAg positivity.

Since 1982, substantial progress has been made toward eliminating HBV transmission in children and reducing the risk for HBV infection in adults.²⁴ Recommendations of ACIP have evolved from universal childhood vaccination, to prevention of perinatal HBV transmission, vaccination of adolescents and adults in high-risk groups, and catch-up vaccinations for susceptible children in high-risk populations.^{25,26} The ACIP vaccination strategies for children and adolescents have been implemented successfully in the United States, and routine immunization of all children is now recommended. The Occupational Safety and Health Administration's (OSHA's) Blood-borne Pathogen Standard mandates provision of vaccine at no cost to all healthcare employees and others at occupational risk for blood exposure.²⁷ Substantial declines in the incidence of acute hepatitis B have occurred among highly vaccinated populations, such as young children and healthcare personnel. Vaccine should also be provided to susceptible individuals before sexual maturity, particularly to teenagers in those settings (e.g., inner cities, concentration of poverty) where HBV is highly prevalent, and to all adults at risk for sexual or occupational exposure.

Preimmunization screening for evidence of prior or persistent infection usually is not cost effective. However, postimmunization testing for antibody response is recommended 1–2 months after the 3rd dose to detect non-responders among persons at high risk for exposure. Titers of HBsAb fall over time and may be undetectable after 5–10 years. The duration of vaccine protection is under investigation. Most data suggest that protection persists even when HBsAb titers fall below the level of detection, and routine screening and boosting are not recommended.

The need for prophylaxis for persons sustaining accidental percutaneous or mucosal exposures to blood should be based on several factors, including the HBsAg status of the source, and the hepatitis B vaccination and vaccine-response status of the exposed person. Such exposures usually involve persons for whom hepatitis B vaccination is recommended. Any blood or body fluid exposure to an unvaccinated person should lead to initiation of the hepatitis B vaccine series. A summary of prophylaxis recommendations for percutaneous or mucosal exposure to blood according to the HBsAg status of the exposure source and the vaccination and vaccine-response status of the exposed person is shown in Table 22.4.²³

When hepatitis B immune globulin (HBIG) is indicated, it should be administered as soon as possible after exposure (preferably within 24 hours). The effectiveness of HBIG when administered more than 7 days after exposure is unknown. When hepatitis B vaccine is indicated, it

Vaccination and antibody response status of exposed healthcare personnel*	Treatment		
	Source HBsAg [†] positive	Source HBsAg [†] negative	Source unknown or not available for testing
Unvaccinated	HBIG§ × 1 and initiate hepatitis B vaccine series	Initiate hepatitis B vaccine series	Initiate hepatitis B vaccine series
Previously vaccinated	No treatment	No treatment	No treatment
Known responder¶	HBIG × 1 and initiate revaccination or HBIG × 2 ^{††}	No treatment	If known high risk source, treat as if source were HBsAg positive
Known non-responder**	Test exposed person for anti-HBs:§§ 1. If adequate,¶ no treatment is necessary 2. If inadequate** HBIG × 1 and vaccine booster	No treatment	Test exposed person for anti-HBs: 1. If adequate, no treatment is necessary 2. If inadequate, administer vaccine booster and recheck titer in 1–2 months
Antibody response unknown			

* Persons who have previously been infected with HBV are immune to reinfection and do not require postexposure prophylaxis.

† Hepatitis B surface antigen.

§ Hepatitis B immune globulin; dose is 0.06 ml/kg intramuscularly.

¶ A responder is a person with adequate levels of serum antibody to HBsAg (i.e., anti-HBs ≥10 mIU/ml).

** A non-responder is a person with inadequate response to vaccination (i.e., serum anti-HBs <10 mIU/ml).

†† The option of giving one dose of HBIG and reinitiating the vaccine series is preferred for non-responders who have not completed a second three-dose vaccine series. For persons who previously completed a second vaccine series but failed to respond, two doses of HBIG are preferred.

§§ Antibody to HBsAg.

Table 22.4 Recommended postexposure prophylaxis for exposure to hepatitis B virus

should also be administered as soon as possible (preferably within 24 hours) and can be administered simultaneously with HBIG at a separate site (vaccine should always be administered in the deltoid muscle).

For exposed persons who are in the process of being vaccinated but have not completed the vaccination series, vaccination should be completed as scheduled, and HBIG should be added as indicated (Table 22.4). Persons exposed to HBsAg-positive blood or body fluids who are known not to have responded to a primary vaccine series should receive a single dose of HBIG and reinstate the hepatitis B vaccine series with the first dose of the hepatitis B vaccine as soon as possible after exposure. Alternatively, they can receive two doses of HBIG, one dose as soon as possible after exposure, and the second dose 1 month later. The option of administering one dose of HBIG and reinstituting the vaccine series is preferred for non-responders who did not complete a second three-dose vaccine series. For persons who previously completed a second vaccine series but failed to respond, two doses of HBIG are preferred.²³

Hepatitis C

Epidemiology Hepatitis C virus (HCV) infection is the most common chronic blood-borne infection in the United States. It is estimated that 1.8% of Americans have been infected with HCV. HCV-associated end-stage liver disease is the most frequent indication for liver transplantation among US adults.²⁸

The incubation period for acute HCV infection ranges from 2 to 24 weeks (averaging 6–7 weeks). HCV transmission occurs primarily through exposure to infected blood, such as through injection drug use, blood transfusion, solid organ transplantation from infected donors, unsafe medical practices, occupational exposure to infected blood, and birth to an infected mother (i.e., vertical transmission). HCV may also be acquired through sexual contact, but the importance of this mode of transmission in the United States is not well characterized. HCV is not transmitted efficiently through occupational exposures to blood. Healthcare personnel who are parenterally exposed to infected blood through needlestick injuries may acquire HCV infection, but the magnitude of risk (approximately 2 in 100 HCV needlesticks) is less than that associated with HBV exposure. One epidemiologic study indicated that transmission occurred only from hollow-bore needles compared with other sharps. Transmission rarely occurs from mucous membrane exposures to blood, and no transmission in HCV has been documented from skin exposures to blood. Data are limited on survival of HCV in the environment.

In contrast to HBV, the epidemiologic data for HCV suggest that environmental contamination with blood containing HCV is not a significant risk for transmission in the healthcare setting, with the possible exception of the hemodialysis setting where HCV transmission related to environmental contamination and poor infection control practices have been implicated. The risk for transmission from exposure to fluids or tissues other than HCV-infected blood also has not been quantified but is expected to be

low. HCV is not known to be transmissible through the airborne route, through casual contact in the workplace, or by fomites.

Clinical syndromes Hepatitis C virus infection produces a spectrum of clinical illness similar to HBV and is indistinguishable from other forms of viral hepatitis based on clinical symptoms alone. Serologic tests are necessary to establish a specific diagnosis of hepatitis C. Most adults acutely infected with HCV are asymptomatic. After acute infection, 15–25% of persons appear to resolve their infection without sequelae as defined by sustained absence of HCV RNA in serum and normalization of ALT levels.²⁸ Chronic HCV infection develops in most persons (75–85%), with persistent or fluctuating ALT elevations indicating active liver disease developing in 60–70% of chronically infected persons. No clinical or epidemiologic features among patients with acute infection have been found to be predictive of either persistent infection or chronic liver disease. Moreover, various ALT patterns have been observed in these patients during follow-up, and patients might have prolonged periods (greater than or equal to 12 months) of normal ALT activity even though they have histologically confirmed chronic hepatitis. Thus, a single ALT determination cannot be used to exclude ongoing hepatic injury, and long-term follow-up of patients with HCV infection is required to determine their clinical status and prognosis.

The course of chronic liver disease is usually insidious, and progresses slowly without symptoms or physical signs in the majority of patients during the first two or more decades after infection. Chronic hepatitis C frequently is not recognized until asymptomatic persons are identified as HCV positive during blood donor screening, or elevated ALT levels are detected during routine physical examinations. Most studies have reported that cirrhosis develops in 10–20% of persons with chronic hepatitis C over a period of 20–30 years, and HCC in 1–5%, with striking geographic variations in rates of this disease. However, when cirrhosis is established, the rate of development of HCC might be as high as 1–4% per year. Longer follow-up studies are needed to assess lifetime consequences of chronic hepatitis C, particularly among those who acquired infection at young ages.

Although factors predicting severity of liver disease have not been well defined, recent data indicate that increased alcohol intake, being aged greater than 40 years at infection, and being male are associated with more severe liver disease. In particular, among persons with alcoholic liver disease and HCV infection, liver disease progresses more rapidly; among those with cirrhosis, a higher risk for development of HCC exists. In addition, persons who have chronic liver disease are at increased risk for fulminant hepatitis A.

Screening enzyme immunoassay (EIA) and supplemental confirmatory immunoblot tests are licensed and commercially available to detect antibodies to HCV (anti-HCV). Anti-HCV may be detected within 5–6 weeks after the onset of infection but a single anti-HCV test cannot

distinguish between acute, chronic, or past infection. HCV RNA can be detected within 1–2 weeks of exposure to the virus and several weeks before elevations of ALT and detection of anti-HCV. Testing for anti-HCV by EIA is recommended 4–6 months after an exposure to detect infection; testing for HCV RNA may be performed 4–6 weeks after exposure if earlier detection of infection is desired.²³

Treatment, prevention, and control HCV-positive patients should be evaluated for the presence and severity of chronic liver disease. Initial evaluation for presence of disease should include multiple measurements of ALT at regular intervals, because ALT activity fluctuates in persons with chronic hepatitis C. Patients with chronic hepatitis C should be evaluated for severity of their liver disease and for possible treatment. Alpha interferon (with or without ribavirin) treatment of HCV appears to prevent HCV replication, decrease hepatic inflammation, and improve symptoms among chronically infected persons. Persons with chronic HCV have undergone successful liver transplantation, although recurrences have been documented in this setting.

Antiviral therapy is recommended for patients with chronic hepatitis C who are at greatest risk for progression to cirrhosis. These persons include anti-HCV-positive patients with persistently elevated ALT levels, detectable HCV RNA, and a liver biopsy that indicates either portal or bridging fibrosis or at least moderate degrees of inflammation and necrosis. Therapy for hepatitis C is a rapidly changing area of clinical practice and consultation with a knowledge specialist (e.g., hepatologist) is recommended.²⁹

No clinical trials have been conducted to assess postexposure use of antiviral agents (e.g., interferon with or without ribavirin) to prevent HCV infection, and antivirals are not FDA approved for this indication. Available data suggest that an established infection might need to be present before interferon can be an effective treatment.^{23,29}

Because there is currently no postexposure prophylaxis (PEP) for HCV, the intent of recommendations for postexposure management is to achieve early identification of infection and, if present, referral for evaluation of treatment options. In addition, no guidelines exist for administration of therapy during the acute phase of HCV infection. However, limited data indicate that antiviral therapy might be beneficial when started early in the course of HCV infection. When HCV infection is identified early, the person should be referred for medical management to a specialist knowledgeable in this area.²³

At present, avoidance of parenteral exposure to blood is the only available strategy for preventing HCV infection.

Human immunodeficiency virus

Epidemiology It is estimated that more than 60 million persons worldwide had been infected by HIV and that 40 million were living with HIV/AIDS by the end of the year 2000.³⁰ In the United States, almost 1 million persons are living with HIV.³⁰ Most individuals with HIV infection are active adults employed in the workforce. The primary means of acquiring infection among adults is either

through behaviors such as unprotected homosexual or heterosexual intercourse with an infected partner, involving the exchange of body fluids, or injecting drug use involving shared needles and syringes. The virus also is perinatally transmitted to approximately 20–40% of children born to infected mothers, (e.g., vertical transmission). Breastfeeding is a bidirectional mode of transmission, to nursing infants of infected mothers and, rarely, to mothers of nursing infants when nipple maceration and biting occur. Since 1985, all donated blood in the United States has been screened for HIV infection. The risk of HIV infection due to transfusion of blood products screened by current methods is estimated to be 1 in 1,900,000 units transfused.³² Screening does not completely eliminate the potential for a seronegative but infected unit from a recently infected donor to escape detection.

HIV is not transmitted by the air-borne route, by household or workplace contact with infected persons, by exposure to contaminated environmental surfaces, or by insect vectors. The virus is easily inactivated by most common disinfectants, including household bleach (diluted 1:100).

Commercial sex workers are at the greatest risk of acquiring HIV infection occupationally. The other group of workers at risk for acquiring HIV infection occupationally is healthcare personnel. Healthcare providers and other workers in contact with blood or other body fluids who sustain accidental percutaneous or mucosal inoculations with virus-infected material are at risk for infection. The magnitude of risk depends on the severity of exposure, but on the average, about 1 in 300 HIV needlesticks results in infection. The risk for infection following mucosal exposures is estimated to be lower at approximately 0.09%. In the absence of direct exposure, healthcare providers are not at occupational risk for HIV infection. In the United States, through December 2002, there have been 57 cases of occupationally acquired HIV infection reported with an additional 139 possible cases.³²

Clinical syndromes The clinical course of HIV infection is variable and changing with the advent of antiretroviral therapy, as well as treatment and prophylaxis for infectious complications. Early after infection, within a few weeks to months, an acute febrile illness characterized by malaise, pharyngitis, lymphadenopathy, maculopapular rash, and headache may occur. The frequency of this mononucleosis-like illness has varied widely in reports of seroconverting individuals. At initial presentation of such patients, HIV antibody screening tests (enzyme immunoassay (EIA)) may be negative, but viral antigen (p24 antigen) and serologic reactivity to one or more viral components (Western blot test) allows the diagnosis to be established at this stage. HIV infection should be suspected in any person with a mononucleosis syndrome lacking a positive heterophil antibody response (monospot test).

Following initial infection, most persons have generalized asymptomatic lymphadenopathy and appear well. However, laboratory tests document a gradual decline in the number of circulating T-helper lymphocytes (CD4 cells), beginning soon after infection and continuing over

the next several years. T-helper cells are essential components of the immune system and mediate aspects of both cellular and humoral immunity.

Symptoms, signs, and illness suggestive of mild to moderate immunodeficiency appear after about 5 years, when CD4 cells decrease by about 50%, to less than 500 cells/dl. Intermittent fever, oral thrush, bacterial pneumonia, enteric infections, and reactivated TB are typically diagnosed at this time. Signs suggestive of more rapid deterioration include oral hairy leukoplakia (a wart-like white growth in the oral cavity), shrinking lymphadenopathy, fever, weight loss, and elevated erythrocyte sedimentation rate. When CD4 cell counts fall below 200, serious opportunistic infections can be anticipated. Pneumocystis pneumonia (PCP) was the most common index diagnosis in the first 5 years of the epidemic, but the advent of effective PCP prophylaxis has altered the picture. Other opportunistic infections and malignancies, including Kaposi's sarcoma, lymphoma, disseminated TB, toxoplasmosis, and cryptococcal meningitis, now account for the majority of index HIV diagnoses.

With the exception of TB, the infectious complications of HIV infection generally are not transmissible to healthy individuals and pose no risk in the workplace. Indeed, the causative organisms are ubiquitous and most adults have already been exposed. Opportunistic infections in HIV-infected patients usually represent reactivation of dormant organisms when the immune system can no longer keep them inactive.

Treatment, prevention, and control Treatment should be offered to all patients with symptoms ascribed to HIV infection.³⁴ Recommendations for offering antiretroviral therapy in asymptomatic patients require analysis of many real and potential risks and benefits. Information regarding treatment of acute HIV infection from clinical trials is very limited. Ongoing clinical trials are addressing the question of the long-term clinical benefit of potent treatment regimens for primary infection. In general, treatment should be offered to individuals with fewer than 350 CD4 T cells/mm or plasma HIV RNA levels exceeding 55,000 copies/rnL (by RT-PCR or bDNA assay). Once the decision has been made to initiate antiretroviral therapy, the goals should be maximal and durable suppression of viral load, restoration and/or preservation of immunologic function, improvement of quality of life, and reduction of HIV-related morbidity and mortality.³³ HIV-infected individuals found to have latent TB infection should be treated with antituberculous therapy to prevent activation of disease.¹³

Persons at risk for direct contact with blood and other potentially infected materials should receive specific instruction in universal/standard precautions for infection control, as recommended by the Centers for Disease Control and Prevention^{34,35} and mandated by the Occupational Safety and Health Administration.²⁷ For most environments outside healthcare settings, common sense and attention to personal hygiene are adequate to protect workers. Gloves should be worn to clean up visible sites of blood contamination. Environmental surfaces can then be

decontaminated with disinfectant solutions or household bleach (diluted 1:100).^{34,36}

Individuals sustaining accidental parenteral exposures to HIV should be counseled to undergo baseline and follow-up testing for 6 months after exposure (e.g., 6 weeks, 3 months, and 6 months) to diagnose occupational infection. Postexposure chemoprophylaxis with antiretroviral agents has been recommended by the US Public Health Service since 1996 after certain exposures to HIV-infected sources which pose a risk of infection transmission, such as needlesticks, mucous membrane, and non-intact skin exposures (Tables 22.5 and 22.6). Data from animal models of prophylaxis with these agents suggest that antiviral activity is diminished when treatment is delayed for more than 24 hours. For this reason, immediate reporting and access to chemoprophylaxis is recommended. Occupational exposure is a frightening experience. Consultation with clinicians knowledgeable about HIV transmission risks who can provide supportive counseling to the worker is essential during the follow-up interval. CDC recommends that occupationally exposed workers refrain from unsafe sexual practices, pregnancy, and blood and organ donation for 6 months after exposure to minimize the risk of transmission.

Occupational zoonoses

Zoonoses are infections that are maintained in nature by transmission between vertebrate animals, and they can be transmitted from other vertebrates to humans or from humans to other vertebrates. Zoonotic pathogens can be divided into two major groups: (1) those transmitted primarily among wild animals (e.g., *Yersinia pestis*, rabies), and (2) those transmitted primarily among domestic animals (e.g., *Sporothrix schenckii*, non-typhoid *Salmonella* spp.). Other infections not properly classified as zoonoses can result from working directly with animals (e.g., infected wounds resulting from animal bites) or with animal products (e.g., anthrax in carpet weavers). Many zoonotic infections present occupational risks, not only to those who work with live or dead vertebrate animals or animal products but also to workers exposed to certain environments contaminated by animals or animal products.

Thus, workers in veterinary medicine, animal husbandry, and animal research are at risk for acquiring a host of zoonotic infections specific to the type of live animal exposure, just as those involved in healthcare work with humans are at risk for infections acquired from humans. Examples of such zoonotic infections include Q fever in veterinarians, psittacosis (caused by *Chlamydia psittaci*) in duck farmers, orf (contagious ecthyma) in shepherds, lymphocytic choriomeningitis (e.g., leptospirosis) in laboratory workers who handle rodents, fatal herpes virus simiae infection in primate handlers, and more recently, monkeypox in veterinarians and pet store owners.^{37,38}

Influenza A (H5NI) (avian flu) infection was shown to have been transmitted from ducks and chickens to poultry workers in Hong Kong and has become an important source of epidemic infection in various international

Exposure type	HIV positive, Class 1*	HIV positive, Class 2*	Infection status of source		Unknown source§	HIV negative
Less severe	Recommend basic 2-drug PEP	Recommend expanded 3-drug PEP	Known source, unknown HIV status†	Generally, no PEP warranted; however, consider basic 2-drug PEP** for source with HIV risk factors††	Generally, no PEP warranted; however, consider basic 2-drug PEP** in settings where exposure to HIV-infected persons is likely	No PEP warranted
More severe§§	Recommend expanded 3-drug PEP	Recommend expanded 3-drug PEP	Generally, no PEP warranted; however, consider basic 2-drug PEP** for source with HIV risk factors††		Generally, no PEP warranted; however, consider basic 2-drug PEP** in settings where exposure to HIV-infected persons is likely	No PEP warranted

* HIV positive, Class 1 – asymptomatic HIV infection or known low viral load (e.g., <1500 RNA copies/ml). HIV positive, Class 2 – symptomatic HIV infection, AIDS, acute seroconversion, or known high viral load. If drug resistance is a concern, obtain expert consultation. Initiation of postexposure prophylaxis (PEP) should not be delayed pending expert consultation, and, because expert consultation alone cannot substitute for face-to-face counseling, resources should be available to provide immediate evaluation and follow-up care for all exposures.

† Source of unknown HIV status (e.g., deceased source person with no samples available for HIV testing).

‡ Unknown source (e.g., a needle from a sharps disposal container).

¶ Less severe (e.g., solid needle and superficial injury).

** The designation ‘consider PEP’ indicates that PEP is optional and should be based on an individualized decision between the exposed person and the treating clinician.

†† If PEP is offered and taken, and the source is later determined to be HIV negative, PEP should be discontinued.

§§ More severe (e.g., large-bore hollow needle, deep puncture, visible blood on device, or needle used in patient’s artery or vein).

Table 22.5 Recommended HIV postexposure prophylaxis (PEP) for percutaneous injuries

*For skin exposures, follow-up is indicated only if there is evidence of compromised skin integrity (e.g., dermatitis, abrasion, or open wound).

†HIV positive, Class 1 – asymptomatic HIV infection or known low viral load (e.g., <1500 RNA copies/ml). HIV positive, Class 2 – symptomatic HIV infection, AIDS, acute seroconversion, or known high viral load. If drug resistance is a concern, obtain expert consultation. Initiation of postexposure prophylaxis (PEP) should not be delayed pending expert consultation, and, because expert consultation alone cannot substitute for face-to-face counseling, resources should be available to provide immediate evaluation and follow-up care for all exposures.

‡ Source of unknown HIV status (e.g., deceased source person with no samples available for HIV testing).

¶ Unknown source (e.g., splash from inappropriately disposed blood).

** Small volume (i.e., a few drops).

†† The designation ‘consider PEP’ indicates that PEP is optional and should be based on an individualized decision between the exposed person and the treating clinician.

§§ If PEP is offered and taken, and the source is later determined to be HIV negative, PEP should be discontinued.

¶¶ Large volume (i.e., major blood splash).

Table 22.6 Recommended HIV postexposure prophylaxis (PEP) for mucous membrane exposures and non-intact skin* exposures

settings;³⁹ lyssavirus (related to rabies virus) infections have been transmitted from bats to humans in Australia,⁴¹ and a large outbreak of febrile encephalitic and respiratory illnesses among workers who had exposure to pigs was shown to be due to infection with a previously unrecognized paramyxovirus (formerly known as Hendra-like virus, now called Nipah virus).⁴¹ Brucellosis is an example of a zoonotic infection in abattoir workers exposed to live or dead animals or animal products. Examples of zoonotic infections acquired by workers exposed to environments harboring or contaminated by contagious animals include leptospirosis in rice field workers, and Argentine hemorrhagic fever typically acquired by adult males harvesting corn in cornfields inhabited by rodents, which serve as the reservoir for Junin or Machupo virus.

It is beyond the scope of this chapter to review the large number of zoonoses (about 200 have been described) that could pose a risk to workers in unique jobs that involve contact with various animals or environments. For each type of occupation that involves regular animal contact, it is important to recognize the types of infectious disease risks involved, consider baseline studies and storage of serum for future serologic tests if risks are high, plan preventive measures when possible, and prepare for early diagnosis and treatment of such infections when illness occurs.⁴² Some of the zoonoses, the occupational groups they affect, and their clinical presentations are included in Table 22.1.

Emerging occupational infectious issues

Infectious diseases continue to emerge, posing threats to the health of workers in numerous settings. A prime example of such a threat is severe acute respiratory syndrome or SARS, first identified in early 2003 and responsible for illness and death primarily among exposed healthcare personnel.⁴³ Emerging infectious issues which may prove to be challenges for occupational health include those posed by bioterrorism, biotechnology,⁴⁴ and emerging and re-emerging infections. These emerging infections emphasize the need for continued vigilance and for careful history taking about occupational exposures when evaluating individuals for illnesses that could possibly be occupationally acquired. Timeliness in identification and reporting of cases assists in the accurate estimation of the magnitude of the infectious disease problem and in the development of additional preventive and therapeutic measures.

PRIMARY PREVENTION: SCREENING, IMMUNIZATION, AND SURVEILLANCE

Initial employee screening and immunization

Screening of employees for infection with or susceptibility to infectious diseases is an important part of healthcare maintenance, especially when the occupational setting

poses a significant risk of transmitting or acquiring infections. Screening also is warranted if specific interventions are available to prevent disease transmission among workers. Assessment of behaviors, such as smoking, that increase the risk of acquiring infections also is valuable so that employees can be provided educational and other interventions to modify risks.

Preventing infectious diseases in workers can decrease absenteeism and financial costs associated with disability, sick leave, and health insurance, even if the primary source of infection is non-occupational. Attending to these issues at the time of employment obviates the need for ongoing surveillance of many infections and simplifies outbreak investigations by documenting the pre-exposure immune status of contacts.

TST screening for active disease identifies those persons who would benefit from prophylaxis (Tables 22.5 and 22.6).¹⁴ TB vaccination with bacillus of Calmette-Guerin (BCG) vaccine, a live attenuated strain of *M. bovis*, is provided for children and some workers in most European countries, but it is not recommended in the United States because of its unproven efficacy when used in adults and because it induces dermal hypersensitivity to purified protein derivative (PPD) tuberculin in most recipients, impeding the usefulness of TST as a screening tool.

Persons age 65 years and older, persons with chronic diseases or pulmonary disorders, and healthcare personnel should be offered pneumococcal vaccine and annual influenza vaccine (Table 22.3).⁴⁵

Rubella immune status should be ascertained and men and women immunized in settings where women of child-bearing age are employed (Table 22.3). Even though rubella is not often transmitted in the workplace, outbreaks can occur among susceptible individuals and vaccination is an important public health intervention. Medical personnel should demonstrate proof of rubella immunity or vaccination prior to patient contact.

Measles vaccine should be provided to all workers born after 1957 with no documented history of measles who have not received two injections of live virus vaccine (Table 22.3). Screening for immunity to varicella and mumps is not routinely recommended, except for healthcare providers and adults with no history of infection with these agents who are exposed to young children.

All adults require tetanus immunization. Tetanus diphtheria toxoid (Td) boosters should be administered every 10 years to adults who have completed primary immunization (Table 22.3). Employees with no prior history of tetanus diphtheria immunization or with uncertain histories should receive a series of three primary vaccine injections.⁴⁵ Similarly, adults with no history of polio immunization should undergo primary immunization with inactivated polio vaccine, especially if they are employed in healthcare settings or when travel to endemic areas is anticipated.

Persons employed in occupations that pose a risk for parenteral contact with blood and other body fluids should be offered hepatitis B immunization (Table 22.3). Healthcare personnel, laboratory workers, animal handlers, first responders, and personal service workers such as

barbers, tattooists, and cosmetologists are included in this category. Adults with multiple sexual partners also should be encouraged to undergo immunization. Serum banking to allow documentation of baseline serostatus is useful for laboratory and healthcare personnel at risk for other blood-borne infections such as HIV or more exotic infections.

Special immunizations

Laboratory workers and animal handlers may be at risk for unusual infectious diseases. Q fever, a rickettsial disease transmitted by the air-borne route, is a special risk encountered by handlers of sheep and similar animals. Serologic testing for Q fever titers prior to occupational exposure is important to document baseline status and to detect seroconversion at follow-up testing. Although smallpox vaccine is no longer recommended routinely, genetically engineered vaccines prepared from vaccinia may pose a risk to researchers and clinicians treating patients enrolled in vaccine trials. Laboratory workers who handle vaccinia or recombinant vaccinia preparations in culture or in animals should receive vaccinia vaccine. Healthcare personnel caring for patients immunized with vaccinia or other orthopoxviruses or tissues and specimens from patients with these infections also should be immunized. A program for smallpox vaccination for selected individuals who may be in the frontline for responding to a bioterrorist attack has recently been initiated in the United States.⁴⁶ Consultation should be obtained to determine the need for screening, immunization, and testing for other exotic infections.

Some animal handlers are at risk of acquiring rabies through bites or exposure to infected secretions and tissues. Immunization with human diploid cell vaccine (three 1-ml intradermal doses on day 0, 7, and 21 or 28) should be provided to workers at risk for rabies and for persons traveling for more than 1 month to areas where rabies is endemic (Table 22.3). Booster injections should be provided every 2 years for those with continuing exposure.

Routine surveillance and outbreak investigation

Surveillance of infectious diseases is conducted to detect increased occurrence of disease so that preventive interventions can be initiated. Surveillance can be passive (based on employee health consultations or reports from contractual providers or supervisors) or active (actual monitoring of disease occurrence).

Active surveillance for infectious diseases is not required in most occupational settings. In work environments where exposure to *M. tuberculosis* may occur – such as healthcare settings, residential care facilities, shelters, and correctional facilities – active TST surveillance among susceptible individuals is indicated. Periodic TSTs are especially important in the wake of several recent outbreaks associated with drug-resistant strains of *M. tuberculosis* in hospitals, adult care settings, and home healthcare settings.¹⁶ Skin testing should be performed at least annually in these settings, and perhaps as often as every 6 months, for personnel at high

risk for exposure to active TB. Surveillance of teachers, travelers to endemic areas, and employees in other institutional settings where close contact with infected individuals is possible also may be warranted, depending on the local prevalence of TB.¹⁴

Surveillance for infections among laboratory workers and animal handlers exposed to specific pathogens should be individualized in accordance with standard guidelines for biosafety in microbiologic and biomedical laboratories.⁴⁷

Maintaining standardized records of reportable infectious diseases is an important component of passive surveillance in the workplace. Centralized collection and assessment of these records at regular intervals may allow early detection of outbreaks of occupational infections amenable to specific control interventions. Geographic or temporal clusters of cases or clustering among persons with similar attributes or occupational tasks suggest a common source of exposure and infection and warrant investigation. Local public health officials and regulatory agencies should be consulted promptly when an outbreak is initially suspected. Reporting of occupationally acquired infections permits public health agencies to identify clusters of old and emerging illnesses and ultimately prevent them. These events should be reported as mandated by state and local regulations.^{48,49}

Return-to-work criteria

Employees diagnosed with communicable infectious diseases should not return to work until the period of infectivity is past. Specific guidelines should be consistent with local public health regulations. Some workers, for example food handlers with certain diarrheal illnesses, cannot resume their duties until culture evidence of cure is obtained. Employees should be advised of the return-to-work policies at the time of employment and when illness is diagnosed. A table for length of work restriction for healthcare personnel can be used to guide return-to-work policies for the workplace (Table 22.2).¹⁹

PRIMARY PREVENTION: INFECTION CONTROL PRECAUTIONS

General infection control in the workplace

Common sense dictates attention to personal hygiene among all workers. Hand washing after using the bathroom and before handling food is essential. The mouth should be covered while sneezing or coughing, and soiled tissues and dressings should be disposed of in trash containers.

Employers have a responsibility to minimize crowding in the work setting. Facilities for hand washing should be available in bathrooms and food preparation areas. Proper ventilation also is important. Trash should be emptied at regular intervals, and work areas should be clean and free of pests. Smoking should be prohibited in common work areas.

Spills of blood, body fluids, and other potentially infectious substances should be removed with disposable paper towels or other suitable procedures. Contaminated areas should then be disinfected with commercial products or with a solution of household bleach (diluted 1:100).^{34,36}

Infection control in healthcare settings

Infection control programs in healthcare settings are necessary to prevent transmission of healthcare-related infections to patients and healthcare personnel. The CDC has established a two-tiered system of infection control precautions.¹⁶ The first tier consists of 'standard precautions' which are precautions recommended for delivery of care to all patients regardless of diagnosis or presumed infection status. They are designed to limit exposure to blood or other body substances and include elements such as hand hygiene and use of appropriate protective barriers, e.g., masks, eye protection, and gloves, as needed to prevent direct contact. The second tier of precautions recommended by CDC are 'transmission-based precautions', designed for the management of patients known or suspected to be infected with pathogens whose transmission can be limited by the adoption of additional measures beyond those which are part of standard precautions. They apply to pathogens transmitted by the air-borne or aerosol routes, droplets, and by direct and indirect contact.

Respiratory precautions are employed for patients with infections communicable by the air-borne route. Such patients are housed in private rooms with special ventilation and should wear surgical masks when leaving their rooms. Respiratory protection (i.e., N-95 respirators) also are advised for providers in close contact with patients on respiratory precautions. However, the re-emergence of epidemic and MDR-TB has led to a re-emphasis of other fundamentals for prevention of transmission of tuberculosis in healthcare and other settings. Early identification of TB allows early indication for therapy, and requires alertness in considering TB in high-risk patients with pulmonary symptoms, especially those with HIV infection. Special ventilation measures and respiratory protection are especially important for cough-inducing procedures, such as sputum induction and aerosolized pentamidine administration. Healthcare personnel who have the potential for being exposed to *M. tuberculosis* should be screened on employment and at least annually thereafter by PPD skin testing, comparing previous test results to current results to identify those who have converted to skin test positivity.¹⁵

Procedures for disposal of infectious wastes have been developed by the CDC.³⁶ Needles and other sharp objects should be sterilized prior to disposal. Liquid and laboratory wastes may be dumped into sewage systems. Materials heavily contaminated with bacteria or blood should be placed in special bags that are specifically labeled for infectious waste and should be disposed of according to community standards for such materials.³⁶

Employers have a responsibility to educate employees about infection control. Barriers to prevent exposure,

including masks, gowns, eye protection, and gloves, should be readily available to workers at risk. Hand washing facilities and hand hygiene supplies are essential. Where access to sinks or running water is not feasible, alcohol hand rubs or packaged towels containing disinfectants should be provided.

Impervious containers for the disposal of needles and other sharp objects are essential.⁵⁰ Such containers should be made available on ambulances and provided to home health aides and other visiting healthcare personnel. Personal service workers who use needles, razors, and other sharp objects also should have access to safe disposal units. Persons receiving care at home who require injections or other procedures that demand the use of needles also should be provided with impervious disposal containers and instructed in proper disposal methods to protect sanitation workers and others in contact with waste.

Infection control in laboratory settings

Despite improvements in engineering controls, work practices, and personal protective equipment, laboratory personnel are nevertheless at risk for occupationally acquired infections. Laboratory personnel may acquire infection by aerosolization of specimens, mouth pipetting, or percutaneous injury or mucocutaneous contact. Methods of infection control applicable to laboratory settings are described in the CDC document entitled 'Biosafety in Microbiological and Biomedical Laboratories'.⁴⁷

Infection control in childcare settings and schools

By 1995, it was estimated that 14.5 million children were attending out-of-home daycare in a variety of settings including licensed child daycare centers, regulated daycare homes, and unregulated family daycare homes.⁵¹

Many serious infections occur as endemic or microepidemic problems in the daycare setting. These include *H. influenzae* type b, hepatitis A, cytomegalovirus, parvovirus B 19, and enteric infections (*Shigella*, *Giardia*, rotavirus, *Clostridium difficile*, *Campylobacter*, *Cryptosporidium*, calcivirus, *Salmonella*, enteric adenovirus, astrovirus, and several types of *E. coli* infections). In addition, the high rate of acute respiratory infections leads to early onset of otitis media, frequent antibiotic use, and emergence of multidrug-resistant enteric pathogens.

Thus, workers in close contact with children risk exposure to a wide variety of communicable pathogens contained in secretions, urine, and stool. All such personnel, as well as all children in schools and daycare centers, should be screened for immunity to common childhood infections and vaccinated if immunity is not present (Table 22.2).

Regulation of childcare facilities is essential to reduce risks to children and workers. National standards for infection control in childcare facilities were promulgated in 1990.⁵² Hand washing facilities and policies are the most important component of disease prevention in school and daycare settings. Hands should be washed after contact

with mucous membranes and potentially infected body fluids. Older children should be instructed in personal hygiene. Children with fever or diagnosed infections should be excluded from attending daycare or school until transmission risk is no longer present, and policies for such exclusion should be in place. Prompt reporting of disease outbreaks and prompt involvement of public health authorities are essential. Employees should be instructed in common-sense first aid procedures for handling wounds, bites, and other situations in which exposure to infected blood or tissues is possible. Barrier protection is rarely required in schools, but gloves should generally be available for emergencies requiring first aid.

Infection control for special occupational groups

Pregnant workers

Infection with a variety of agents during pregnancy has the potential to cause fetal damage, especially when primary infection occurs. While a number of these infections can be community acquired, the likelihood of exposure to certain of these pathogens can be greater in healthcare settings. Infections with as rubella, CMV, and parvovirus are among the infectious agents which may be of special concern to pregnant healthcare personnel. In general, adherence to standard precautions as well as pre-exposure immunizations when available and appropriate are the best way of preventing the devastating effects of such infections (Table 22.2).^{19,21}

Immunodeficient workers

Immunodeficient workers are at increased risk of devastating infections, particularly with opportunistic agents. The greatest risk for such workers is likely in the healthcare setting where there can be ample opportunity for exposure to these agents. Many immunocompromising illnesses would be viewed by the US legal system as disabilities and therefore, individuals with those conditions would be covered under the provisions of the Americans with Disabilities Act of 1990 (see Chapter 57.1).⁵³ Such persons should be informed about their risks and furthermore, their employers should make reasonable accommodations to allow their employees to continue to perform their jobs, taking into consideration the provisions of applicable federal, state, and local regulations.

CONCLUSIONS

Occupational infectious diseases encompass a large variety of infections which can involve many organ systems. They include some common infections, such as influenza, that pose a special problem in the workplace because of close interpersonal contact and crowding, and that taken together account for a large proportion of time lost from work. Many of these infections are preventable by policies that promote hygiene and provide exclusion from work during periods of contagion. In addition, a variety of less

common, but sometimes serious, infections are particularly associated with specific occupations. Recognition of the types of infection risk associated with specific occupations can, in most cases, lead to effective, often simple steps for primary prevention, as well as opportunities for early diagnosis and treatment.

Chapter 23

Musculoskeletal Disorders

23.1 Overall Approach to Managing Musculoskeletal Disorders

David M Rempel, Bradley A Evanoff

The musculoskeletal disorders considered in this section are conditions with typically long natural histories such as tendonitis, rotator cuff syndrome, low back pain, osteoarthritis, and entrapment neuropathies. They are usually not acute injuries, preceded by a single high-force event, but rather are associated with weeks, months or years of exposure to rapid motions or repeated forceful tasks. In the past these disorders have been labeled with various terms, such as cumulative trauma disorders (CTD), repetitive strain injuries (RSI), and repetitive motion disorders (RMD). However, the term musculoskeletal disorders (MSDs) is preferred as it does not focus on causation in the name. These conditions may be due to rapid, repeated motions or forceful pinching, or a medical condition, such as pregnancy. Each must be evaluated for causation separately.

In the US, almost 1 million workers annually report taking time away from work for treatment and recovery from musculoskeletal pain or loss of function due to overexertion or repetitive motion of the back or upper extremities.¹ Estimated workers' compensation costs for these lost workdays range from \$13 to \$20 billion.

Medical management

Good medical management of MSDs includes: (1) early reporting of symptoms, (2) timely access to healthcare providers and appropriate medical treatment, (3) rapid evaluation and modification of job risk factors, (4) the provision for limited or modified work duties when necessary, and (5) close medical follow-up. Comprehensive programs that integrate ergonomic evaluations with medical treatment are effective in reducing the incidence and severity of work-related musculoskeletal disorders.

The goals of a medical management program should be to reduce or eliminate symptoms, prevent progression of the disorder, and reduce the duration and severity of functional impairment and related disability. In other words, to keep the patient functional at work and prevent disease progression. The long-term goals of treatment and prognosis should be discussed with the patient, and the workers' compensation carrier. Employers should be notified of any necessary time-loss or work restrictions. Modifications to the treatment plan or work expectation should be communicated.

Encourage early reporting of symptoms

Appropriate treatment and workplace interventions should be implemented promptly. A delay in treatment can

contribute to the severity and duration of disability. If the patient presents early, when the symptom intensity is mild, it may be possible to manage the disorder without lost time or without limiting the employee's essential job duties.

Conservative treatment is most effective when begun in the early stages of these disorders. Patients who are treated after a prolonged symptomatic period are less likely to respond favorably than those treated earlier.²⁻⁵ With some disorders, such as carpal tunnel syndrome, patients can often be treated conservatively in the early stages of disease, while surgery is usually necessary when patients present with advanced disease.⁶

Healthcare providers

The choice of healthcare providers for treating the injured workers is important. The healthcare provider should have training or experience in ergonomics and the role of work modifications in the treatment of work-related musculoskeletal disorders. Effective treatment requires an accurate diagnosis and identification of aggravating factors including home and work mechanical factors, psychosocial factors and other aggravating medical factors (e.g., diabetes mellitus, pregnancy, etc). Treatment and determination of work-relatedness also require knowledge of specific job duties.

The best way for a healthcare provider to obtain knowledge of job duties is through a worksite visit. Since this is impractical in many clinical settings, information about exposures and job duties can also be obtained through a written work description, a videotape of the job tasks, or even a picture of the employee working at the workstation. The physician should have access to a person at the workplace with knowledge of job activities and the ability to coordinate a job evaluation and facilitate modifications of the job. If modifications are not possible, then the person may facilitate appropriate job placement during the recovery period. Working knowledge of the industry and the specific workplace is also needed in order to make appropriate recommendations regarding temporary or permanent job modifications. Many employers will provide detailed information about job duties and physical exposures to the treating physician. It is difficult to provide optimal care for employees when this information is not available.

Ergonomic interventions

A number of studies have documented the importance of ergonomic changes in treating workers with work-related

musculoskeletal disorders.⁷⁻¹⁴ Comprehensive ergonomic programs that incorporate primary prevention of MSDs through ergonomic changes in jobs, early detection of MSDs through surveillance, and early treatment of MSDs with an emphasis on early return to modified work have been endorsed by many corporations, professional guidelines and the National Research Council.^{1,15} The approach involves the application of ergonomic principles to job design for primary and secondary prevention.

The majority of injured or symptomatic employees require no lost time and are able to return to productive work quickly, as long as their work is modified to reduce physical exposures to the affected body part. Job modifications which reduce physical exposures can be inexpensive and simple. Examples of job modifications include training or retraining, modifications of the job to reduce awkward postures (e.g., tilted work surfaces, change in work surface height), changes in tool design or maintenance, and changes in work procedures (job rotation, work-break pattern, limit overtime).

Where it is difficult to reduce risk factors through engineering modifications, temporary job transfer or restrictions may be necessary. Examples of temporary restrictions include restriction of specific tasks, reduction in pace or quantity of work, or limitation of hours worked. If an employee is to be transferred to a different job, the new job should be assessed by the employer and the healthcare provider to be sure that the employee will not be exposed to aggravating factors. In most cases, keeping an injured or symptomatic employee at work in an appropriate, modified duty position is preferable to time loss.

Examples of successful programs

The medical literature has examples of successful programs which have decreased the length or severity of disability resulting from injuries, through integrating ergonomic interventions as part of medical treatment of injured workers. One such study evaluated workers from a variety of industries who had lost more than 4 weeks of work due to back injuries.¹⁶ Workers were randomly assigned to receive an ergonomics intervention, an intensive clinical and rehabilitation intervention, neither, or both. The ergonomics intervention consisted of a worksite ergonomics evaluation that included labor and employer representatives in determining the need for job modification. After observation of a worker's tasks with a trained ergonomist, these parties determined the need for modifications to improve the worksite. Implementation of the modifications remained the employer's responsibility. The clinical and rehabilitation intervention consisted of patient education ('back school'), referral to a back pain specialist, and a multidisciplinary work rehabilitation intervention. Combination of the rehabilitation intervention along with the ergonomics intervention was the most successful in returning injured workers to work. The ergonomics intervention was the most effective element of the program, resulting in more than a two-fold increase in the rate of return to usual work. By facilitating return to usual work, the ergonomics

intervention reduced the rate of long-term disability. In this study, the intensive clinical and rehabilitation intervention did not significantly reduce the time of absence from regular work when applied separately from the ergonomics intervention.

Another example of an integrated program was reported for sheet metal workers at an aircraft manufacturer.⁷ This program combined pre-placement evaluations of workers with ongoing surveillance for symptoms and signs of upper extremity musculoskeletal disorders. Job modification was implemented for those with signs of early disorders, through restriction of work hours and restriction of use of vibrating hand tools. This program reported decreased workers' compensation costs, decreased time loss, and decreased severity of injury.

Other authors have described comprehensive initiatives to manage the incidence and cost of occupational injuries, that included an ergonomics component directed specifically toward injured workers. One such program has been described among hospital employees at an academic health center.¹⁷ This study demonstrated decreases in musculoskeletal injuries, lost time (change from 10.4 days to 6.6 days average time loss), and total case costs (18% cost reduction) following the implementation of a comprehensive intervention that included case management, treatment by physicians experienced with work injuries, and the use of ergonomic worksite evaluation and modification. A later report from this group described elements of the program aimed at the early diagnosis and treatment of work-related upper extremity disorders. The program included ergonomic assessment and abatement of the affected employees' work areas, and close coordination between the treating physicians and the ergonomists. The program resulted in pronounced decrease in the number of work-related upper extremity MSDs and a virtual elimination of cases which required surgery.¹⁸

These and other peer-reviewed studies indicate that a multifaceted program can reduce the cost and burden of MSDs in different working populations. Many corporations have ergonomics programs based on the efficacy of such programs in reducing injuries.¹⁹ Successful approaches have most often used a combination of ergonomic principles for prevention, as well as improved recognition and management of MSDs.

Patient education

Patient education is critical to successful management of MSDs. Since many MSDs are chronic, a successful outcome would be one where the patient knows enough about the aggravating factors and methods of treatment so that he or she can participate in management independently with minimal disruption of essential work and home duties. It is critical that the patient hears a consistent message from all involved healthcare providers. Since much of the recovery is dependent on appropriate patient behavior (home exercise program, modifying home activities, modifying work pattern) contradictory messages will interfere with recovery. If the physician tells the patient to

reduce forward bending, and this is not reinforced by the therapist, then there will likely be little effect on patient behavior.

Splints for the thumb, wrist or elbow may be useful to immobilize and protect a joint during the acute phase of injury. However, the use of the splint should be reduced relatively rapidly, within weeks, in order to avoid complications. Prolonged splint usage can lead to muscle atrophy, joint stiffness, or splint dependency. Exceptions are sprains (ligament), which may require splinting for longer periods. Some splints are worn to protect the underlying soft tissue (e.g., soft elbow splint for ulnar neuropathy).

Splints should be relatively loose and comfortable and not so snug that they restrict circulation or cause localized pressure. Generally, splints should not be worn during work. In order to accomplish the work task, the patient may 'fight' the splint and thereby aggravate the condition.

Therapy modalities

Physical therapy modalities include immobilization, traction, massage, passive range-of-motion, ultrasound, heat, cold, the percutaneous delivery of medications with electrical charge of ultrasound (ionto- and phonophoresis), work conditioning, and patient education. The most valuable of these may be patient education directed at modifying daily activities at home and work. Improper therapy can delay recovery.

Not all therapists have the same approach to treating patients. In some cases, this is based on maintaining outdated ideas that place the patient in a passive role, as the 'recipient' of hot packs, massage, and other ineffective treatments. Successful practices of occupational and physical therapy are based on an active approach that incorporates graded exercise and increasing the level of responsibility on the part of the patient to protect and rehabilitate the injured area.

Home exercise program

Some conditions (e.g., wrist tendinitis, epicondylitis, low back pain) may benefit from a progressive home exercise program, following the acute phase of injury. The general strategy is to transition rapidly from immobilization to stretching, then slowly advance the strengthening protocol. For example, after the acute phase of tendonitis, when the pain becomes intermittent and dull, passive tendon stretching should be initiated. This stretching should continue even after symptoms have resolved. When the pain has become infrequent and of low intensity, strengthening should begin. The weights initially used should be small and increased very gradually. For example, for epicondylitis, initially 1/4 kg weights can be used during wrist extension and flexion with 10 to 20 repetitions, twice daily. The motions should be performed slowly. The load may be increased gradually every 2–4 weeks. There may be some discomfort after strengthening. If the discomfort lasts more than an hour then the load or repetition rate should be decreased.

Case management

Three of the most common barriers to improvement are: (1) a delay in implementing prescribed workplace modifications, (2) a delay in starting therapy, and (3) poor patient compliance. Much of this is due to poor communication between the involved parties: employee, human resources contact, claims examiner, employer, and healthcare providers. Case managers, who are usually nurses, can help coordinate communication to address these barriers.²⁰

Appropriate administration of paperwork with the workers' compensation carrier can lead to more rapid approval for treatments. Case managers can assist with arranging specific referrals (e.g., occupational therapist, ergonomist, medical specialist) in unison with the treating physician. They can also help in scheduling appointments to minimize time loss. The case manager can expedite obtaining items, such as special tools or chairs recommended by an ergonomist, through direct communications with the claims examiner. In order to facilitate return to work, the case manager can clarify or negotiate modified duty with the employer and treating physician, and assist the employer in maintaining compliance with prescribed workplace modifications.

The case manager can also maintain regular contact with the patient to improve compliance with home treatments. Employees usually need help understanding the abilities and limitations of workers' compensation.

OSHA 300 Log

After the physician evaluation, the employer must make a determination of whether the case should be recorded as an injury or illness in the OSHA Log. As of January 1 2002, the rules for reporting an injury or illness on the OSHA Log have changed (www.osha-slc.gov/recordkeeping/index.html). The old OSHA 200 Log has been replaced by the OSHA 300 Log. An injury or illness is now considered work related if work 'caused or contributed to the condition or significantly aggravated a preexisting condition'. It is recorded on the Log if any of these occur:

- death,
- loss of consciousness,
- restricted work activities or job transfer,
- days away from work,
- medical treatment beyond first aid, or
- a significant work-related injury or illness is diagnosed by a physician or other licensed healthcare professional.

The distinction between a 'new' case and a 'recurring' case has also changed. A 'new' case is one in which there is no previously recorded injury or illness of the same type affecting the same body part, or if signs and symptoms reappear after complete recovery from a previous injury or illness. Other cases are 'recurring pre-existing conditions' and include signs and symptoms that are associated with chronic illnesses.

For some companies the addition of a recordable case on their Log has serious ramifications. These companies may be concerned that they will be targeted for an OSHA

inspection if their recordable rate is high. Or they may link management bonuses to low recordable rate. A more progressive approach places emphasis on controlling lost time and less on the recordable rate. This approach encourages early reporting of symptoms in order to prevent disability, even if this increases OSHA recordables.

Psychosocial factors

Psychosocial factors at work such as high job demands, high job stress, lack of job satisfaction, deadline work, lack of support from coworkers or supervisor should also be addressed. If these factors interfere with recovery, it may be necessary to discuss them with the supervisor or someone from the company's human resources office to attempt to resolve the problem. Other psychosocial factors may also interfere with recovery or be of concern to the patient. These include job insecurity, concern about future employment, financial consequences of the disorder, lack of support from family members, and depression. These should be dealt with directly.

Success

A successful outcome is one in which the patient is able to perform the essential duties of the job and desired home activities with minimal symptoms and limitations. Given the chronic nature of these conditions, the patient may continue to have episodes of pain. However, he or she will understand how to minimize the impact of a pain flare. Generally, this point is achieved when the employee: (1) has an intimate knowledge of activities that aggravate the condition, (2) identifies ways of avoiding or reducing those activities, (3) has support from the supervisor and coworkers, (4) has knowledge of pacing and pain management techniques, and (5) participates in daily home exercises.

The symptoms may resolve rapidly or may take months or even years to reach an acceptable outcome. During this time the healthcare providers play an essential role in continuing patient education, providing encouragement, and setting reasonable expectations.

23.2 Neck and Shoulder Disorders

Mats Hagberg

Disorders of the shoulder and neck region are a common problem in the general population and among industrial workers. In the general population, as many as one in every third woman and one in every fourth man report pain in the neck and shoulder that is present on a near daily basis. Pain in the neck region in the past year was reported by 34% of British workers.¹ Reported neck and shoulder pain is often non-specific and may not correlate with a pathoanatomic process. Both physical and psychosocial factors have been reported as risk factors.²

Several reviews have addressed the association between occupational stressors and disorders of the neck and shoulder.³⁻⁵ The most common specific disorder of the neck and shoulder region is shoulder tendinitis. The prevalence of shoulder tendinitis in the general population is approximately 2%. Among US workers, the prevalence of shoulder tendinitis was 8% for those exposed to highly repetitive or forceful upper extremity and hand motions compared with 1% among non-exposed workers. Similarly in sport, the pattern of usage and cumulative trauma has been associated with disorders of the neck and shoulder. Thus there is a consistency between both occupational and non-occupational activities for work-related disorders in the neck and shoulder.⁶ The importance of preventative measures to address work-related neck and shoulder disorders has been recognized in Canada, the USA and in the European Union.^{3,4,7}

CLINICAL EVALUATION

Accurate assessment of neck and shoulder symptoms is essential, because shoulder symptoms may be referred from processes of pulmonary, cardiac or abdominal origin. Neck symptoms may also be related to cranial disorders.⁸ Neck and shoulder disorders may also cause symptoms to the upper extremity and hand, as frequently occurs with compression of cervical nerve roots. Patients seeking medical attention for persistent musculoskeletal illness should thus be examined comprehensively in these anatomic regions.

History

The type, onset, and localization of symptoms should be explored in great detail. Visual aids, such as the use of a diagram or manikins to let the patient mark the type and location of pain, have demonstrated reliability.⁹ It is important to distinguish between nociceptive and neurogenic pain.¹⁰ Nociceptive pain usually originates from peripheral pain receptors reacting to mechanical or chemical stimuli. Muscle pain can be regarded as a nociceptive pain. Neurogenic pain is caused by a dysfunction in the nervous system, commonly causing sensory disturbances, as occurs with entrapment of nerves. Whereas neurogenic pain may follow the sensory distribution of a nerve, noci-

ceptive pain may be more diffuse and correlate poorly with a specific nerve distribution.

Radiating pain in a dermatomal distribution may indicate a cervical root process (radiculopathy). The character, quality, distribution, intensity, frequency and duration of symptoms should be described. Information should be elicited about the relationship between symptoms and posture, movements, and physical loading during occupational activity. The temporal relation between symptoms during recreational activities and rest should also be explored.

General medical history should also be addressed. Concerns for systemic disease include weight loss, severe pain or morning stiffness which may indicate an endocrine disorder, infection, or tumor. Family and past medical history addressing rheumatologic disorders should also be addressed.

Individual susceptibility factors, such as genetic factors or lack of fitness, should be elicited, as they may result in a lower than normal threshold for related musculoskeletal injury. Furthermore, local strain may trigger symptoms early in an individual with a preclinical systemic disease. Important individual factors that may increase the risk of contracting a work-related musculoskeletal disorder in the neck and shoulder include congenital malformations, age, smoking, inflammatory, and endocrine disorders.

Work and exposure history

Job title alone offers insufficient information to determine whether neck and shoulder disorders are work related, and whether the patient can return to his or her job. Specific work tasks should be delineated, including work posture, repetition, weight and nature of material handled, and work organization. A history of sudden high energy transfers or precipitating events or accidents resulting in clinical or subclinical injury should be elicited.¹¹

While the work and exposure history will assist the clinician in determining work relatedness in most cases, direct evaluation of the workplace may be useful in some cases, particularly regarding job redesign and return-to-work programs for rehabilitation. Such evaluations can be performed by direct observation at the work site or representative video recordings.

Work postures and repetition

Special attention should be directed to the frequency and duration of extreme positions of the head and arms. The examiner should inquire about the duration and frequency of work done with hands at or above the shoulder level. Specific inquiry regarding maintaining the head in a flexed or twisted position should be addressed. Even a position with a slightly flexed neck may result in severe discomfort if sustained for a significant period of time. It is possible that discomfort during work hours will progress to more persistent or chronic pain for some workers over time (Fig. 23.2.1).

Figure 23.2.1: The relation between forward flexion in the neck, and pain and stiffness in the neck.

Material handling

Figure 23.2.2: The strength utilization ratio for a woman (solid line) and a man (dotted line) when holding a 1 kg tool in the hand with a straight arm at different angles of shoulder flexion. The strength utilization ratio is the fraction of the maximal capacity that is needed to perform the contraction.

The degree of shoulder flexion during lifting, in addition to the actual weight lifted, determines the physical load on the shoulder. Figure 23.2.2 presents the utilization ratio of each lift in relation to the individual maximal capacity. For instance, lifting a 2-pound weight (1 kg) by hand with a straight arm at 90 degrees of forward flexion required 45% of maximal muscular capacity in an average man and 81% of capacity in a woman. Material handling performed near maximal capacity (80–100% of maximal) will increase the risk for strain injuries due to poorly controlled movements.

The strength utilization ratio in the shoulder for a given position can be calculated by simple biomechanical principles. The shoulder joint torque is obtained by adding the torque produced by the lifted object and the torque produced by the weight of the arm. The torque of the lifted object is calculated by multiplying the weight of the object in newtons (kilograms \times 10) by the length of

the lever arm in meters. The torque produced by the weight of the arm is calculated the same way, by multiplying the weight of the arm in newtons by the lever arm (the weight of the arm is 5% of the body weight). The center of gravity for the weight of the arm is located approximately at half the distance of the arm (upper arm + forearm) from the shoulder joint (0.6 meters is a typical measure for the length of the arm for average-sized men and women). At 90 degree of forward flexion, the torque in the shoulder joint produced by the weight of the arm would be about 12 newton-meters in a 80 kg man ($5\% \times 80 \text{ kg} \times 10 \times 0.6 \times 1/2 \text{ m}$) and 10 newton-meters in a 65 kg woman. The maximal capacity for shoulder joint torque is 27 newton-meters for women and 53 newton-meters for men. Hence the strength utilization ratio when holding the arm in 90 degrees of forward flexion without any load would be on average 37% for a woman (60 kg) and 23% for a man.

Work organization

A self-regulated work pace may result in a different exposure compared with that determined by preset machine-paced work. The patient should be asked about the frequency, distribution, and duration of pauses and breaks. Working in the same position for sustained periods of time, even when work posture is not extreme, may result in a static loading of muscles and an increased risk of muscle strain injuries. Psychosocial factors such as psychological job demands, decision latitude, social support, and job satisfaction are all variables with a strong influence on symptoms.² These variables may also influence shoulder muscle tension, directly affecting discomfort and pain. In computer-based work, the type of work (e.g., data entry, information retrieval, or programming) results in different pause patterns and exposures on the neck and shoulder. Continuous data entry work for more than 4 hours per day, without significant pauses, increases the risk of discomfort and muscle pain syndromes in the shoulder and neck region.

Physical examination

The physical examination of the shoulder and neck includes the following steps: (1) inspection for local swelling, erythema, and muscle atrophy; (2) testing the range of motion; (3) testing for muscle contraction pain

and muscle strength; (4) palpation of muscle tendons and insertions; (5) specific provocative maneuvers.

Testing the range of motion

When the active range of motion is impaired, passive range of movement should also be tested. The passive range of motion is the range that the patient can achieve when assisted by the examiner. The following movements should be tested in the neck (cervical spine): forward flexion-extension, rotation and lateral flexion. In the shoulder, testing of forward flexion-extension, abduction, internal and outward rotation should be performed. Descriptions of range of motion limits are provided in the useful reference 'The Clinical Measurement of Joint Motion' published by the American Association of Orthopedic Surgeons.¹²

Determination of contraction pain and muscle strength in the neck

The examiner puts a firm grip on the head of the patient and then asks the patient to tilt his/her head to the side, to rotate, and to flex and to extend. The patient is instructed to report any feeling of discomfort during contraction. In the shoulder, forward flexion, abduction at 30 degrees, and outward and inward rotation in the neutral position are tested against the resistance of the examiner's hands. The best position for the examiner is to stand behind the standing or seated patient during these isometric maneuvers.

Palpation

Palpation of the bony structures, tendons, and muscles is performed while the patient is standing or sitting. By comparing right and left sides, abnormal tenderness is effectively identified. Palpation of the neck is most easily performed with the patient in the supine position with the shoulder at the top end of the examination table. With the patient relaxed, the head should be held by the examiner with one hand while the other hand examines the bony structures and muscles of the neck. If the patient experiences pain in the forearm and hand during compression maneuvers, a cervical hernia may be present, particularly if this pain is relieved by traction applied to the patient's head. In contrast, when traction of the cervical spine results in pain, this may indicate strain or damage to other musculoskeletal structures of the cervical spine, such as ligaments, articular capsules, or muscles.

Specific provocative maneuvers

The *foramen compression test* is performed with the patient in the sitting position. The examiner rotates the patient's head, while at the same time flexing it laterally to the same side. This maneuver results in narrowing of the intervertebral cervical foramina allowing detection of a nerve root compression and irritation (cervical radiculopathy). A positive test result occurs when the patient experiences pain or numbness in the forearm and hand of the side to which the head is rotated and flexed.

In the same position, the *Arm-Lasegue test* is performed by the examiner who tilts the patient's head to one side

(lateral flexion) and, on the other side, depresses the shoulder girdle. In this test, the nerves of the cervical brachial plexus are stretched and abnormal irritation to these structures will result in pain or paresthesias in the forearm and hand on the side of the depressed shoulder.

Another test of compression of the nerve roots of the brachial plexus is the *Roos test*, which additionally allows assessment of thoracic outlet syndrome. The patient is again in a sitting position and elevates both the arms to 90 degrees abduction with external rotation ('hands up' position). The patient is instructed to open and clench the hands at a rate of once per second for 3 minutes. The normal experience during the test is a forearm tightness and neck and shoulder fatigue. Patients with abnormal irritation involving the lower trunk of the brachial plexus develop progressive tingling and pain of the ulnar side of the forearm and hand.

The *bursa test* for shoulder bursitis is performed by compressing the upper arm against the coracoacromial arch. The presence of shoulder pain during this maneuver may indicate subacromial bursitis, frequently associated with shoulder tendinitis. The *Yeargason maneuver* is an isometric test to assess bicipital tendinitis. With the upper arm along the body, in 90 degrees flexion at the elbow joint, the examiner takes the hand of the patient and asks him or her to supinate the forearm. A positive result is elicited if this contraction evokes pain in the shoulder, as the biceps is the main supinator of the forearm.

Laboratory tests

Blood tests such as erythrocyte sedimentation rate and rheumatoid factor may be useful to assess inflammatory and rheumatologic disorders. Imaging tests such as radiographs, ultrasound, CT, and MRI to detect anatomic abnormalities should be performed as directed by the clinical findings reviewed above. Radiographic findings must be placed in the context of clinical findings. For instance, degenerative changes are common, and may not be related to the neck-shoulder symptoms.

CLASSIFICATION

A common nosology for disorders of the neck and shoulder does not currently exist. This has impeded agreement on the associations between these disorders and specific occupations or stresses. Criteria for various musculoskeletal disorders have been proposed as case definitions for surveillance and epidemiological studies.¹³ The use of terms such as RSI (repetitive strain injuries) and CTD (cumulative trauma disorders), while useful for general characterizations, should be avoided as specific diagnoses.

In industrial settings, the ergonomic exposure may modify symptoms and signs of disorders and diseases.¹⁴ For instance, in job tasks involving repetitive arm elevations, signs of both tendinitis and non-specific regional pain may be present, related to both repetitive strain on rotator cuff tendons and static strain on neck and shoulder

muscles. If the presence of musculoskeletal symptoms and signs does not correlate with criteria for a specific disease diagnosis, an ICD label that focuses on the symptoms rather than the pathology is recommended.¹⁵ An example of a non-specific neck-shoulder pain condition is the label 'cervicobrachial syndrome' M53.1 (ICD-10). For simplicity, we discuss disorders based on anatomy, beginning with syndromes with clearly defined anatomic relations. The major disorders include:

- rotator cuff disorders and biceps tendinitis
- cervical spondylosis and osteoarthritis of the shoulder and acromioclavicular joints
- cervical radiculopathy
- thoracic outlet syndrome
- cervicobrachial pain syndromes.

Rotator cuff disorders and biceps tendinitis

Tendinitis and tenosynovitis are inflammatory conditions of the tendon and the synovial membrane of tendon sheath. Common sites for inflammation of the shoulder are the tendons to the rotator cuff muscles (supraspinatus, infraspinatus, subscapularis, and teres minor muscles), and long head of the biceps brachii. At these locations the tendons perform large movements as they pass through relatively narrow spaces in the periarticular regions of the shoulder joint.

Inflammation of a tendon can be part of a general inflammatory disease such as rheumatoid arthritis, but is most frequently caused by local inflammation as a result of mechanical irritation and friction. For the latter, signs of inflammation may be subtle, and some advocate use of the term tendopathies or tendalgias rather than tendinitis.

Epidemiology and work relatedness

Posture and force are the main risk factors for shoulder tendinitis. For instance, automobile assemblers with acute shoulder pain and tendinitis have higher frequency and longer duration of elevation of the arms during work compared to controls. Among exposed US industrial workers, there was a 7.8% prevalence of shoulder cumulative trauma disorders, involving both shoulder tendinitis and degenerative joint disease. Work tasks with high force and/or repetition on the wrist and hands were associated with a greater than five-fold risk of injury. Similarly, female students performing repetitive shoulder flexion developed shoulder tendinitis frequently. Among professional pitchers, approximately 10% had experienced shoulder tendinitis. In a survey of swimmers in Canadian swimming clubs, 15% reported having significant shoulder disability, primarily due to impingement syndromes related to the butterfly and freestyle strokes. Tendinitis of the biceps brachii was identified in 11% of elite tennis players.

Pathophysiology of shoulder tendinitis

The pathophysiologic process for shoulder tendinitis involves tendon degeneration. Degeneration of the tendon

is caused by impairment of perfusion and nutrition, in addition to mechanical stress. Cellular injury within the tendon results in debris formation progressing to calcium deposition over time. The tendons to the supraspinatus, the biceps brachii (long head), and the upper parts of the infraspinatus muscle groups have a zone of avascularity. Signs of degeneration, including cell death, calcification, and microruptures are located predominantly in this region of avascularity. Impairment of circulation, and accelerated degeneration is caused by compression and static tension of these shoulder tendons. Compression of tendons occurs when the arm is elevated. During elevation of the arm, the rotator cuff tendons and the insertions on the greater tuberosity are forced under the coracoacromial arch, resulting in impingement. Compression of the rotator cuff tendons, particularly the supraspinatus tendon, results from the narrow space between the humeral head and the tight coracoacromial arch (Fig. 23.2.3). Chronic bursitis, as well as complete or partial tears of the rotator cuff tendons or biceps brachii, may result in a chronically disabling impingement syndrome.

In addition to impingement, circulation of the tendon may also be affected by muscle tension. Circulation in the tendon is inversely proportional to muscle tension, and ceases at higher tension levels. Studies have demonstrated that when the intramuscular pressure in the supraspinatus muscle exceeds 30 mmHg at 30 degrees of forward flexion or abduction in the shoulder joint (Fig. 23.2.4), an impairment of blood circulation occurs at this level. Because the major blood vessel supplying the supraspinatus tendon runs through the supraspinatus muscle, it is likely that circulation of the tendon is disturbed under these conditions. It is thus not surprising to find a high risk of shoulder tendon lesions in activities involving static contractions of the supraspinatus muscle, or repetitive shoulder forward flexions and abductions. Occupational groups with static tension of the supraspinatus muscle include welders and seamstresses. Groups that perform repetitive shoulder joint movements include assembly line workers in the automotive industry, painters, and athletes such as swimmers.

Degenerative changes in the tendon may trigger an inflammatory 'foreign body' response to the debris of dead cells, resulting in an active tendinitis. Additionally, infection (e.g., viral, urogenital) or systemic inflammation may precipitate an episode of tendinitis in the shoulder, likely representing an immune-mediated response.

Clinical effects and course

Degenerative changes beginning in the avascular zone of tendons progress to calcium deposition, associated with increased friction between the humeral head and the coracoacromial arch. Progressive calcification may result in tendon rupture with subacromial bursitis. Rotator cuff tendon rupture may be partial or complete. Tendinitis is classified into different stages.¹⁶ Stage I is characterized by edema and hemorrhage, often seen acutely after excessive tendon stress during overhead use. Stage II is characterized by fibrotic and degenerative changes resulting from

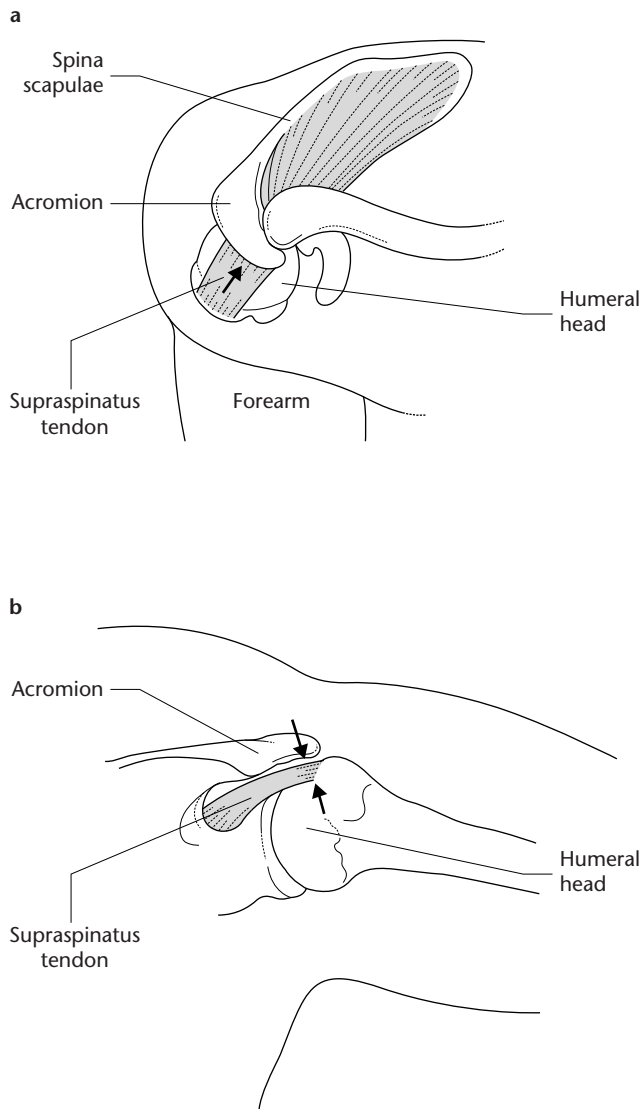

Figure 23.2.3: Impingement. (a) The distal part of the supraspinatus tendon will slide under the anterior part of the acromion (arrow). (b) During this process impingement occurs against the undersurface of the anterior aspect of the acromion. The pressure and mechanical friction are centered on the supraspinatus tendon.

repeated episodes of mechanical inflammation. More extensive calcification, often accompanied by bone spurs and tendon rupture, is associated with tendinitis.

Diagnosis

The diagnosis of rotator cuff and bicipital tendinitis is based on typical distinct shoulder complaints, such as pain with isometric abduction, flexion, inward and outward rotation in the shoulder, and tenderness over the tendons at the humeral head. Limitation of the active range of shoulder motion is included in the diagnostic criteria. Evidence of calcium deposition at the shoulder joint radiographically may support the diagnosis of tendinitis. Tendinitis appearing in a worker with high local load on the shoulder can be considered work related, in the absence of systemic inflammatory conditions or infection (reactive tendinitis). High local load of the shoulder can occur in job tasks requiring repetitive shoulder flexions (or abductions), or work with the hands at or above shoulder level. Leisure time activities should be reviewed, as both sport and household work can precipitate tendinitis. While no established threshold limit levels exist for shoulder load, high local load on the shoulder is considered present when the hand is kept one hour per working day at or above shoulder level, or when repetitive flexions or abductions more than 60 degrees in the shoulder joint are performed frequently and regularly during the working day.

Management

Conservative measures including rest, ice application to tendons following exertion, and use of non-steroidal anti-inflammatory therapy should be initiated. Efficient treatment for more persistent shoulder tendinitis following these conservative measures is a single subacromial steroid injection mixed with local anesthetics. In chronic severe shoulder tendinitis, surgical removal of the lateral part of the acromion may ameliorate pain. A change in workplace design or work task may be necessary if the tendinitis is related to high local shoulder load. A history of prior shoulder tendinitis (stages I or II) results in increased risk

Figure 23.2.4: Intramuscular pressure in the supraspinatus muscle at different angles of abduction and forward flexion. Pressure exceeding 30 mmHg may impair blood circulation.

for relapse among workers continuing to perform repetitive or forceful movements.

Prognosis

The clinical course may progress from stage I to III, but recovery of the tendon can also occur within each stage. A stage III impingement may lead to progressive disability. In a study of assembly workers with chronic tendinitis (stage II and III) a 2-year follow-up revealed that only 8 out of 20 patients had experienced significant recovery.

Cervical spondylosis, shoulder joint and acromioclavicular joint osteoarthritis

Cervical spondylosis and shoulder joint osteoarthritis (OA) are degenerative changes of cartilage and bone in the joints and intervertebral discs.

Epidemiology and work relatedness

Cervical spondylosis is common in the general population. More than 80% of the population over the age of 50 years have radiographic signs of cervical spondylosis. Dentists and miners have been reported to have an increased risk of spondylosis (age-standardized odds ratio 2 to 5). Notably, referent groups (frequently representing office workers) have also had a high prevalence of cervical spondylosis (14–38%). Loading of the cervical spine by extreme position of the head may represent the pathogenic mechanism for spondylosis among dentists and miners. This is consistent with a finding of increased cervical spondylosis in a Jamaican rural population where loads were carried on the head.

OA in the shoulder joint usually occurs late in life, and is often bilateral. Shoulder joint osteoarthritis was found more commonly in dentists compared to farmers, however specific ergonomic exposures related to shoulder joint OA have not been well characterized. Occupations with high physical demand have been associated with degenerative changes in the shoulder joint (see Chapter 23.3). An increased risk for acromioclavicular OA has been reported among construction workers. Heavy lifting and handling of heavy tools with hand-arm vibration have been suggested as the exposure-related factors for development of acromioclavicular joint OA.¹⁷

Pathogenesis

The pathogenesis of primary OA is frequently not known. Primary (idiopathic) OA is the most common diagnosis, in the absence of predisposing factors such as previous fractures. If such predisposing factors exist, the OA is termed secondary. There are disputes regarding the pathogenic mechanism for work-related OA, with hypotheses including metabolic trauma, or microfractures due to sudden impact or repetitive impact loading.

Clinical presentation

The clinical presentation of OA is variable. While there may be a discrepancy between radiographic findings and patients' symptoms and signs, there is frequently strong

correlation in advanced disease. Symptoms may include pain during movement, and when loading the joint during forceful or repetitive activities. In severe osteoarthritis the range of motion is diminished.

Diagnosis

The diagnosis of osteoarthritis relies mainly on imaging techniques. In the shoulder joint, arthroscopy may reveal early signs of osteoarthritis.

Management

Symptoms of inflammation may be ameliorated by oral non-steroidal anti-inflammatory medications. Local steroid injections should generally be avoided, since the degenerative process is accelerated by steroids. Loading of the osteoarthritic joint should be minimized by work redesign.

Prognosis

Osteoarthritis usually occurs late in life, but may result in substantial limitations on work activities in younger individuals. Symptomatic improvement is often seen with NSAIDs and reduction of joint load (e.g., work restrictions).

Cervical radiculopathy

Radiculopathy represents a compression of the nerve root caused by a herniated disc or narrowed intervertebral foramen.

Epidemiology and work relatedness

Cervical radiculopathy has a prevalence of 1–5%. In studies of data entry operators, dock workers, and assembly line packers, a risk ratio below one was observed. Cervical radiculopathy has not been well characterized in terms of physical or other work stresses, though it clearly represents a complication of traumatic cervical spinal injury.

Pathogenesis and clinical effects

The etiology of cervical herniation and narrowed intervertebral foramen remains obscure. Symptoms include severe pain, with distinct radiation of the pain to specific dermatomes. Tingling and numbness may be present. Wasting of muscles can occasionally be seen, as in a C7 syndrome where atrophy of the first dorsal interosseus muscle may occur. Loss of muscle strength may result in impairment.

Diagnosis

The diagnosis of cervical radiopathy may be established by clinical examination, where the findings are specific sensory loss in affected dermatomes, diminished motor reflexes, and a positive result on testing of compression of the cervical spine or the intervertebral foramina. Radiographic examination with CT scan, MRI or myelography may show the hernia or the impingement on a spinal nerve. Nerve conduction studies may demonstrate changes in nerve function.

Management

Surgical release of the herniation is rarely required, as traction therapy of the cervical spine is sufficient (e.g., with use of a soft cervical collar).

Prognosis

The prognosis is good in most cases. At least partial recovery with improved symptoms is often observed within several weeks or months following initiation of treatment.

Thoracic outlet syndrome

The diagnosis of thoracic outlet syndrome (TOS) has generated much controversy regarding definition and treatment. TOS has been associated with several syndromes of distinct etiology and clinical course.^{18,19}

Pathogenesis

TOS is a neurovascular impingement syndrome occurring at different anatomical levels where the brachial plexus and the subclavian vessels may be entrapped as they pass en route from the cervical spine to the upper extremity. TOS can be divided into neurogenic and vascular etiologies. Neurogenic symptoms and signs result from compression of the brachial plexus at various levels, and is more prevalent than vascular compression. The level of compression is described as subtypes of TOS, including: (1) cervical rib or fibrous band syndrome, (2) scalenus syndrome, (3) costoclavicular syndrome, and (4) hyperabduction syndrome (or pectoralis minor syndrome).

Epidemiology and work relatedness

The prevalence rate of neurogenic TOS varies considerably among industrial workers, ranging from reported rates of 44% for female assembly line workers, to 0.3% for industrial workers in the USA. Differences in reported prevalences may reflect variable and poorly characterized diagnostic criteria for TOS. In a prospective study, a positive Roos test (abduction external rotation maneuver) for neurogenic TOS predicted a slowing of the nerve conduction velocities in the wrist region.²⁰

Clinical presentation

Shoulder and neck pain of variable character, with or without radiation to the arm and hand, is the hallmark of TOS. Symptoms reflect the degree to which particular nerves are compressed. A common type of neurogenic TOS is caused by a cervical rib or a fibrous band that may impinge the lowest part of the brachial plexus, causing pain radiating down the ulnar side of the arm, forearm and hand. This pain may be exacerbated by strenuous use of the hand.

Diagnosis

The diagnosis of TOS is based on history and clinical examination. Roos test (or abduction external rotation – AER – maneuver) is typically positive. In epidemiologic studies, diagnostic criteria of neurogenic TOS have included positive outcomes of the Roos test in association with shoulder and arm pain. These diagnostic criteria are criticized by

some because they do not require more quantitative physiologic measures such as NCV/EMG abnormalities. Vascular forms of TOS are rare. Radiographic findings may include identification of a cervical rib.

Management

Surgery may be indicated in severe cases, with progressive neuropathy or vascular symptoms. Conservative management with strength training, work redesign, or work transfer is often sufficient to allow significant recovery.

Cervicobrachial pain syndromes

Cervicobrachial pain syndrome, characterized by non-localized pain in the neck and shoulder, is among the most common work-related conditions involving the neck and shoulder. Cervicobrachial pain syndrome is defined as pain in the shoulder and neck, with or without radiation to the arm and hand, where the anatomic basis for the pain cannot be identified. Symptoms and signs may resemble or overlap those associated with TOS and primary fibromyalgia. However, the condition does not conform totally to any specific diagnosis. The term cervicobrachial pain syndrome may include different entities such as myofascial pain syndrome, cervical spondylosis, tension neck syndrome, or enthesopathy (periarticular inflammation).

The following discussion focuses on regional muscle pain syndrome, since it probably represents the majority of cases of cervicobrachial pain syndrome. Regional muscle pain syndrome is often termed myofascial syndrome. Tension neck syndrome is a term widely used in epidemiologic studies of work-related pain, localized to the shoulder and neck region. The criteria for tension neck syndrome are usually pain in the shoulder or neck in addition to tenderness over the descending part of trapezius muscle (shoulder–neck area).

Epidemiology and work relatedness

Non-specific neck and shoulder pain syndrome is more common among females than males, with an almost six-fold increase in females observed in some studies of industrial workers. The occupational groups with repetitive arm work task and constrained work postures showed high rates of the syndrome, often exceeding 50% prevalence.

Pathogenesis

Prolonged static contraction of the trapezius muscle during work or in daily activity results in an overload of the type 1 muscle fibers, and may represent the pathogenetic mechanism for non-specific neck shoulder pain syndrome. The type 1 muscle fibers are used in low static contractions. In biopsies from patients with chronic trapezius muscle pain, findings of ‘ragged red fibers’ involving large type 1 fibers were observed. This may be one explanation of the rapid fatigue and pain in such patients. When the demand for energy in the muscle fiber is higher than available, muscle pain may occur. Postural pain syndrome associated with sagging shoulders is a type of cervicobrachial syndrome that may be caused by

prolonged stretching of the trapezius muscle or the brachial plexus.

Common to the cervicobrachial pain syndrome is that discomfort may be triggered by a pain locus in muscles, tendons, joint capsules, or ligaments in the shoulder-neck area. Nociceptors (pain receptors) in these loci may be the origin of not only the neck-shoulder pain, but also diffuse referred pain to the arm and hand. The nociceptive pain may trigger a chronic pain syndrome that can effect the sympathetic nervous system. A possible pathogenic mechanism for chronic pain is that an initial injury caused by strain (e.g., microrupture) does not recover fully, and is followed by subsequent injury events. Pain receptors induce a pathway of signals to the central nervous system, with progressively increasing susceptibility to stimuli. The neurologic response to normal activity is eventually perceived as a painful stimulus (e.g., chronic pain syndrome). Psychosocial factors at home and at work may represent contributing factors, by stress alone or by psychologically mediated muscle tension.

Clinical effects

The predominant clinical symptom is activity-related pain. Stiffness and severe pain at extreme postures are also common. A chronic pain syndrome should be recognized as soon as possible for proper treatment and rehabilitation, preferably in a multidisciplinary pain clinic, with emphasis on maximizing function.

Diagnosis

It is important to rule out specific lesions, which may include neurodiagnostic, imaging, or other laboratory studies. Rarely does a muscle biopsy yield important diagnostic information. Often there is a significant discrepancy between the patient's significant level of symptoms and minimal objective findings by the physician. Blood test and radiographic examination are typically normal. In many patients, the Roos test for TOS may be positive, although a true TOS with mechanical compression on the neurovascular bundle does not exist. In this case the test may indicate an increased sensitivity and irritability of the brachial plexus or adjacent muscular structures. More generalized muscle pain indicates primarily fibromyalgia. Specific criteria have been set by the American College of Rheumatology.

Management

A thorough examination is necessary to exclude other diagnoses related to the neck and shoulder (see sections above). Emphasis is placed on maintaining the patient's functional status. This may include ergonomic modifications, job redesign, and technique training to minimize strain during work by avoiding prolonged static contractions. Physical training reduces pain and increases performance, although an initial pain increase is often experienced when training is started.²¹ Management of chronic pain may include physical therapy, acupuncture, use of local anesthetics, or biofeedback. Psychosocial factors at work and at home can be the obstacle to successful management.

Prognosis

The prognosis for cervicobrachial pain syndrome is variable. The general experience is that pain and discomfort may be decreased, but not eliminated, in the majority of cases. It is important to initiate rehabilitation early, with the goal of minimizing time loss and disability.

23.3 Upper Extremity Disorders

Martin Cherniack

Because the upper extremity frequently manipulates and contacts the work environment, it is not surprising that signs and symptoms affecting the hand and arm are frequent in clinical occupational medicine practice. Evaluation and treatment of acute traumatic events, such as crush injuries, burns, amputations, and lacerations, have been characterized in the hand surgery literature and are beyond the scope of this text. Unlike acute injuries, activity-related disorders of the musculoskeletal and neuromuscular systems, acquired in the course of adult working life, are often not attributable to a single traumatic event, but rather repetitive trauma. In the past decade, public controversies over issues such as work attribution in carpal tunnel syndrome and the government's role in enforcing ergonomic principles in the workplace have been challenged with evolving medical consensus on causation, etiology and treatment.

In the 1990s, the incidence of repetitive trauma disorders (RTDs) affecting the upper extremity reported by the US Department of Labor surpassed all other occupational disorders, in both frequency and cost.¹ While there is no single comprehensive data source that reliably records medically diagnosed musculoskeletal disease, analyses of National Health Interview Survey have suggested that chronic musculoskeletal diseases of the upper extremity affect approximately 10% of the population. A similar fraction of work-associated cases appears to be reported to either the Bureau of Labor Statistics or to State Workers Compensation authorities.^{2,3} One difficulty encountered in characterizing this phenomenon is the abundance of terms that have been applied to symptoms associated with cumulative or repetitive work.^{4,5} They include cumulative trauma disorders (CTDs), repetitive trauma disorders (RTDs), repetitive strain injuries (RSIs), overuse syndrome, and repetitive stress disorders (RSDs) (Table 23.3.1).^{6,7}

Since clinicians are often faced with problems of attribution of work-related upper extremity disease and with providing recommendations for workplace modification, it is worthwhile to address the question of risk or exposure factors. For MSDs, microanatomic injury and repair is often subclinical and in its early stages may not be associated with objective findings.^{8,9} Although the object of much active research, the relationship between subthreshold injury and the onset of recognized clinical disorders is imprecisely understood.¹⁰⁻¹² It is thus particularly important to identify workplace factors that may contribute to disease progression. In the past 5 years, extensive structured reviews of the peer review literature by the National Institute of Occupational Safety and Health,¹³ the Institute of Medicine and the National Research Council,^{14,15} and the Occupational Safety and Health Administration¹⁶ have generated a consensus on known ergonomic risk factors for musculoskeletal disease. These are summarized in Table 23.3.2.

CLINICAL EVALUATION

Establishing an etiology for complaints affecting the upper extremity requires careful assessment of the pathophysio-

logic basis of signs and symptoms.¹⁷⁻¹⁹ Prior to attributing an upper extremity disorder to workplace factors, the clinician must address two basic clinical questions.

1. Is the process local, involving anatomically isolated structures or groups of structures; is it regional, involving an area of the arm and shoulder without anatomic focus; or is it systemic, involving multiple discrete or more distal organ systems?

2. What is the specific site of disturbance? For example, can pain be assigned to joints, entrapped nerves, tendon dysfunction or vascular insufficiency?

Behind this are important distinctions between inflammation and chronic degeneration, in tendons for example, or between nerve entrapment and intrinsic neuropathy. Since muscle, tendon, and nerve have considerable plasticity, the delineation between reversible symptomatic disorders and more persistent pathological changes is important.

History

Because symptoms affecting the upper extremity are relatively common and are frequently chronic, the medical history must concentrate on prior symptoms as well as the presenting complaint. A history that includes previous trauma, use of medications, and other medical conditions is essential.²⁰⁻²³ Because joint pain, neuritic symptoms, myalgias, and cold-related symptoms may overlap with rheumatologic illnesses, particularly collagen vascular diseases, a review of constitutional, dermatologic, and other internal organ system disease or symptoms should be elicited. The importance of identifying previous trauma, particularly for proximal upper extremity disorders, cannot be overstated.

General medical history

Frequency and duration of symptoms are especially important. Because many upper extremity complaints are chronic, the eliciting event initiating a visit to the physician's office may be only indirectly related to the natural history of the condition. This poses particular problems for accurately defining the interval between the initial occurrence of symptoms and their clinical recognition. Temporal considerations also apply to the frequency of symptoms, whether they are episodic or continuous, and whether there is a seasonal or climatic component. Because distinctions between pain, numbness and dysesthesias, loss of sensation, and loss of function may be critical for both staging and diagnosis, specialized questions should be addressed, including daily performance skills, such as dressing, grasping slippery objects, and using fine implements. Shift work deserves special consideration, because unusual sleep patterns may be the result of a change in schedule or physical discomfort.

Work-related factors such as repetitive and forceful motion may interact with non-work-related factors to injure the upper extremity. The medical history should emphasize systemic disorders associated with neuropathy,

Repetitive strain injury
Repetitive motion injury
Diseases of acquired function
Cumulative musculoskeletal disorder
Computer-related health epidemic
Cumulative trauma disorder
Overuse syndrome
Occupational myalgia
Video display terminal (VDT) syndrome

articular, and periarticular disorders.^{24,25} For instance, a mild diabetic neuropathy may have a more pronounced symptomatic expression in a heavily used upper limb. Alternatively, clinicians have often recognized that patients with musculoskeletal pain report local or referred phenomena such as paraesthesias or numbness in the hands. Common work-related musculoskeletal disorders such as epicondylitis without nerve entrapment have been associated with reduced subjective sensory perception.^{26,27}

Predisposing conditions for tendinitis include rheumatoid arthritis, gout, pseudogout, Ehlers–Danlos syndrome, hypothyroidism, diabetes, Dupuytren's contractures, and infections, such as tuberculosis and atypical *Mycobacteria*. Rheumatoid arthritis and other collagen vascular disorders also have been associated with secondary Raynaud's phenomenon, mononeuritis, and synovial inflammatory conditions causing nerve compression. Hepatitis B and C are also relatively common in some industrial populations and are associated with muscle and joint complaints. Although these disorders account for less than 5% of presenting patients evaluated for work-related upper extremity disorders, their potential presence should be elicited, particularly because continuous occupational exposures may aggravate underlying disease.

A history of hand injuries, including those due to frostbite, crush, penetrating trauma, and fracture, is important, because callosities and nerve and vascular injury may be independently associated with physiologic impairment or increase susceptibility to workplace factors.^{28,29} Personal habits, including tobacco and alcohol use, should be assessed. Tobacco use may significantly complicate and exacerbate vasospastic episodes^{30,31} (e.g., Burger's disease) and alcohol use is an important source of metabolic neuropathies.

The occupational history

In selected settings, a single traumatic episode or recent change in work organization may obviate the need for comprehensive history taking, but in most instances, particularly in cases in which the onset is more insidious, a full occupational history is essential. Because job titles may not accurately describe job activity, particularly in the building trades, it is essential that tasks be described in detail, even acted out. This accounting should include identifying specific tools, fittings, and uses, and weekly or monthly hours of total use. Tool weight, time in overhead postures, and approximate force and strength requirements should be characterized. Handedness and hand position are particularly important, and symptoms that are unilateral may not always follow the predicted pattern.

Although symptoms in the dominant tool-wielding hand predominate among poultry workers,³²⁻³⁴ a high incidence of carpal tunnel syndrome (CTS) in the non-dominant (carcass-supporting) hand has been described in butchers.³⁵ Similarly, although vibration-induced symptoms are usually bilateral, the plane of vector forces may be greater in the non-dominant supporting hand. The dramatic transition to the electronic office also requires greater detail than 'computer work' or 'data entry'.^{36,37} Office-related musculoskeletal disorders usually involve reversible pathology, and worksite modification is frequently a key component of cure (see Chapter 15). Accordingly, the history should include an estimate of actual hours spent in keying or inputting, and descriptions of work surface height, position and type of input device, and adjustability of chairs and work surfaces.^{38,39}

The following points should be included in the occupational history.

1. Symptoms in previous jobs.
2. Previous occupations and job responsibilities and tasks.
3. Home and ambient use of tools such as chain saws and other power tools.
4. The duration between employment and symptom onset.
5. The presence and description of symptoms in coworkers.
6. The relationship between symptom onset and temperature, and stage of the work shift.
7. The presence of symptoms on vacations and time off.
8. Previous diagnosis, treatment, and response.
9. Broader changes in work equipment, management organization, materials and products, and organization of teams and work assignments.
10. Individual factors such as the initiation of bonus or incentive programs; recent return to work following pregnancy, illness, or lay-off; and the quality of training.

While a history of hobbies and other non-work activities is important, such risk factors are as likely to exacerbate existing or work-related disease as to cause new disorders.^{40,41} Most non-work activities are not performed with the duration or intensity, or under the time constraints characteristic of occupational exposures. In addition, certain industries, such as meatpacking, demonstrate disease clusters and rates of disease that are substantially above population

background rates and rates found in other industries. Investigators in Washington State found that, compared to industry-wide carpal tunnel syndrome (CTS) incidence rates, oyster and crab packers demonstrated a relative risk (RR) of 14.8 (95% CI: 11.2–19.5) and the meat and poultry industries had a relative risk of 13.8 (95% CI: 11.6–16.4).³ Thus, the likelihood of detecting the presence of disease rises with recognition of high risk within an industry.

Although the general elements of the occupational history cannot be overemphasized, there are some specific exposures, chemical and physical, that require special inquiry, because upper extremity tissue damage may actually be worse than can be determined from physical inspection alone. A distant history of cold injury may clarify contemporary dysesthesias and cold intolerance. Sensory abnormalities in workers exposed to extreme cold have persisted for years after pertinent exposures. Microwave radiation exposure, which may occur from unexpected sources, such as food preparation, drying or kilning of wood products, sealing of packaging, and rubber and polymer curing, may cause significant soft tissue injury, including surgical emergencies requiring decompression with trivial skin damage. Similar considerations apply to thermal and electrical burns, particularly in cases in which the injury is not circumscribed by an area of direct contact. The occupational history should attempt to differentiate between trivial first aid and extended medical evaluation and observation.

Physical examination

Despite notable advances in imaging, the physical examination of the upper extremity is the most important component of upper extremity assessment and definition of treatment course. While inherent limitations in reliability, sensitivity and specificity of clinical testing exist, there have been several consensus reviews on the utility of clinical tests and their administration.^{19,42,125}

The examination should include inspection of the neck, shoulder girdle, upper arm, forearm, wrist, and hand. In the absence of obvious anatomic change, injury, or abnormal movement, a detailed examination should follow, focusing on patterns of weakness, swelling, numbness, and paresthesias. Provocative tests are highly important: they highlight the important distinction between pain syndromes and painless dysfunction. Because pain syndromes associated with repetition and chronicity are frequent, there should be special consideration to palpation of muscle bellies and musculotendinous junctions, as well as to joint capsules and ligaments. Pain during active isometric resistance of wrist and forearm flexion and extension, respectively, is indicative of tenosynovitis.

Bilateral examination is important, even when symptoms are unilateral. Delayed arterial refill in the hand (assessed by Allen's test) or pulse drop on neck and shoulder manipulation may suggest a vascular cause of unilateral dysesthesias, but contralateral delay in the absence of symptoms may suggest an alternate diagnosis. The pattern of elicited pain also may be useful in differentiating a diagnosis. Tendon ruptures, inflammatory tenosynovitis, and

arthritides should be sharply localized. More diffuse pain is characteristic of cervical disease, tumors, and dislocations. Retrograde pain suggests a distal nerve entrapment.

Anatomically well-defined nerve entrapment disorders are detected by tapping over the nerve (e.g., Tinel's sign for carpal tunnel syndrome), demonstration of motor weakness, and dermatomal patterns of abnormal sensation in involved nerves.^{42,43} Stretching an entrapped nerve may exacerbate symptoms, as in the wrist flexion maneuver of Phalen's test. Physical examination may be less sensitive in milder cases. Provocative tests must, however, be put in a context. Reviews of the ability for Phalen's test to distinguish between subjects with and without carpal tunnel syndrome (CTS) have varied in the published literature, although they generally do not exceed 80%.

Usually, physical examination provides little insight into the cause of the injury. However, there are some characteristic physical findings that may directly suggest an association with a work-related source.

Hand, wrist, and forearm

A cool cyanotic hand may be the result of arterial damage from repeated percussion (e.g., ulnar hammer syndrome) or traumatically induced vasospasm, as is seen in vibration-induced Raynaud's phenomenon. In cases in which vascular insufficiency is severe, trophic changes at the fingertips may be visualized.

A claw hand implicates brachial plexus compression or proximal median nerve injury. Acute injury or chronic supportive wrist abduction from climbing may be important associations. Wrist drop, characterized by extensor weakness, is rarely seen in the context of a metabolic neuropathy but has classic associations with arsenic and lead. Trigger digits, caused by narrowed flexor sheaths or tendon thickening, produce an audible snapping and are associated with repetitive work and forceful grasping of hand tools, such as pliers. Dupuytren's contractures, although more often associated with liver disease and alcohol consumption, have been linked to percussive work. In these examples, it is important to differentiate between fixed anatomic conditions and conditions which are transient. Transient flexor contraction, usually in the early morning, is common following trauma or surgery, but it is mechanical rather than neurologic in nature. Hyperkeratoses of the palms usually reflect the existence of callosities; the association with arsenic toxicity is less common than in previous eras.

The forearm

Forearm pain in extensor and flexor compartments is common and usually related to muscle and tendon dysfunction, strain or shortening. Forearm pain has been attributed to median nerve compression – the so-called pronator syndrome – associated with muscle hypertrophy and overuse. Nerve entrapments in the forearm are much less common than at the wrist or elbow.^{44,45}

The elbow

Extensive leaning on the elbows and forceful manipulation, such as in slaughterhouse work, has been associated with

nerve compressions at the elbow. The evaluation of occupational elbow pain should merit a search for motor weakness in the hand. Chronic injury at the lateral epicondyle can be confirmed by eliciting tenderness over the common extensor origin, which frequently radiates toward the wrist on resisted extension. Although lateral epicondylitis has been associated with tennis playing (e.g., 'tennis elbow'), traumas other than racquet sports have been implicated. The presence of radiating pain emanating from the medial elbow suggests possible ulnar nerve compression, especially after forceful elbow extension.

Shoulder

Impingement syndromes, characterized by limited range of motion of the shoulder, are common where overhead work is a frequent activity. It is important to recognize that in almost all cases, impairment guidelines, such as the AMA Guide, suppose structural pathology, and are not suitable for establishing normal range of motion. Physical therapy guidelines are a more useful source of reference values for range of motion.

In summary, the physical examination remains a critical component of the evaluation of the upper extremity and should include the following components useful for diagnosis. An organized approach may be useful. Either proximal to distal (neck-shoulder to digit) or distal to proximal (digit to neck-shoulder) is practical, but it is usually more efficient to progress from anatomic region. The following sequence may prove helpful.

1. General inspection
2. Local inspection and physical examination (color, temperature, tissue integrity)
3. Derivation of pain – static or in movement
4. Measurement of range of motion
5. Provocative tests
6. Motor and sensory exam
7. Preliminary diagnoses

Laboratory evaluation

Laboratory evaluation is important in diagnosing upper extremity disorders. In general, in the past decade there have been few significant additions to laboratory medicine which bear directly on occupational disorders of the upper extremity. Principal modalities include radiographs, electrophysiologic tests, vascular tests, quantitative sensory tests such as vibrometry, and serologic, hematologic, and blood chemistry profiles. In general, the more mechanistic tests have application to local disorders, whereas serology and blood chemistries have relevance to systemic disorders. There are substantial areas of overlap and potential differentiation. Joint pain and motor disturbances from lead toxicity may be exhibited by anemia. Diabetes is a great masquerader and may be confused with or complicate occupationally induced neuropathy. Cold intolerance and peripheral nerve dysfunction due to vibration may be complicated by thyroid disorders. Vascular imaging plays an important role in detecting uncommon but important disorders such as distal arterial obstruction or vascular thoracic outlet compression.

Radiographic studies

X-ray studies of the hands and joints may be critical in the diagnosis of arthritides and traumatic synovitis. Calcification of ligaments can reflect overuse as well as fluorosis. Bone cysts appear more commonly in manual workers, although neither the pathology nor clinical significance is clear.²¹ The presence of epicondylar bone spurs may clarify a suspicion of epicondylitis, but their absence does not exclude the diagnosis. Abnormal neck films are notoriously imprecise localizers of cervical spine radicular disease; however, normal films are a useful screen. There appears to be a relatively good assessment of patency of the carpal tunnel by CT, and the median nerve is well visualized by MRI. The diagnostic utility may be compromised by cost, institutional experience, and the greater physiologic relevance of electrodiagnostic studies.

MRI has an important place, particularly in more complex diagnosis. For example, the relative morbidity of angiographic studies of hand circulation discouraged vascular studies in the past. MR(A) currently provides excellent resolution and is the test of choice, unless an intervention such as thrombolytic therapy is considered. MRI of peripheral nerves is also an important potential diagnostic tool. Recurrent symptoms following carpal tunnel release present problems of management, because of the high morbidity associated with repeated surgery. Visualization of nerve flattening or scar formation provides an objective basis for re-instrumentation. MRI has an important role in hand pain. Carpal ischemia, ligamentous injuries and erosions of carpal bones, and early breakdown of repetitively stressed joints, such as the CMC joint of the thumb, will elude standard x-ray diagnosis. They are often highly responsive to conservative therapeutic intervention, when diagnosed at an early stage.

Electrophysiologic studies

The laboratory is essential for the diagnosis of entrapment neuropathies, peripheral and polyneuropathies due to diabetes, and metabolic and inflammatory diseases.⁴⁶⁻⁴⁹ Certain electrodiagnostic patterns may be helpful in differentiating a distal exposure-related neuropathy,⁵⁰ such as that seen with vibration, and the EMG can be specific in conditions such as delayed organophosphorus-induced neurotoxicity. Two common uses in an industrial cohort are for diagnosis of CTS, in which sensory or motor median nerve conduction may be focally blocked at the wrist, and in cervical radiculitis, in which denervation on the EMG may present a diagnostic pattern. Cross-elbow studies are also commonly ordered in the assessment of ulnar nerve entrapment at the elbow, although these studies have a limited sensitivity, even when compression is identified at surgery. F waves and somatosensory-evoked responses have been used in the diagnosis of the thoracic outlet syndrome, although their interpretation has been questioned. The wide disparity in reported results would indicate that they are not an efficacious diagnostic tool.

In earlier studies of American hand surgeon practice, it appeared that CTS was diagnosed in the absence of nerve conduction studies about one-third of the time.^{12,51}

However, in a recent study of the practices of physicians certified in physical medicine, rehabilitation and electrodiagnostic medicine, electrophysiologic testing substantially altered 42% of diagnostic decisions.⁵⁰ The recognition among many physicians that carpal tunnel release is performed too frequently, and the requirement by some insurance carriers that nerve conduction studies always precede release surgery, may exert impact on the standard of practice. While electronegative carpal tunnel syndrome has been frequently described in the clinical literature, population-based studies have conversely demonstrated that as many as 40% of workers with heavy use patterns may have delayed median nerve latencies in the absence of significant symptoms.^{12,52} There is controversy over the sensitivity of electrophysiologic studies because there is no pathologic or other gold standard for CTS (see Chapter 19.2). One difficulty is the age specificity of the tests as well as the wide variation of reported normal values.

There is also the important recognition that conventional nerve conduction studies are summaries of function. The onset latency of the action potential relates only to the fastest conducting fibers, while its waveform reveals the functional status of the remaining, slower conducting fibers. Slowed conduction itself leads to few, if any, clinical symptoms, as long as all the impulses arrive at the target organ. It is also widely recognized that the relative degree of slowing does not correspond with clinical severity. Conduction block, however, is often accompanied by symptoms of major loss of strength. In summary, the EMG indicates the need for therapeutic intervention when there is evidence of cervical root irritation or when specific motor branches of the ulnar nerve demonstrate denervation. However, slowing at the carpal tunnel, the most frequently utilized finding, usually does not require a specific generic intervention. It should be remembered that paresthesias (ectopic peripheral nerve activity), functional deficits, positional or nocturnal brachalgias, and digital cramping require a differential diagnosis, and the nerve conduction study provides a physiologic measurement, not an anatomic image.

Quantitative sensory tests

Tests for vibrotactile threshold at single or multiple frequencies and tests of thermographic threshold have become available for use in the industrial setting and have been the subject of international standardization.^{53,54} Their simplicity and portability define them as potentially powerful surveillance instruments, and in principle they can measure specific mechanoreceptor thresholds and different fiber types (heat and cold) in the digit.^{50,55,56} Moreover, certain mechanoreceptor populations appear to be age specific, whereas others are not age sensitive.

Vibrometry alone may not differentiate between focal receptor injury, such as can be caused by cold and vibration, and more proximal compression neuropathy. There is convincing evidence that while these are preferred tests for small fiber nerve injury, they provide insensitive measures of nerve compression, which will be the more common concern in most work settings. The testing algorithm should be carefully reviewed before initiating screening

programs in working populations. Although not currently available, it would be highly attractive to have a portable, simply operated, and relatively inexpensive device that differentiates cervical myelopathy, median nerve mononeuropathy and small fiber dysfunction with a high level of sensitivity and reliability.

Blood testing

Elevated muscle enzymes (creatine kinase [CK], aldolase) have been reported in industrial workers with acute neck and shoulder disorders, but a more conventional use of muscle enzymes is in the identification of inflammatory myositis, particularly as it may coexist with degenerative upper extremity diseases. Rheumatoid arthritis, collagen vascular diseases, and gout all merit the appropriate serologic and chemistry studies (see Chapter 23.5). An elevation in the sedimentation rate is both common and non-specific, limiting its diagnostic value.

Raynaud's phenomenon, attributable to impact and vibration from power tools, will usually not require an extensive rheumatologic workup when workplace risk factors are identified, and when signs and symptoms are confined to the hands and have a gradual onset of expression. However, since isolated Raynaud's may precede a full presentation of an autoimmune disorder by several years, specialized laboratory tests (e.g., anti-centromere antibody, anti-topoisomerase I) are warranted at baseline, particularly when cases are sporadic. In the past decade, Lyme disease and hepatitis C have also been recognized in the differential diagnosis of generalized joint or muscle pain.

Classification

Because diagnostic criteria have varying levels of specificity, even for the most frequently diagnosed upper extremity diseases, there have been significant challenges for case definitions. For this reason it is useful to aggregate soft tissue disorders affecting the upper extremity into the categories outlined in Table 23.3.3 and discussed below.

DISORDERS OF DEFINED ANATOMY AND QUANTIFIABLE PATHOPHYSIOLOGY BY OBJECTIVE MEASUREMENT

Hand-arm vibration syndrome

Vibration exposure to the hands and arms associated with pneumatic hand tools and larger stationary tools, such as rock drills, has been associated with a characteristic pattern of neurologic, peripheral vascular, and musculoskeletal signs and symptoms.⁵⁷⁻⁵⁹ Outcomes involving measurable neurologic and arterial dysfunction have added substantially to clinical assessment of pain and function. Tools implicated in the disorder include chain saws, rock drills, grinders, pneumatic hammers, and jackhammers. Changes in disease prevalence associated with the chainsaw, the hallmark vibratory tool, has been due to industrial modifi-

I Disorders of defined anatomy and quantifiable pathophysiology by objective measurements

- Hand-arm vibration syndrome – vasospasm and small fiber neuropathy
 - Nerve entrapment and occlusion disorders which can be assessed by electrophysiologic tests
 - Median nerve
 - Carpal tunnel syndrome
 - Anterior interosseous nerve syndrome
 - Ulnar nerve
 - Cubital tunnel syndrome (entrapment at the elbow)
 - Ulnar nerve syndrome (canal of Guyon)
 - Radial nerve
 - Radial tunnel syndrome – posterior interosseous nerve (motor)
 - Radial tunnel syndrome – posterior interosseous nerve (sensory)
 - Wartenburg's syndrome
 - Occupationally induced distal polyneuropathy
 - Vaso-occlusive disorders and disorders of peripheral circulation
- II Anatomically defined and semiquantified disorders based on clinical assessment*
- Tendinitis of the hand and wrist
 - Extensor and flexor tendinitis of the forearm
 - Trigger digits

cation. While the emphasis on air-powered and electrical tools increases power and portability, these modifications may also result in increasing risk for disease.

The most commonly described symptom has been cold-induced vasospasm, detectable as finger blanching, which is often indistinguishable from Raynaud's phenomenon of primary and secondary origin. The most frequent clinical abnormality has been a quantifiable deficit in cutaneous sensory performance; another common occurrence has been pain and paresthesias suggestive of peripheral neuropathy or focal compression, which greatly complicates differentiation from the CTS. A pattern of declining hand strength and electromyographically defined early fatigability is common. Because of the involvement of multiple organ systems, a more general acronym, HAVS (hand-arm vibration syndrome), has come into common usage.

The contribution of small fiber injury to deficits in touch and temperature sensation is consistent with the observation that the tissues of the digit and palm absorb well over 90% of transmitted energy from a conventional vibrating tool, contributing to small fiber nerve injury.

Pathogenesis

The principal clinical presentations of HAVS – vasospasm, quantitative cutaneous sensory deficits, and nerve conduction abnormalities, frequently at the wrist – involve different anatomic sites and, accordingly, different mechanisms of injury. Vibration is measured in terms of the frequency distribution of oscillations; the direction, velocity, and

acceleration of those oscillations; and the impulsivity, or force range (amplitude), expressed in each impact cycle. Each of these physical characteristics has a bearing on symptoms and tissue injuries that may occur, particularly in the palms and digits, but also more proximally in the shoulder and neck when frequencies are very low. For example, large impact tools, such as jackhammers, produce tissue waves that can affect the shoulder and neck. On the other hand, electric rotary tools can produce energies that are entirely absorbed in the hand and wrist. Although cold-related vascular symptoms frequently follow neurologic symptoms chronologically, the vascular and neurovascular symptoms appear to be independent, and pure vasospastic disease is common.

Quantitative sensory abnormalities, presumed to be due to injury to local fingertip receptors, represent the most common abnormality.^{60,61} There is controversy over the prevalence of nerve conduction abnormalities in workers exposed to vibration, as about 20% of symptomatic cases may have median nerve slowing at the wrist, which is indistinguishable from CTS.⁶²⁻⁶⁴ Because HAVS more frequently involves the palm and the distal ulnar nerve, there is usually a poor response to carpal tunnel release, particularly if there is a return to the former worksite. In each case, the common etiology is vibration, predominantly in the 30–500 Hz range, although there is debate about the identity and weighting of the most damaging frequencies. The role of very high frequencies (above the 1500 Hz 'upper limit' of conventional measurement) from high-speed tools, including medical and dental drills, saws, and ultrasonic devices, is uncertain. Several studies have indentified small fiber and vascular dysfunction but the mechanisms have not been defined.⁶⁵

Clinical course

There is little evidence that tolerance plays a major role in vibratory disorders, and vascular attacks may affect the majority of dedicated workforce within a decade of exposure. Over time attacks generally increase in frequency and are elicited by milder temperatures. There are two predominant patterns – diffuse attacks and a cold-intolerant pattern. These patterns do not differ on quantitative tests, and the delineating factor may be the ability to seek cold protection. Unlike Raynaud's phenomenon resulting from other causes, trophism and gangrene are extremely rare. In cooler climates, the onset of summer markedly attenuates the vascular condition. It is also important to recognize that cold-related pain is a hallmark of chronic peripheral nerve injury. Symptoms that follow the dermatome of an established peripheral nerve injury should be confirmed by laboratory testing, or a history which indicates a well-circumscribed blanching pattern.

A traditional distinction has been made between HAVS and an 'acute vibration syndrome', where hand paresthesias induced by power tool use will remit symptomatically after several hours. However, more recent information has associated the severity of these paresthesias with the duration and intensity of exposure, suggesting that even apparent reversibility may disguise a cumulative disease process.

Because anti-vibration gloves do not effectively protect the hands, clinical management involves work attenuation or removal, if tool types remain unchanged. Since small fiber nerve injury appears to be largely irreversible, and Raynaud's is at best partially reversible, there is a compelling case for termination of exposure. On the other hand, industrial indemnification policies in the United States provide limited material support, even when disease is advanced. The decision to remove from work is therefore complicated and frequently involves a balance between risk for disease progression and implications of disability.

Diagnosis

Although history and clinical presentation are important, there should be particular emphasis on quantitative testing, to reinforce a decision on the individual's removal from exposure, assess intervention, and to stage subclinical disease. Digital vasospasm has been traditionally tested by cold water immersion, but temperature recovery testing appears to be without value. Cold challenge plethysmography, where available, offers greater precision with reliable quantitation. Workers with non-detectable finger systolic blood pressures or with reductions of more than 30–40% with moderate cold stimulation have vasospastic disease that will become aggravated by further exposure.^{30,66} In contrast, vascular tests, such as brachial/digital blood pressure comparisons, doppler and pulse-volume plethysmography at ambient temperatures, and temperature recovery following cold challenge, have no significant role in the diagnosis of cold-induced vasospastic disease.

Nerve conduction studies, particularly segmental studies, can delineate isolated median nerve wrist abnormalities from more diffuse neuropathies and systemic polyneuropathies. Cutaneous neurologic abnormalities are well assessed by quantitative sensory tests, particularly vibrotactile thresholds that are abnormal in a majority of exposed workers.^{60,67} Hand weakness is a common complaint, and is often influenced by diffuse slowing of myelinated nerves.⁶⁸ Because there is great age and population specificity to these tests, they should not be used for pre-employment or cross-sectional screening without a well-documented parameter for normalcy. Hand x-ray studies frequently are abnormal in manual workers, with degenerative joint disease, trauma, and bone cysts a common finding; these conditions rarely contribute to the diagnosis.^{21,69}

Differential diagnosis

Principal competing diagnoses include Raynaud's phenomenon (both primary and secondary), peripheral obstructive arterial disease, associated systemic conditions such as diabetes and rheumatoid arthritis, and peripheral neuropathy.⁷⁰ Occlusive disease, such as the ulnar hammer syndrome, will often present as a Raynaud's pattern, but the distribution and onset usually make diagnosis clear. Routine vascular laboratory studies will generally establish the diagnosis. The differentiation from other entrapment neuropathies (e.g., CTS) and more proximal lesions is

particularly important.⁷¹ There has been considerable attention in the vibration literature to differentiating entrapment neuropathies such as CTS from distal small fiber nerve injuries in the digits. In the past 15 years, most investigators have recognized that small fiber injury to fingertip nociceptors is distinctly more common than CTS in vibration-exposed workers, that electrodiagnostic studies are insensitive measures of this type of injury, and that quantitative sensory testing is essential if unnecessary carpal tunnel surgery is to be avoided. These tests, particularly measurement of vibrotactile thresholds, have consistently demonstrated deficits in perception in both symptomatic and asymptomatic patients exposed to vibration.

As noted, a suspicion for collagen vascular disease warrants laboratory studies. Screening laboratory studies should include a complete blood count, blood chemistry studies, ESR, rheumatoid factor, ANA, thyroid function tests, and in some settings, cold agglutinins, cryoglobulins, and assays for Lyme disease. There are good reasons to obtain specific antibodies for collagen vascular disease that may present as isolated Raynaud's phenomenon. Degenerative conditions, such as rheumatoid arthritis, usually preclude significant vibratory exposure from heavy tools.

Treatment and prognosis

For established disease with positive plethysmography, abnormal vibrotactility, functional interference with perception, and increasing pain, exposure removal is generally necessary for effective management. A decade ago, NIOSH recommended mandatory work removal at a specified symptom level. Because removal from exposure may mean loss of employment, alternative approaches may be necessary. These alternative approaches include calcium channel blockers, including sublingual administration to abort attacks in extreme conditions, and liberal use of hand warmers in cases in which vascular symptoms predominate. In general, however, medication is poorly tolerated at doses needed to eliminate Raynaud's attacks, and is therefore not a practical option. Anti-vibration gloves, particularly those with wrist supports, should be used regardless of the presence of symptoms as they block higher frequencies, but are ineffective against the most damaging frequencies. Until it can be demonstrated that higher frequencies are benign, the role of gloves is justified.

Smoking reduction reduces the frequency and intensity of vascular attacks. Continued smoking prolongs measurable vascular dysfunction when exposure is terminated. A restrictive program of administrative controls that reduces exposures to less than 2 hours per day, coupled with vigorous tool maintenance and replacement with less vibration-producing machines, may abort clinical and subclinical progression. Fortunately, if exposures are attenuated or eliminated, the prognosis for milder cases is relatively good, with almost 50% of patients improving to near their baseline in about 5 years following last exposure. Unfortunately, when neurologic disease is well established, improvement is more modest.

Carpal tunnel syndrome

Carpal tunnel syndrome (CTS) (Fig. 23.3.1) is identified by a characteristic pattern of pain, paresthesias, and weakness following the distribution of the median nerve distal to the transcarpal ligament in the wrist. Along with tenosynovitis, it is one of the two diagnoses most frequently ascribed to repetitive workplace injury.⁷² Although the median nerve provides only limited motor innervation to the hand, in the earliest accounts by surgical pioneers, such as Paget and Hunt (1911), thenar atrophy and compressive neuritis were the predominant described pathologies.⁷³ Despite clinical series evolving over the past 40 years that include several thousands of patients, aggressive carpal tunnel release is a relatively new surgical procedure.⁷⁴ Allowing for the earlier misdiagnosis as TOS for conditions which would currently be called CTS, only 12 releases were described in the surgical literature prior to 1950. It is now an extremely frequent procedure, with the average American hand surgeon performing more than 100 per year, more than 90% on an outpatient basis.

There appears to be widespread confidence in the clinical presentation among specialists, independent of nerve conduction studies. Although in the 1960s Phelan, who

Table 23.3.4 Occupations associated with carpal tunnel syndrome

did much to advance surgical technique and recognition in the United States, denied a particular role for occupation,⁷⁵ there is substantial recent literature that associates CTS with work.^{70,76-78} Because of the strong association of carpal tunnel syndrome with repetitive and forceful activities and awkward postures, there has been particular attention to the process by which joint deviation, loading and repetitive muscle contraction may raise pressure within the carpal tunnel. Table 23.3.4 lists occupations with increased risk of CTS.

In spite of the wide acceptance of the diagnosis and the availability of confirmatory electrodiagnostic testing, recent studies have provided evidence for potential confusion. Motor and sensory nerve conduction delays have been described in 25% of asymptomatic individuals in workforces with primary repetitive manual tasks.⁷⁹ In some workforces, when classic paresthesias are present, positive nerve conduction studies are recognized in less than 60% of cases. Intermittent nocturnal brachalgias, which are a hallmark of carpal tunnel syndrome, when routinely screened, may be recognized commonly in adults over 60 years of age. In short, both the basis for and consequences of diagnosis are ambiguous. Even when the pattern of nerve injury distinctly implicates a focal site of compression, the indication for surgical decompression may be unclear.

Pathogenesis

Because of its tight internal dimensions and prodigious content of nine flexor tendons enclosed in synovial sheaths, the carpal canal offers little tolerance for volume change. In principal, median nerve compression can result from space-occupying lesions, such as neuromas; expansion of soft tissues, as with synovitis or accessory muscles; bony protrusions,⁸⁰ such as calluses; or intrinsic susceptibility from primary nerve pathology, as in diabetic neuropathy. Many systemic diseases, including amyloidosis, hypothyroidism, acromegaly, and Paget's disease, have been associated with CTS. With the exception of rheumatoid arthritis, diabetes, and pregnancy, underlying conditions have been relatively infrequent in large case series. Such conditions are even rarer in occupational cohorts, usually involving less than 5% of cases.

Recent efforts at defining CTS in the workplace have focused on extrinsic cumulative trauma to soft tissues in the wrist. Force, repetition, and vibration have emerged most consistently as relevant job risks. No simple correlation exists between force and symptoms. Newer data have cast doubt on a single mechanism involving extrinsic compression caused by an inflamed synovium. For example, force exerted over the base of the palm during assembly tasks may cause mechanical damage to the median nerve in the palm, causing signs and symptoms of carpal tunnel syndrome. Internal responses may include inflammatory responses to tissue injury, neurochemical changes, and altered metabolism. Force and vibration may cause an intrinsic and reversible swelling of myelinated nerves, and in some cases, more distal injury to glabrous skin receptors or small nerve fibers with a carpal tunnel-like pattern.^{77,81,82}

The narrow anatomic confines of the carpal canal lends credence to the presumption that extreme postures would be a risk factor. Studies of intracarpal pressure in these more exaggerated or non-neutral positions have been consistent, generally demonstrating large increases in pressure, when the wrist is forcefully stressed, particularly in hyperextension. Relatively low fingertip loads also raise carpal pressure. Pinching, grasping and wrist angulation are often accompanied by classic symptoms in diagnosed cases.

Clinical course

Because clinically identified CTS represents a spectrum of diseases ranging from vague paresthesias in a median nerve distribution to frank thenar atrophy, there is no universal clinical course. The literature on outcomes is limited, mostly characterizing results of surgical interventions. The condition is often progressive, unless there is medical intervention or, in the occupational setting, workplace alterations are made. However, intermittent symptoms, particularly if they occur during sleep or if they are positional, will often resolve with only modest intervention. Because longstanding paresthesias and muscle atrophy bring a worse prognostic outcome, an argument exists for early surgical intervention. While plausible, many cases will persist at a low level without aggravation for many years. Alternatively, the rapid relief that may accompany rest or a work change, and the frequent necessity for job change even after surgery, complicates the decision on intervention. Given the potentially benign course of uncomplicated nerve compression, and access to ergonomic interventions, conservative management can and should play a larger role. It is also important to recognize that accompanying symptoms, such as painful tendons and joints, limited range of motion and diminished wrist mechanics, and problems with dexterity, will usually not be addressed by surgery. If these are the main source of disability, the limits of carpal tunnel release require consideration.

Diagnosis

Because compressive neuropathy can result in local demyelination or more serious axonal degeneration, a differentia-

tion between paresthesias (numbness and tingling) and loss of sensation is important. Clumsiness due to sensory and proprioceptive impairment suggests a more serious condition. A history of night-time and morning symptoms, sometimes occurring with driving, and relief by shaking or movement, is particularly useful in differentiating CTS from cervical myelopathy and more diffuse processes that involve small nerve fibers. The classic physical diagnostic tests, Phelan's maneuver and Tinel's sign, are positive in many asymptomatic individuals and correlate poorly with nerve conduction tests.

Electrodiagnostic studies are at the core of clinical decision making, although reports of surgical amelioration in patients with negative electrodiagnostic results is well established when other clinical evidence is documented. Muscle wasting can be difficult to determine clinically, so reports of thenar weakness should warrant full EMG studies. Because rheumatoid arthritis, thyroid disease, and diabetes mellitus have all been associated with CTS, and because they are relatively common disorders, screening tests are often warranted, even when a secondary etiology seems improbable. The coexistence of a work-related disorder and neuropathy from another disease process is important, as additive insults may significantly limit future function.

Differential diagnosis

The diagnosis of CTS poses three difficulties for the clinician: (1) differentiation from musculoskeletal pain syndromes and other anatomically non-specific soft tissue disorders, (2) differentiation from other entrapment neuropathies with a peripheral presentation, and (3) differentiation of purely localized nerve compression from systemic disorders.

Systemic causes of CTS include conditions producing edema (pregnancy, cirrhosis, and the nephrotic syndrome); infiltrative disorders such as amyloidosis, myxedema, and acromegaly; and soft tissue inflammatory states, such as rheumatoid arthritis. One of the most important causes is diabetic neuropathy, which may place the nerve at increased risk of injury, causing a more severe pattern of pain and sensory loss in the upper extremity than in the lower extremity. In most working cohorts, systemic diseases are uncommon. Differentiation of CTS from other causes of nerve entrapment and neuropathy is summarized in Table 23.3.5.

Treatment

In the absence of gross weakness or atrophy, conservative management, including hand splints at night, is the first line of treatment.⁸³ Job task modification is often critical in this phase. Corticosteroid injection into the carpal tunnel may have some short-term value while carrying a small risk of nerve injury. The role of physical and occupational therapy is equivocal. However, many cases of carpal tunnel syndrome are accompanied by significant wrist and flexor inflammation with associated compression. These associated structural abnormalities may benefit from physical therapy, including iontophoresis. Persistent pain, progres-

Disorder	Similarities	Differences
Vibration neuropathy	Finger paresthesias	Exposure history; sensorineural distribution beyond median nerve
Radiculopathies	Reduced grip, Nerve conduction abnormalities	
C6	Paresthesias of digits I and II	Neck, shoulder, chest wall pain; Use pain, night improvement, normal nerve conduction at wrist, abnormal EMG
C7	Paresthesias, Pain on dorsum of hand	Decreased elbow extension and finger extension and flexion, abnormal EMG
Neurogenic TOS	Paresthesias relieved by position or shaking	Association with arm elevation
Reflex sympathetic dystrophy	Pain and paresthesias, sensation of edema, reduced flexion	Rubor, cyanosis, trophic finger changes
Diabetic mononeuritis	Pain and weakness	Asymmetry, diffuse reduction in nerve conduction

Table 23.3.5 Differential diagnostic considerations for carpal tunnel syndrome

sive symptoms, and EMG abnormalities are indications for surgery, which is usually successful in relieving nighttime and positional paresthesias. A common postsurgical complaint of diminished hand strength must be weighed in the management of manual workers. A minority of occupationally induced cases are initially surgical candidates, and in almost all cases, a return to the previous conditions of employment will prove painful, if not impossible, after surgery.⁸⁴ Therefore, hand rehabilitation and worksite assessment are key components of clinical management.

Anterior interosseous syndrome (Fig. 23.3.1)

The anterior interosseous nerve arises distal to the lateral epicondyle as the last major branch of the median nerve. It contains no superficial sensory fibers but innervates the long flexor of the thumb, the deep flexors to the second and third digits, and the pronator quadratus. The classic clinical findings are forearm pain and diminished pinch.⁸⁵ The EMG is the definitive diagnostic test, and the differential diagnosis includes tendon rupture and repetitive injury. Occupational etiologies are prominent, particularly in jobs requiring repetitive flexion and pronation of the elbow. Workers at risk include butchers, carpenters, and leather cutters; heavy lifting also has been implicated. Except in acute rupture, rest and immobilization rather than surgery is the primary intervention, with work reassignment frequently necessary. Recovery may be slow, and rehabilitation needs are extensive. These conditions are relatively rare compared with the more common entrapment neuropathies.

Cubital tunnel syndrome (Fig. 23.3.1)

Ulnar nerve compression at the elbow may be caused by acute or chronic trauma and the condition has been associated with chronic upper body weight bearing by the elbow, and has been frequently diagnosed in computer use. It is the second most common entrapment neuropathy. Diagnosis may be challenging, as paresthesias in an ulnar distribution and positive percussion signs (Tinel's at the triceps sulcus, medial epicondyle, and cubital tunnel) are rather common. Because of the extensive motor inner-

vation to the hand from the ulnar nerve, functional limitations may be very significant and may be manifested by diminished hand strength. The ulnar nerve supplies the adductor pollicis brevis, a portion of the flexor pollicis brevis, the digital flexors in the ulnar hand, and the first dorsal interosseous muscle. In classic ulnar nerve compression, the loss of pinch function may be almost complete; however, a more generalized weakness is the usual pattern. Digital coordination may be limited. Because of diminished innervation of the hypothenar muscle group, opposition function may be significantly reduced. Nerve conduction studies applied above and below the elbow can localize the lesion and differentiate ulnar nerve compression at the wrist, which may have a similar presentation. Because splinted immobilization may require many weeks of observation and because surgery often has little success, the clinician has limited courses for action.

The principal diagnostic challenge is that nerve conduction studies are normal as much as 50% of the time, even when symptoms are classic.⁸⁶ Occupational therapy is often highly effective, particularly when there are mechanical limitations in the pronator-flexor complex. In many cases, the exposed ulnar nerve is irritated by pressure at the elbow and the simple modification of posture or provision of protection is sufficient. When motor lesions are expected, however, it is important that an EMG is performed to identify affected motor groups. Because of a problematic surgical success rate, ulnar nerve compression at the elbow requires careful management.

Ulnar tunnel syndrome (Fig. 23.3.1)

Ulnar nerve compression at the wrist (Guyon's canal) is associated with repetitive blunt trauma to the hypothenar region, and it may occur in carpentry, auto repair, and polishing, as well as from handle pressure from hand tools. Many cases are attributable to the workplace. However, compared to carpal tunnel syndrome and cubital tunnel syndrome, it is rather uncommon. Accordingly, the tendency to simultaneously release the canal of Guyon during carpal tunnel syndrome should be discouraged.

Depending on the branches affected, loss may be motor, sensory, or combined. Nerve conduction studies are diagnostic and assist in the differentiation from ulnar nerve

entrapment at the elbow and from C8 to T1 radiculopathy. Pisiform fracture is one reason for surgical intervention, although the presenting complaint will be pain. However, in general, ulnar tunnel syndrome is relatively rare, and combined carpal tunnel and ulnar tunnel releases for hand paresthesias probably involve misdiagnosis of a more general peripheral neuritic pattern.

Radial tunnel syndrome

Posterior interosseous nerve motor branch compression in the radial forearm is a relatively uncommon condition. While pain below the radial head of the humerus may be present, the primary finding is incomplete paralysis of the wrist extensors. It is a surgical condition that is confirmed by electrodiagnostic studies. A more controversial and common disorder involving the sensory branch of the posterior interosseous nerve is so-called 'resistant tennis elbow'. The predominant symptom, pain distal to the lateral epicondyle, complicates differentiation from lateral epicondylitis. The syndrome is most common in manual workers performing repetitive tasks involving forceful twisting pronation, supination, elbow flexion and extension.

Pain in lateral epicondylitis is more often provoked by forceful grip and wrist extension, but differentiating nerve entrapment from tendinitis may prove difficult. There are significant implications for clinical management. Radial tunnel syndrome affecting the motor branch is often a surgical condition, whereas lateral epicondylitis is probably best treated with rest and physical therapy. While an anatomic band at the arcade of Frohse may affect the sensory branch and is a disorder subject to release, the more common presentation is a combination of pain distal to the lateral epicondyle accompanied by a positive provocative test (resisted middle finger extension and resisted supination). Radial sensory nerve conduction studies correlate poorly with symptoms. This presentation occurs commonly in the setting of apparent multiple entrapments and should be categorized as such when multiple compression signs are present.

Because of its superficial course through the wrist, the radial nerve is susceptible to entrapment and injury, causing dorsal and radial wrist pain. Although associated with iatrogenic interventions from tenosynovectomy and tight casting, Wartenburg's syndrome may evolve from wristbands and tight industrial gloves. The latter is an important consideration, given the recent introduction of splinted industrial gloves for carpal tunnel prevention support. Relief from external compression is generally curative.

Occupationally induced distal neuropathies

Toxic neuropathies are addressed in Chapter 28.2. The preeminence of hand symptoms in manual workers may make differentiation from entrapments difficult. The neuropathies caused by lead, arsenic, some organophosphorus pesticides, and n-hexane, although involving both upper and lower extremities, may be more obvious in the

upper extremity because of interference with fine coordinative tasks. There may be the additional problem of local trauma to an injured nerve.

Vasooclusive disorders and disorders of peripheral circulation

Arterial occlusive disease, expressed as either Raynaud's phenomenon or digital pain, has been described in a variety of hand-intensive tasks. Palmar and digital artery occlusion that is work induced is usually due to traumatic ulnar artery occlusion, the so-called *hypothener syndrome* or *ulnar hammer syndrome*.^{87,88} The general mechanism causing thrombotic emboli in the palm and fingers is blunt trauma, caused by using the hand as a percussive object or by aggressively twisting hard objects. The disorder has also been described, although uncommonly, with the use of hand-held pneumatic tools. The usual mechanism is ascribed to trauma and abrupt endothelial injury, with the ulnar artery being bludgeoned against the hook of the hamate. Contraction around the ulnar artery by an anatomic muscle sling or anomalous hypothener muscle have also been described. Physiologically the lesion is the consequence of thrombi or small clots that lodge in smaller or more peripheral vessels. This can occur because of pressure, the abruptness of blood flow, and stasis-related clot formation.

It is also hypothesized that shear forces injure the blood vessel lining or endothelium, with repair mechanisms within the vascular intima leading to clot formation. The use of large vibratory tools, such as jackhammers and posting drills, can produce a combined disorder of traumatically induced arterial vasospasm and occlusion. Diagnostic tests include clinical assessment of refill time, plethysmography, Doppler studies, MR(A) and arteriography. The acute presentation of Raynaud's, particularly in an ulnar distribution, is grounds for immediate intervention, with thrombolytic therapy.⁸⁹ Given the irreversibility of symptoms when clot is organized, even a moderate level of suspicion warrants immediate imaging.

ANATOMICALLY DEFINED AND SEMIQUANTIFIABLE DISORDERS BASED ON CLINICAL ASSESSMENT

Tendinitis of the hand and wrist (Fig. 23.3.2)

To assist in their gliding movement, tendons are surrounded by a layer of tenosynovium, which in the flexor and extensor hand compartments become synovial sheaths.⁹⁰ These sheaths are a frequent site of inflammation and tendinitis. Pathophysiologically, four main types of non-acute tendon disorders have been suggested.⁹ Paratenonitis (tenosynovitis) is the inflammation of the paratenon with symptoms including pain, swelling, warmth and tenderness. Tendinosis

Figure 23.3.2: Dorsal (a) and volar (b) locations of tendinitis in the upper extremity. (Adapted from Thorson EP, Szabo RM. Tendinitis of the wrist and elbow. *J Occup Med* 1989;4:419–31.)

involves intratendinous degeneration with fiber disorientation, scattered vascular ingrowth, occasional necrosis and calcification. Tendon nodularity may be noted, but swelling of the tendon sheath is absent. Paratenonitis may be observed with tendinosis and corresponding signs of inflammation and nodularity.

Tendinitis (tendon strain or tear) may range from inflammation with acute hemorrhage and tear to inflammation with chronic degeneration. While this classification is not universally accepted, the basic distinctions between inflammation, degeneration and nodularity have treatment consequences. Local tissue pressure and pain also may accompany inflamed synovium at the elbow, wrist, and finger joints. Two anatomically specific and discrete disorders are tenosynovitis – inflammation of synovial linings, confined to the wrist and hand, and peritendinitis crepitans – inflammation of musculotendinous junctions that may extend into the muscle bellies themselves. The cardinal tenet of diagnosis is anatomic localization, through stretching and isometric resistance of the tendon. Treatment includes rest and non-steroidal anti-inflammatory therapy.

Although poorly localized pain syndromes are sometimes labeled as tendinitis or tenosynovitis, this practice is inappropriate and leads to incorrect management and prevention. A history of previous injury should be pursued, and radiographic evaluation is sometimes merited, because even minor anatomic anomalies may become a focus for inflammation due to repetition. Particular problems have been associated with sharp handle edges and excessive deviations from a neutral axis in either a radial–ulnar or flexor–extensor plane.

Extensor and flexor tendinitis of the forearm

The most important extensor tendinitis involves the long abductor of the thumb and its short extensor.^{91–93} This inflammatory condition, called de Quervain's syndrome, is characterized by pain and swelling over the radial styloid process. The classic physical diagnostic maneuver, Finkelstein's test, involves elicitation of typical pain with the hand in ulnar deviation and the thumb adducted to the palm. A palpable nodule in the first dorsal compartment or early ganglion cyst formation may be diagnostic. Included in the differential diagnosis is arthritis of the first metacarpal phalangeal joint that may arise from repetitive tasks, such as are found in light assembly. Fractures, sprains, ligamentous tears, and avascular necrosis also may cause a similar pattern of pain over the dorsum of the hand. Immobilization, thumb splints, and NSAIDs may be curative in conjunction with job modification. Injection of the tendon sheath with steroids is effective and benign and an alternative first-line treatment in severe cases. Fibrosis may warrant surgery, but surgery should not be a first line of approach.

An intersection syndrome involving tendinitis of both the extensor carpi radialis longus and brevis may involve pain and crepitus over the distal extensor forearm.⁹⁴ This is a relatively common disorder, which has been associated with repetitive wrist movement, weight training, and rowing. This is a non-surgical condition, which responds to the familiar triad of rest, NSAIDs, and injection of corticosteroids, if necessary.

Tendinitis of the flexor carpi ulnaris is characterized by wrist pain with flexion and extension. It is associated with repetitive use and racquet sports. Pain and weakness should be reproduced by forced ulnar deviation. Conservative management usually is effective. A less common condition involves the flexor carpi radialis, which may impede wrist flexion, causing a trigger wrist. Tendinitis of the digital flexors may occur in the setting of CTS, with palmar pain exacerbated by digital flexion against resistance. Treatment is part of general carpal tunnel therapy discussed above. Wrist range of motion, defined by flexor and extensor tendons, is a good gauge of overall dynamic function.

A principle of hand therapy is that restoration of normal wrist dynamics is central to the treatment of nerve compression and soft tissue hand pain. Although 60 degrees of flexion and extension is often described as normal, a healthy wrist should be capable of 80 degrees of active motion. A subset of individuals will have wrist hyperlaxity with flexion well in excess of 90 degrees, MCP extension in excess of 45 degrees, and hyperextensibility of the IP of the thumb and DIPs of the four digits. 'Double jointedness' or hyperlaxity also poses risks of injury because of the tendency to eccentrically contract small muscle groups. Intrinsic muscle training with a hand therapist is critical, as conventional exercises that promote range of motion may exacerbate this problem.

Involvement of the musculotendinous junction of the extensor muscle mass in the forearm is common in workers performing intensive manual tasks. It is important that localization distinguishes pain in the muscle body from tendon pain and tendon insertion pain at the lateral epicondyle. Vague forearm functional pain can often be localized to these structures and may be accompanied by tendon tautness, provoked by direct palpation. These types of trigger points (tendon jump signs) may be mistaken for a multiple trigger point syndrome; but they respond well to manual therapy. Pain at the musculotendinous junction may mimic a nerve compression disorder (radial tunnel syndrome, ulnar nerve compression, pronator syndrome). Provocative testing of the muscle tendon groups against resistance is an important feature of diagnosis.

Experience indicates that tendinitis can resolve with surprising slowness. The reasons can be found in the pathophysiology of tendon repair. Exercise and movement are fundamental to the therapeutic process of an injured tendon; however, movement of a deformed, devascularized, or inflamed tendon will provoke further injury and breakdown. A knee injury may take up to 2 years to fully repair, and the same mechanisms prevail in the upper extremity.

Trigger digits

A snapping sound, usually of the first and third digit, is commonly related to nodular enlargement of the tendon or narrowing of the flexor tendon sheath.⁹⁵ Severe pain is uncommon, although clicking or snapping is often alarming. Because of the intrinsic strength in finger flexors, a locked flexed position may occur. Local steroid injection may abort an early presentation, but elimination usually

requires surgery, which is usually successful and minimally traumatic. There are several considerations for prevention when early nodularity occurs at a threshold where surgery is not yet required. Friction is generated at these locations as the tendon slides against adjacent surfaces, causing a shearing force. Higher levels of muscle tension are required to achieve a specific level of strength at the fingertip during non-neutral wrist postures, and tendons are subject to greater shear stress with non-neutral wrist postures. Similarly, compressive force in the A1 pulley has been demonstrated to dramatically rise from the neutral posture to full flexion. In short, although attention is usually paid to the digit itself, many of the same measures that may prevent carpal tunnel syndrome and flexor tendinitis are pertinent to the avoidance of trigger digits.

Lateral and medial epicondylitis

Lateral epicondylitis usually is attributed to tears and associated inflammation in the common extensors at elbow level. It is this anatomic location that is useful in the differentiation from radial tunnel syndrome, because pain is often reproducible with firm palpation over the lateral epicondyle and extensor muscle mass.⁹⁶ The condition has been associated with heavy lifting and occurs most frequently in the fourth and fifth decades of life. The characteristic symptoms are pain with lifting, gripping, and wrist extension. The popular epithet of tennis elbow notwithstanding, it is a common condition among industrial workers. In the case of epicondylitis, the insertional tears seen in young athletes playing racket sports have little in common with the non-inflammatory degeneration seen in older populations, whether or not work is implicated as a risk factor. Restrictions from lifting and gripping are common approaches to care, with immobilization and steroid injection being more aggressive, though frequently necessary treatments. Because the condition is usually non-inflammatory, NSAIDs are usually of limited value; however, limiting wrist flexion and stabilizing the forearm extensor insertion at the lateral elbow with a support strap may be helpful. Because grip and extension are so central to many jobs, lateral epicondylitis is a condition that can be irreconcilably chronic and produce major and undesirable changes in life and work.

Skilled occupational therapy has a distinctive place, particularly since limited mobility of forearm extensors is often a precipitating condition. Medial epicondylitis (golfer's elbow) is attributable to tears or chronic inflammation of the common flexors or pronator teres at the level of the elbow. The same considerations articulated for lateral epicondylitis apply to medial involvement of the elbow, except that extension limitations at the wrist may be more important. Medial epicondylitis is also important because of intermittent trapping or stretching of the ulnar nerve. This complex is particularly common in keyboard use, and its identification is important, since surgical release is almost never warranted. For both lateral and medial epicondylitis, equal attention should be paid to muscle and musculotendinous units as to elbow inser-

tions. For this reason elbow injection accompanied by muscle stretching and strengthening is often an effective therapeutic strategy.

ENTRAPMENT SYNDROMES WHICH SUGGEST MULTILEVEL DISEASE AND SYMPTOMS WITHOUT ANATOMIC LOCALIZATION

Multiple site or multineve compression syndromes

At times, workers may experience anatomic and tissue changes with multiple sites of nerve compression, that cause greater symptoms than would be experienced with a single site of compression. Many patients with diffuse upper extremity symptoms may also experience problems with nerve compression that appear to arise at multiple levels. The best-known manifestation is the so-called 'double crush' syndrome, which can be a consequence of degenerative cervical spine disease or acquired postural torsion at the brachial plexus.^{97,98} In the classic 'double crush' syndrome, there is compression at the carpal tunnel as well. Other potential scenarios could include ulnar nerve entrapment at the brachial plexus and cubital tunnel, or at the cubital tunnel and Guyon's canal. The delineation of multiple compression abnormalities most often arises in the distribution of the ulnar nerve. Since Tinel's sign at the elbow is easily elicited, and ulnar nerve compression at the elbow often eludes electrodiagnostic verification, the presence of a multiple site disorder is easily missed.

Nerve compression at the neck, and especially postural nerve compression at the brachial plexus, may lead to peripheral nerve impairment distally, expressed as symptoms or through provocative palpation or extended movement, as with Adson's test. These observations can be significant in situations where work postures place muscles in shortened positions. For example, workers who perform tasks requiring prolonged or resisted pronation may develop pronator muscle shortening that compresses the median nerve in the forearm when the forearm is placed in supination. Alternatively, prolonged and static work postures that result in pectoralis minor or scalene muscle tightness can compress the brachial plexus. Alterations in axoplasmic flow and transport of nutrient substances has been proposed as the mechanism of this injury.^{8,99} Metabolic abnormalities (e.g., diabetes, alcoholic neuropathy, collagen vascular disease) can contribute to nerve dysfunction and make it more susceptible to injury. Recognition is important, because even provocatively derived symptoms that appear anatomically specific are unlikely to be alleviated by surgery when there are signs of multiple compression. Postural therapy, particularly oriented to the cervical spine, scapula, and brachial plexus, is usually the first treatment option.

Neurogenic thoracic outlet syndrome

Thoracic outlet syndrome (TOS), presumed compression of the brachial plexus, subclavian artery, or both at the level of the shoulder, is often suspected and diagnosed. It is a diagnosis with a history of broad application to a wide variety of upper extremity symptoms and signs, and it is discussed in detail in Chapter 23.2. True vascular TOS that compresses the subclavian artery is rather rare,^{100,101} and even the apparent loss of pulse with shoulder abduction may not be clinically significant. On the other hand there is a distinctive postural pattern of shoulder protraction, neck immobility with head forward projection, shortening and pain in the pectoralis minor muscles, and trigger points in the scalene muscles that has been associated with positional paresthesias.¹⁰² This has been called *neurogenic thoracic outlet syndrome* and it is relatively common in industrial workers performing extended overhead work and in computer workers with weakened proximal musculature.^{103,104}

The pattern of cold clammy hands, and dermal mottling in the hands, is an accompanying observation of TOS. The latter has been attributed to sympathetic ectopic activity rather than to true vascular compression. These presentations usually respond to stretching and upper back strengthening. It is important to recognize that the controversies over thoracic outlet syndrome are decidedly semantic and the distinction is between a rare and fixed neurovascular compression and a much more common acquired postural syndrome.¹⁰⁵ Some proponents argue that congenital and acquired fibrous bands or anomalous muscle slings, discovered at surgery, are fairly common and form a predisposition to symptom presentation.¹⁰⁶ In any event, postural issues are frequently important, and even in classic presentations, physical therapy is the first line of treatment.

Diffuse myalgias

Diffuse myalgias in general, and fibromyalgia in particular, remain controversial. What is less controversial is the patient presenting with multiple areas of soft tissue pain, that are aggravated by use, and lack localizing signs. This minority of patients that present with multiple signs represents a therapeutic dilemma. In some settings, the localization in muscle bellies associated with measurable levels of activity suggests an inflammatory state.

Increasing attention has been paid to metabolic and neuroregulatory factors to better understand the relationship between acute muscle fatigue and the development of chronic muscle disorders, as well as to characterize the pattern of pain symptoms that affect the neck, shoulders, forearms, wrists, and fingers in manually intensive tasks that occur well below the muscles' maximum voluntary contraction (MVC). Neurohumoral substances are chemicals that affect cell membranes and function, and excite afferent nerves. Muscle pain, inflammation, and ischemia, or sustained static contraction, lead to release of potassium chloride, lactate, arachidonic acid, bradykinins, serotonin, and histamine. In addition to producing pain, these agents can excite chemosensitive afferents – gamma

muscle spindles – that respond to stretch. It is hypothesized that increased spindle excitation can cause the stiffness and pain of ‘myalgia’.

Reduced blood flow that is characteristic of static contraction and increased transmural pressure is reversible, but there is additional evidence that the pattern of reduced flow, injury and diminished repair, and chronic fiber damage all contribute to muscle pain. Higher subjective levels of fatigue, as well as electrophysiologic evidence of fatigue, are more common in large muscle groups, such as the neck and shoulder muscles, when activities are static and repetitive rather than dynamic. While the links between physiology and clinical diagnosis are sometimes obscure, a therapeutic program which emphasizes pharmacologic control of nerve pain with increasing exercise tolerance offers a basis for improvement. It is also important to recognize that in a dynamic view of nerve and muscle dysfunction, the generation of pain from multiple symptoms is not surprising and necessitates a dynamic therapy.

Regional complex pain and vascular pain

Pain syndromes are beyond the scope of this chapter, but there are several relevant observations that pertain to the management of upper extremity disorders. Patients meeting clinical criteria for complex regional pain syndrome (CRPS) present rather uncommonly, representing less than 1% of all patients with upper extremity disorders. Conversely, the presentation of cool mottled hands may occur in as many as 20% of patients, and symptoms of neurogenic thoracic outlet syndrome signs may be present in more than half of patients. The critical distinction is between mild and relatively easily reversed proximal compressive disorders and major regional and vascular pain syndromes. Intransigent pain, the presence of edema, and severe mottling aggravated by exertion suggest a shift in the axis from mild autonomic dysfunction to vascular pain.¹⁰⁷ Recognition and early treatment, including physical therapy and ganglion blockade in more severe cases are important, because of the evidence that significant sympathetic dysfunction is a precursor of full-blown CRPS.

CUMULATIVE TRAUMA DISORDERS REPRESENTING PARTICULAR CLINICAL CHALLENGES

Cumulative trauma disorders in the office environment

A virtual epidemic reporting of computer-related upper extremity injuries in public sector workers in New South Wales and Victoria gave birth to the term RSI in the early 1980s.¹⁰⁸⁻¹¹¹ Subsequently the electronic office has been associated with frequent upper extremity syndromes but limited lost work time. There are compelling arguments that biomechanical factors lie at the root of these computer-

related syndromes.^{77,112-114} Physical risk factors include entry speed and duration, insufficient rest cycles, and non-neutral joint postures; intrinsic risk factors include anthropometry, age and gender; and work organizational factors have also been ascribed (see Chapter 15).

Etiology

Common triggering factors in office work usually include static loading of the neck, shoulder, and proximal upper extremity, coupled with dynamic, repetitive loading of the wrist and hand. Neck and shoulder complaints have been particularly common among video display terminal (VDT) operators, and have been attributed to prolonged isometric muscle contraction.¹¹⁵⁻¹¹⁸ There is more ambiguity in identifying the pathologic mechanism associated with repetitive wrist and finger movement, pinching and grasping, wrist extension and flexion, and ulnar deviation because of the intrinsic complexity of hand movements, particularly in office work, and because of the difficulty in quantifying variables of exposure in hand pain syndromes. Stereotypy appears to be an important factor in wrist complaints, reflected in symptom prevalence among mail sorters and supermarket checkout workers,⁷⁶ although evidence for more anatomically defined disorders exists in these settings. The high proportion of proximal disorders, such as neurogenic TOS, in office workers, and relatively high level of ulnar nerve compression syndromes are somewhat surprising given the hand intensity of work. However, the relationship between individual posture and anthropometry and the work surface and seating suggest an etiology that requires a multilevel approach.

Investigations of the relationship between duration of employment and symptoms are contradictory and complicated.^{119,120} Because arm and hand pain problems tend to emerge early in employment, programs emphasizing job training and adaptation are justified. Work organization has been interpreted as a source of psychosocially driven symptoms. There is a companion viewpoint that automation of the office, carried out rapidly and driven by technology and organizational needs, rather than the experience of the semiskilled workforce, is a contributory social factor.

Treatment

Although there are few treatment recommendations unique to office work, job uniformity in the office often obviates the types of transfer or reassignment that are practical in other work settings.⁸³ For VDT operators, the balance lies between individual job modification and the kind of generic adaptations that have occurred in Australia. These include providing comfortable workstation design, limiting the keystroke rate and duration, and providing regular, frequent rest breaks. There are some excellent materials available through the internet and OSHA for optimizing the office set-up. Moreover, because the physical inputs are limited – chairs, keyboards, monitors, trays, pads, headsets, and their placement – the electronic office may be an ideal environment for retraining and reacclimatizing individuals with upper extremity disorders, even when derived from the office. That is,

while job content may be difficult to modify, there are many opportunities for manipulating hardware in the office.

Cumulative trauma disorder in the heavy industrial environment

Hand and wrist problems, loosely diagnosed as CTS, have been observed among garment workers and meatpackers, and in a variety of manufacturing settings. More than is the case with white collar work, industrial CTDs have a substantial overlap with some of the anatomically specific disorders, especially CTS. In general, work involving dynamic loading, force, and stereotypy is somewhat easier to detail in manufacturing, although with changes in work organization, the distinctions elude a simple exposure classification. A challenging set of findings, enhanced by aging of the workforce, involves industrial workers who present with combined disorders affecting muscle, nerve, tendon and joint.

Epidemiology

When jobs have been compared cross-sectionally, symptoms are more common among the most physically demanding job categories. When white and blue collar incidence rates have been compared within the same facility, there is a clear gradient indicating a greater incidence of symptoms among manual workers. However, associations between specific causative factors and symptoms have been difficult to substantiate in many analyses. Similarly, force and repetition, two putatively strong causal factors, have been implicated with variable weight (see Chapter 32). There is, however, considerably greater prevalence in largely female occupations, such as textiles manufacture, in which symptoms have been widely reported.

Etiology

Very different symptom rates within the same plant and reduction by ergonomic intervention support a causative role for specific processes. Stereotypy, coupled with forceful exertions and postures requiring static loading, has been identified as a prominent risk factor. The association between symptoms and a specific job has focused on biomechanics (centered on the worker) and ergonomics (centered on the task). Forceful exertion, repetition rate, and awkward postures, such as hyperflexion or ulnar deviation, are frequent biomechanical factors.

Ergonomic considerations have included workstation design, tool construction, and physical factors, such as temperature, lighting, and humidity. Particularly troublesome are hand tools that extend physical strength by requiring resistance against the base of the palm. Thus, screwdrivers, scrapers, buffers, and polishing tools have been implicated. In physically demanding and stereotyped jobs, such as in the meat processing industry, a particularly high incidence of symptoms is common early in employment, implicating overexertion, if not overuse, and the importance of training and experience. In many metal trades prolonged work at shoulder height is common.

Treatment and ergonomics

The approach to individual therapy is complicated by social considerations, usually the need for continued employment, limited modified duty, and insufficient impairment to merit sufficient income replacement.¹²¹⁻¹²⁴ Aggressive physical therapy is helpful, although with involvement of multiple anatomic sites, the prospects for full alleviation may be limited. Job analysis can range from simple time and motion and postural checklists, to more sophisticated slow motion videotape studies and translation of specific tasks into quantitative components. EMGs may be recorded for specific work processes. Because of the complexity and academic nature of these investigations, they generally have limited practical application, and the absence of a reference standard places great weight on the experience of the clinician. Nevertheless, some job modification may be useful, including the following.

1. Identification and attenuation or elimination of offending tasks or equipment.
2. Reduction of work rate, overtime hours, and pain-inducing activities.
3. Job rotation or reassignment, at least until symptoms abate.
4. Investigation of job retraining, while function is maintained.

In general, ergonomic assessment has a clearer focus in industrial or other physical work than in office work, particularly when symptoms occur primarily in specific departments or processes.

23.4 Back and Lower Extremity Disorders

Bradley A Evanoff

Low back pain is among the most common health complaints among working-aged populations around the globe, ranking second only to respiratory illnesses as a symptom-related reason for visits to a physician.¹ In the United States 70–80% of adults will experience a significant episode of low back pain at least once in their lives;² similar levels of lifetime prevalence are reported from other industrialized countries.³ Data from the National Health Interview Survey (NHIS) indicate that there are over 22 million cases of back pain annually in the US that last 1 week or more, resulting in almost 150 million lost workdays.⁴

Although common, low back pain is usually a benign condition. Only a small fraction of back pain episodes involve nerve root impingement and even for those cases, the natural history favors recovery.⁵ Only rarely does back pain herald a significant infection, malignancy, or systemic rheumatologic disorder.⁶

Nonetheless, low back pain is a major cause of disability, limitation of activity, and economic loss in western, industrialized countries. Disability due to low back pain is a complicated phenomenon influenced not only by the physical condition of an individual person, but by other personal factors and by societal factors including medical care, the work environment, and the workers' compensation system. Rapid rises in reported disability due to low back pain in the 1970s and 1980s led some authors to describe an 'epidemic' of low back pain. More recent data have shown a 34% decrease in the number of low back pain claims and an even sharper decline in compensation payments for low back pain in the US between 1987 and 1995.⁷ Data from the Bureau of Labor Statistics (<http://bls.gov.oshhome.htm>) have shown a decline over the past decade in the number of reported cases of back or spinal injury associated with lost work days.

Despite apparent improvements over the past decade, low back pain accounts for a substantial burden of cost and disability. It has been estimated that approximately 1% of the US working-aged population is permanently disabled due to back pain, while at any given time up to 1% of workers are temporarily disabled due to back pain.⁸ Back impairments remain the most common chronic conditions causing activity limitation in persons under age 45 in the United States. Back pain is the most common reason for filing a workers' compensation claim,⁹ reportedly accounting for 16–25% of all workers' compensation claims and 23–33% of all workers' compensation claim costs.^{4,7,9,10} Annual costs of low back pain in terms of workers' compensation claims have been estimated at over \$9–11 billion, while the total economic impact of low back pain in the US, including lost earnings and other uncompensated losses, has been estimated at \$75–100 billion.^{2,11}

While there is widespread agreement about the severity and widespread nature of low back pain, there is much less agreement concerning the etiology, or even the definition, of low back pain. One of the difficulties in interpreting the literature on low back pain is the plethora of clinical defi-

nitions and the different ways in which patients can be identified, e.g., by symptoms, by medical treatment, or by disability. Most people with symptoms of low back pain do not come to medical attention; most episodes of low back pain which come to medical attention result in no change in work status; most alterations of work status due to low back pain do not lead to long-term disability. Very different pictures of low back pain may thus emerge from differing case definitions. Interpretation of the literature is further complicated given the multifactorial origin of low back pain. In a given patient, the onset, severity, reporting, and prognosis of low back pain may be influenced by a variety of work and non-work factors. The presence of personal risk factors in a patient does not rule out work-relatedness, just as work may not be the sole cause of an individual patient's symptoms.

Studies of the epidemiology of back pain have linked the frequency and severity of low back pain with a variety of personal, lifestyle, and occupational factors. A number of non-work factors have been associated with low back pain. These include age, gender, overall level of physical fitness, lumbar mobility, lumbar strength, tobacco use, non-work physical activities, past history of low back disorders, and congenital structural abnormalities such as spondylolisthesis.^{3,6,12}

Recent comprehensive reviews of the scientific literature on work-relatedness of low back pain have been conducted by NIOSH and by the National Academy of Sciences.^{3,13,14} These reviews have concluded that there is strong evidence that low back pain disorders are associated with work-related lifting and forceful movements, and with whole-body vibration. There is also evidence that work in awkward postures (bending and twisting) and heavy physical work are associated with increased risk for low back pain disorders. These reviews have also noted that psychosocial factors such as job satisfaction, personality traits, perception of intensified workload, and job control are associated with low back pain.

Identified workplace factors include frequent bending and twisting, heavy physical labor, and prolonged sedentary work. Jobs requiring frequent lifting of objects weighing 25 pounds or more seem to be associated with an increase in risk, as are sudden, unexpected maximal lifting efforts. The effect of lifting may be modified by individual fitness and strength capability, and by the rate, position, distance, and height of the lifting task. The exposure to vibration that accompanies motor vehicle operation (4–6 Hz) also has been shown to be a risk factor for low back pain. Truck drivers, manual material handlers, and nursing personnel are among the occupations with the highest rates of compensable back pain episodes.

CLINICAL EVALUATION

Low back pain may arise from any of a host of structures comprising the lumbosacral spine and its associated soft

tissues or from abdominal, retroperitoneal, or pelvic structures. It may be the result of local or systemic processes. With current clinical tests and imaging procedures, however, the cause of most episodes of low back pain remains unclear, and perhaps 85% of patients cannot be given a precise pathoanatomic diagnosis.¹⁵ Pain in these cases is typically assumed to be related to soft tissue injury or to degenerative changes, and non-specific terms such as sprain or strain are commonly used to describe the etiology of low back pain.

Given the idiopathic nature of most episodes of low back pain, the primary goals of the evaluation are to identify: (1) any systemic or visceral cause of pain, (2) any neurologic compromise requiring urgent surgery, (3) any other findings that influence the choice of therapy or prognosis, including workplace exposures which may incite or exacerbate symptoms. A limited diagnostic evaluation, combined with strong reassurance regarding prognosis and careful attention to the patient's concerns, best serves the needs of most patients. In cases of back pain which are work related, it is also important to define work exposures which may need modification in order to improve functional recovery or prevent recurrence.

HISTORY

Current consensus guidelines and expert opinion on the appropriate diagnostic evaluations of low back pain (LBP) recommend that the evaluation focus on three questions: (1) Is the pain caused by a systemic disease? (2) Is there neurologic compromise that may require surgical evaluation? (3) Is there social or psychological distress that may amplify or prolong the pain?¹⁵ These guidelines, intended for general medical practice, give scant attention to issues of work-relatedness or fitness for work. Thus, like Ramazzini, the physician treating a patient with low back pain should 'venture to add one more question: What occupation does he follow? Though this question may be concerned with the exciting causes, yet I regard it as well timed or rather indispensable, and it should be particularly kept in mind when the patient to be treated belongs to the common people.'¹⁶

The most important immediate goal of the history is to determine if a patient has pain related to a serious local condition such as a fracture, a systemic disorder such as malignancy or infection, or a neurologic disorder requiring surgical evaluation, such as cauda equina syndrome. The history should focus on 'red flags' which indicate the possible presence of a disorder more serious than non-specific LBP. These red flags include a history of trauma, age >50 or <20, history of malignancy or immune compromise, pain which worsens when supine, recent onset bowel or bladder dysfunction, saddle anesthesia, and severe or progressive neurologic deficit of the lower extremities.^{6,17,18}

Other history which may suggest a medically serious cause of low back pain includes age over 70 or a history of corticosteroid use (suggesting compression fracture), unexplained weight loss (suggestive of malignancy), IV drug use or recent urinary tract infection (which raise suspicion for

spinal infection), pain of over 1 month duration, or failure to improve with conservative therapy. A history of prolonged early morning back pain and stiffness, especially in persons under age 40, may be a clue to inflammatory spinal arthritis. These conditions, exemplified by ankylosing spondylitis (AS), are often associated with insidious onset and symptomatic improvement with exercise.

The vast majority of cases seen in a primary care setting or in an occupational medicine clinic will present with non-specific low back pain or with symptoms of sciatica. Past history of low back disorders should be sought, as should information on the onset and time course of symptoms, and any functional limitations due to symptoms. Location of symptoms should be determined, specifically radiation of pain or paresthesias to the distal lower extremity. Other important historical points include the temporal pattern, relation to work or other daily activities, other precipitating factors, and evidence of functional disability related to the syndrome. These factors are particularly important in planning the individual's return to work. Inquiry about alcohol or drug abuse and depressive symptoms may identify factors that amplify or prolong pain and are amenable to specific intervention.

Often neglected in the history is a description of the patient's work activities, including descriptions of awkward working postures, lifting requirements, other forceful movements, whole body vibration, and need for bending and twisting of the back. Information on monotonous work, job control, and job satisfaction should also be sought. This information is essential for making determinations about work-relatedness, as well as for planning work restrictions and return to full work.

PHYSICAL EXAMINATION

As with the history, the most important immediate goal of the physical examination is to seek physical signs which may indicate a serious medical condition. Severe localized tenderness or percussion tenderness may indicate fracture, infection, or a tumor. Fever or tachycardia may indicate a systemic or local infection. Cauda equina syndrome is indicated by laxity of the anal sphincter, perineal or perianal sensory loss, major motor weakness or paraparesis, and hyperactive or hypoactive reflexes. Progressive neurologic deficit is indicated by new or progressive motor weakness, and increased sensory loss. Tenderness at the costovertebral angle may suggest renal colic or pyelonephritis, while a pulsatile abdominal mass indicates an abdominal aortic aneurysm. In older patients with a suggestive history, breast or prostate examination may be appropriate to look for evidence of malignancy.

Examination of the lumbosacral spine includes musculoskeletal and neurologic components, and should proceed according to an organized routine. Unfortunately, most of the items commonly assessed on physical examination have limited reproducibility between different examiners, as well as having limited prognostic significance.¹⁹ However, in addition to excluding the serious disorders listed above, a careful baseline physical examination is

necessary to allow clinical progression to be assessed. Beginning with the patient disrobed and standing, the alignment, curvature, and symmetry of the spine, pelvis, and lower extremities are evaluated. The range of motion of the lumbosacral spine is assessed in flexion and extension. Visual estimation of range of motion is adequate for general clinical purposes, though goniometers can also be used for more precise measurement. Measurement of minimum distance from fingertips to floor is useful to assess the effect of treatment on combined lumbar and hip mobility. A lateral bending maneuver is performed to each side to assess symmetry and any resultant effect on symptoms. Toe raises, heel walking, and standing on one leg (Trendelenburg's test) assist the evaluation of lower extremity muscle weakness.

A thorough neurologic examination is essential in patients with sciatica or lower extremity neurologic complaints. With the patient sitting, patellar and Achilles reflexes are tested. Strength of the quadriceps and psoas muscles is assessed. With the patient supine, the straight leg raising maneuver is performed. Radicular symptoms extending into the lower leg and foot, as opposed to increased back or thigh pain, suggest compression and inflammation of the L4, L5, or S1 spinal nerve root (sciatic nerve). Radicular symptoms should not be produced until the leg is raised to 30 or 35 degrees, at which point dural movement begins. No further tension is applied beyond 60 to 70 degrees. Confirmation of a positive finding is elicited if the leg is lowered to an asymptomatic angle and radicular symptoms are reproduced by passive dorsiflexion of the foot. Pain in the contralateral leg on straight leg raising (crossed straight leg raising sign) is highly specific for nerve root impingement.

Another widely used root tension sign consists of flexing the hip to 90 degrees, then slowly extending the knee until sciatic pain is elicited. Hip joint range of motion should be assessed. Circumferential measurements of the thigh and calf aid in the detection of muscle atrophy. A dermatomal sensory and motor examination of the lower extremities also is performed. Painful areas in the lower extremities are palpated to identify any locally inflamed structures requiring specific treatment.

Palpation is continued in the prone position and includes the spine, paravertebral musculature, and sciatic notches. Localized tenderness or reproduction of referred symptoms typically is noted. These findings help confirm the mechanical nature of the symptoms.

A number of other examination techniques for spinal motion, muscle spasm, sacroiliac joint function, and facet joint disease are recommended by various experts but are not in wide clinical use, and have limited documentation of their diagnostic utility. Non-organic physical signs, including observed pain behavior and a non-anatomic distribution of tenderness and neurologic findings, are widely used to identify magnified illness behavior. Although clinically useful in individual patients, these signs should not be taken to establish an artificial distinction between organic and psychogenic contributions to pain, because the two almost always coexist.

LABORATORY EVALUATION AND DIAGNOSTIC IMAGING

Diagnostic tests play a very limited role in the initial management of acute low back pain. In the absence of 'red flags' on history as discussed above, plain radiographs of the lumbosacral spine are unlikely to change diagnosis or therapy, and are widely overused. Radiographs are appropriate in cases of chronic or recurrent low back pain, but should be ordered acutely to rule out fracture or systemic disorder only if suggested by the history. For patients aged 20 to 50 with non-radicular back pain and no suggestive history of potentially serious underlying condition, it is most appropriate to wait 4 weeks before obtaining AP radiographs. If symptoms have not improved in 4 weeks, plain radiographs of the lumbar spine should be obtained, along with a complete blood count and erythrocyte sedimentation rate in order to help rule out occult neoplasm or osteomyelitis.^{6,20,21} If osteomyelitis or neoplasm is suspected but not detected on the plain radiographs, these tests should be followed by a bone scan or by MRI of the spine.

Patients with radicular back pain may also derive little benefit from early diagnostic imaging, since many of these patients will have spontaneous resolution of their symptoms, and early surgical management is indicated only in cases of severe or progressive neurological deficits. Patients with persistent or progressive neurological deficits and an exam consistent with a nerve root impingement should be referred for MRI to evaluate the anatomic basis of the nerve root symptoms. Patients with more ambiguous nerve root involvement may benefit from electromyography in order to determine if nerve root impingement is present. Counseling and education of patients are important, as patients may request imaging which is inappropriate. The use of MRI is especially problematic because a substantial proportion of persons without back pain have disk abnormalities revealed by MRI. Among asymptomatic adults, studies have shown a prevalence of disk herniation of 22–40%, and a prevalence of bulging disk of 24–79%.^{22–24} Anatomic abnormalities seen on MRI must be evaluated critically for their clinical importance in each patient.

Older adults with symptoms suggestive of spinal stenosis (pain or paresthesias in the legs relieved by spinal flexion, pseudoclaudication) should be evaluated for the presence of this disorder. The diagnosis can usually be made on the basis of CT or MRI; electromyography may be useful to determine the extent of neurologic impairment.²⁵

THERAPY

Non-specific low back pain

Management

Evidence-based guidelines for the treatment of low back pain have been provided by several expert panels and should be referred to for the management of most cases.^{6,21,26} For acute cases, the provider should offer a confident and positive approach, which is justified by the

generally good prognosis of acute low back pain. Reassurance regarding prognosis should be provided, as many workers with low back pain are apprehensive about the potentially disabling nature of their injury. Early return-to-work activities, with work modifications as necessary, and re-establishment of normal or near-normal activities of daily living are important aspects of care. Efforts to alter lifestyle factors associated with low back pain (smoking, sedentary lifestyle, obesity) should be made, although these efforts are unlikely to be of short-term benefit.

Non-steroidal anti-inflammatory drugs (NSAIDs) are effective for relief of symptoms and provide adequate relief in most patients. Opioid analgesics may be considered in the small minority of patients who do not attain adequate symptom relief from NSAIDs; opioid drugs should be used with caution and for a clearly limited time. Muscle relaxants may also be of use in relief of symptoms, though clinical studies do not clearly identify which patients will benefit from these drugs. Sedation is a common side effect, though in patients who are having trouble sleeping due to back pain this can be used to therapeutic advantage through evening dosing. Physical therapy and spinal manipulation are also effective in providing temporary symptom relief in patients with acute or subacute low back pain.²⁷

Many experts believe that use of manipulation or physical therapy should be delayed until 2–3 weeks following the onset of symptoms, because a substantial fraction of patients will improve spontaneously within this time. Back exercises do not seem to be useful in the acute phase, though there is evidence that exercise is helpful in chronic back pain and in the prevention of recurrence. Massage therapy has not received extensive study but shows promise in clinical trials.²⁸ A wide array of alternative therapies are advocated by practitioners but lack consistent evidence of effectiveness in clinical trials. These treatments include laser stimulation of trigger points, various injection therapies, acupuncture, reflexology, traction, and corsets.

In cases of chronic low back pain, current clinical judgment favors use of an active exercise program. Treatment of chronic cases emphasizes strengthening and range-of-motion exercises and aerobic conditioning in the context of formal assessment of baseline and progressive function (physical capacities evaluation). Maintaining patient adherence to an intensive exercise regimen may be difficult. Referral to a multidisciplinary pain center may be beneficial to some patients with low back pain. Such centers usually employ multiple, simultaneous treatments including supervised, graded exercise, cognitive or behavioral therapy, and patient education in concert with medical therapies. Antidepressants are useful in patients with depression (one-third of patients with chronic low back pain), though there is conflicting evidence about their use in patients without clinical depression.¹⁵ Tricyclic antidepressants may be more effective than serotonin reuptake inhibitors in the treatment of chronic pain patients.

In workers who have been temporarily disabled from work due to low back pain, decisions about return to work

cannot be made in isolation from knowledge about their work and their workplace. The modification of physical job demands to facilitate early return to work is felt by many experienced clinicians to be a critical element in the prevention of longer-term disability. Such a view is supported by a study of work-related back pain among workers from a variety of industries who had been away from work for more than 4 weeks due to their back injuries.²⁹ Workers were randomly assigned to receive an ergonomics intervention, an intensive clinical and rehabilitation intervention, neither, or both (see study description in Chapter 23.1). The ergonomics intervention was the most successful element of this program, resulting in more than a two-fold increase in the rate of return to usual work. By facilitating return to usual work, the ergonomics intervention appeared to reduce progression to long-term disability. In this study, the intensive clinical and rehabilitation intervention did not significantly reduce the time of absence from regular work when applied separately from the ergonomics intervention.

Herniated intervertebral disk

Management

In the absence of cauda equina syndrome or progressive neurologic deficit, conservative (non-surgical) management should be pursued for at least a month in the majority of cases. After 6 weeks of treatment, only about 10% of patients still have sufficient symptoms that surgical management is considered. Early treatment parallels the treatment of non-specific low back pain, with the caveat that the safety and effectiveness of spinal manipulation are not clear. Epidural corticosteroid injections offer temporary symptomatic relief in some patients, and their use may reduce rates of surgery in patients who otherwise would be candidates for surgical decompression.³⁰

In patients who still have significant pain or neurologic deficits after 4 weeks, discectomy should be considered in order to provide quicker symptom relief and return to function. Patients with herniated disks who undergo surgery do not return to work more quickly than those treated with non-surgical therapy, though surgery appears to lead to improved functional and symptomatic outcomes at 1 year.^{31,32} Long-term outcomes are similar among patients treated surgically and non-surgically.^{33,34} The result of surgical treatment of these patients is strongly related to the findings at surgery. The better defined the clinical syndrome is, the better the surgical outcome will be, with at least partial relief of sciatica in up to 90% of carefully selected patients. Approximately 70% of patients experience relief of back pain. Surgical outcomes also can be adversely affected by unrealistic patient expectations, depression, and substance abuse.

Determination of work-relatedness

The determination of work-relatedness of this common condition often is a substantially more complex matter. The onset of symptoms after an obvious physical stress or

impact, such as a fall, blunt trauma, or sudden, unaccustomed lifting, is usually accepted as *prima facie* evidence of work-relatedness. This is probably appropriate in most cases. However, the unfounded assumptions that back pain must result from an injury and that work-related back pain implies an injury in the workplace underlie these determinations in many jurisdictions. As a result of this misconception, onset of back symptoms in association with an obvious physical insult in the workplace often is considered a necessary condition for acceptance of work-relatedness.

This approach misses an important distinction between the back injury with immediate onset of symptoms following (and presumably due to) a physical insult and the painful condition of the low back that may result from repetitive exposure to physical or other stressors in the workplace. Either scenario is consistent with a work-related back condition, and the circumstances surrounding the onset of back symptoms have relatively little to contribute to etiologic attribution in the latter case.

That said, the scientific basis for work attribution is limited due to the absence of useful means to measure in the workplace the actual load on the lumbar spine and to correlate measured load with risk of back pain in a given case. Careful assessment of job activities interpreted in light of available epidemiologic and biomechanical evidence can be used to arrive at the best estimate of the associated risk of back pain.

The job activities assessment should, to the greatest extent possible, quantify the worker's exposure to the variety of factors found to be associated with an increased risk of back pain. Quantitative assessment of these risk factors in the workplace remains difficult, and definitions of what constitutes high versus low risk on these parameters have yet to be clarified. The National Institute for Occupational Safety and Health has published guidelines for manual lifting in industry.^{35,36} These guidelines are based on relative risk estimates derived from detailed biomechanical analyses of simplified lifting models. Further work is needed to make this approach more clinically applicable.

Potential interactions among these risk factors and possible effects of longstanding exposure to one or more of them also require further research. In addition to these physical factors, some studies of the psychosocial environment in the workplace have found markedly increased relative risks for back-related disability claims associated with such factors as job monotony and poor work satisfaction. Few studies have adequately measured both physical and psychosocial risk factors for low back pain. One such study in transport workers found that physical workloads and psychosocial factors were independent risk factors for the development of back pain.³⁷

In sum, difficulties with exposure assessment and exposure-response estimation substantially complicate the determination of work-relatedness for low back pain. In the absence of an acute physical insult, the challenge to the clinician is to: (1) ascertain the frequency and intensity of exposure to one or more identified risk factors, (2) interpret the exposure in light of available biomechanical and epidemiologic evidence, and (3) estimate the likely

effect of that exposure relative to the legal standard for occupational causation operative in a given jurisdiction.

Prevention of low back pain

The use of preplacement screening with low back radiographs should not be employed, as plain radiographs are not a useful predictor of future low back disorders.³⁸ There is some evidence that exercise programs which combine aerobic conditioning with specific strengthening of the back and legs can reduce the frequency of recurrence of low back pain.^{39,40}

Lifting education programs have generally been ineffective at reducing the frequency of occurrence of low back pain.^{39,41,42} Lumbar corsets or back belts do not seem to be effective in reducing the occurrence of low back pain.⁴²⁻⁴⁴

A growing body of evidence suggests that ergonomic interventions that reduce physical exposures can lead to reduced frequency or severity of low back pain disorders in high-risk jobs. Although few high-quality studies currently exist to assess the effectiveness of such interventions, a number of retrospective analyses and case studies have shown that engineering changes that alter the physical aspects of work can reduce the frequency of low back disorders.¹⁴ Appropriate interventions must be specific to the biomechanical risk factors encountered in a particular work-place. In addition to engineering controls (incorporating ergonomic design), there is evidence to support the effectiveness of administrative controls (changing workplace culture), modification of individual risk factors (through exercise programs), and the use of programs utilizing a combined approach. Multidisciplinary, participatory approaches which involve employers and employees appear to be successful at reducing back pain and disability, and foster compliance and acceptance of changes.⁴⁵⁻⁴⁷

Guidance on the design of safer lifting jobs is provided by NIOSH (www.cdc.gov/niosh/lifitng1.html) and by other organizations.

23.5 Systemic Rheumatologic Disorders

Paul S Darby, Carl A Brodtkin

Work-related musculoskeletal disorders (MSDs) comprise a substantial portion of the cost of occupational illness. The National Institute for Occupational Safety and Health (NIOSH) in 1996 estimated the US cost to be \$13 billion annually, while the AFL-CIO in 1997 estimated the annual cost at \$20 billion.¹ As of 1999, MSDs accounted for one in every three injuries and/or illnesses that resulted in lost time.² In a recent US survey of persons more than 18 years of age, the leading reported cause of disability significant enough to interfere with daily life and/or work was arthritis and rheumatism (non-back or spine).³

The implications, then, of rheumatologic conditions on the practice of occupational medicine are substantial. In contrast to the previous chapters in this section, this chapter will not focus on ergonomic issues and localized injury associated with repetitive movements. Rather, the concern here will be systemic inflammatory diseases that traditionally fall under the realm of the subspecialty of rheumatology. Clinically apparent rheumatologic disease may, of course, be limited to a single body location. The usual characteristic, whether manifestations are localized or systemic, is chronic pain and progressive physical impairment of the musculoskeletal system. Disease may also involve numerous other body systems, including the hematopoietic, cardiopulmonary, vascular, central nervous, genitourinary, and dermatologic systems. As summarized in Table 23.5.1, some rheumatologic conditions are associated with workplace or environmental exposures. Other pre-existing conditions may be exacerbated by the workplace. This chapter covers the major rheumatologic diseases that may arise from workplace or environmental exposures.

EVALUATION OF THE WORKER WITH SUSPECTED MUSCULOSKELETAL OR RHEUMATIC DISEASE

The cornerstones of the evaluation of a patient with musculoskeletal or rheumatic complaints are a careful history and physical examination. The history should distinguish inflammatory and non-inflammatory conditions. Inflammatory conditions, such as rheumatoid arthritis (RA), are generally accompanied by significant (often greater than 1 hour) of morning stiffness, a sensation of gelling after inactivity, and, frequently, systemic symptoms such as fatigue and malaise. In contrast, patients with non-inflammatory, mechanical conditions, such as osteoarthritis (OA), generally have less than a half hour of morning stiffness and are more symptomatic with prolonged joint use toward the end of the day. The history also should elicit other symptoms that may provide a clue that a systemic illness is present. For example, RA and

systemic lupus erythematosus (SLE) can involve the skin, cardiac or pulmonary systems.

The goal of the physical examination is to identify organs involved, and to distinguish between intra-articular and periarticular conditions. Periarticular disorders, such as tendinitis and bursitis, are characterized by pain or focal tenderness with movement of the joint in the specific planes that stress the involved structure, with additional objective findings of stiffness, or localized pain during isometric loading of the tendon. Inflammatory synovitis, in contrast, is accompanied by pain on movement of the affected joint in all directions, with warmth and swelling. Testing for joint stability and noting deformities document the consequences of underlying joint pathology. Particular attention should be directed towards the hands, one of the most fruitful areas of examination in systemic inflammatory disease, especially given the occupational implications.

The laboratory evaluation, though often informative, must be based upon a careful history and physical examination. Nevertheless, certain laboratory tests are of definite value. An elevated erythrocyte sedimentation rate (ESR) may help distinguish between inflammatory and non-inflammatory conditions, although elevated sedimentation rates can be seen in association with age, infections, cancer, and other disorders. C-reactive protein (CRP) levels respond more rapidly than the ESR to changes in inflammatory activity, and thus CRP is probably a more sensitive early measure of inflammation.⁴ A plethora of autoantibody tests are available for the assessment of rheumatic diseases. Rheumatoid factor, while a useful screening test for RA, has limited efficacy due to a very high false-positive rate. Interpretation of findings of low serologic titers represents a challenge. Antinuclear antibodies (ANA) are highly sensitive for SLE, but are also limited by low specificity. ANA subsets such as anti-smooth muscle antibody (Sm) and double-stranded DNA (dsDNA) are highly specific for SLE and are useful ancillary tests when ANA is positive. When the ANA is negative, and the diagnosis of SLE is strongly suspected, anti-Ro antibody and a CH50 should be ordered, as some patients will be anti-Ro positive or complement deficient.⁴⁻⁶ Assays for complement components and immune complexes are expensive, and are seldom helpful in the initial evaluation of patients with suspected rheumatic disease. Despite the strong association between the HLA-B27 allele and the seronegative spondyloarthropathies such as ankylosing spondylitis, the high background prevalence of this genetic marker, particularly in Caucasians, limits its usefulness. X-ray studies may suggest destruction of cartilage or bone but are only occasionally useful in the initial management of atraumatic rheumatologic conditions. Aspiration of synovial fluid can be very informative: fluid containing more than 2000 white cells per cubic centimeter is considered inflammatory. Synovial fluid white blood cell counts of less than 2000 are typically seen in OA.

Rheumatic condition association	Exposure	Strength of association
Osteoarthritis	Repetitive trauma	Suspected
Rheumatoid arthritis	Silica	Reported
	Agricultural work	Reported
Systemic lupus erythematosus	Hydrazine	Reported
Systemic sclerosis	Silica	Suspected
Scleroderma-like disorders	Vinyl chloride monomer	Known
	Solvents	Suspected
	L-Tryptophan (contaminant)	Known
Fibromyalgia	Chemical or factory work	Reported
Gout	Lead	Known
Brucellosis	Sheep, dogs, cattle	Known
Lyme disease	Outdoor work	Known
Parvovirus infection	Day care	Suspected
Osteonecrosis	Diving	Known
	Tunnel work	Known
Osseous fluorosis	Fluoride	Known
Muscle disorders	Halogenated hydrocarbons	Known
	Firefighting	Reported

Table 23.5.1 Associations between rheumatic conditions and occupational or environmental exposures

OSTEOARTHRITIS

OA is the most common form of arthritis, and it is seen radiographically in at least one joint in more than 80% of individuals over 70 years of age. The lifetime prevalence of involvement of weight-bearing joints exceeds 40%. Although the precise pathogenesis of OA is unknown, several etiologic factors are well recognized. Age is the strongest risk factor,⁷ although it is unclear whether the age-related changes are primarily biochemical or mechanical. Alterations in the cartilage matrix may occur with acute trauma, infection, calcium pyrophosphate dihydrate (CPPD) deposition disease, acromegaly, hemochromatosis, Wilson's disease, and gout. It also has been proposed that repetitive forceful loading of joints in occupational settings leads to cartilage injury and the development of OA.⁸ While there remains some controversy over specific pathogenic theories, the epidemiologic studies reviewed below clearly document OA in joints exposed to repetitive stress trauma.

Occupational epidemiology

People with pre-existing OA often experience work disability, especially when faced with physically demanding jobs in which they have little control over the pace or the specific physical demands of work.⁹ Felson and colleagues observed an association between occupations that require repetitive knee bending, such as mining and farming, and OA;^{10–13} farming was also associated with hip OA. Several reports suggest that occupational repetitive trauma may cause OA in joints generally unaffected by idiopathic OA. For example, Hadler and colleagues investigated three groups of females employed for at least 20 years in textile manufacturing jobs requiring repetitive winding, burling, or spinning.¹⁴ The burlers and spinners had more radiologic evidence of OA in the dominant second

and third distal interphalangeal joints than had the winders, suggesting that repetitive use may cause distinct osteoarthritic syndromes in the hand.

Obesity has been demonstrated to predispose individuals to OA of the knee, suggesting that mechanical loading is associated with an excess of OA.¹⁵ In a large Scandinavian study, radiographic evidence of OA of the knee was found in 3.9% of laboring dock-workers as compared with 1.4% of white-collar shipyard workers and 1.6% of community controls, a significant difference.¹⁶ Similarly, among a well-studied group of 347 Swedish men, there was a strong association between radiographic evidence of OA of the hip and exposure to heavy labor, heavy lifting, and much tractor driving.¹⁷ These studies are limited because radiographic studies were not obtained routinely on all workers. A recent study from Japan, where obesity is rare, nonetheless found an association between hip OA and heavy occupational lifting.¹⁸ The association between hip OA and heavy work has been well demonstrated in case-control studies controlling for obesity and participation in sports, with a 2.4-fold increase in hip OA in workers performing heavy compared to light work.¹⁹

A number of uncontrolled observations also point to the role of repetitive trauma in the pathogenesis of OA in joints not usually affected in idiopathic OA. For example, eight foundry workers who sustained considerable repetitive forces at the elbow joint have been reported with clinical and radiographic evidence of OA of the elbow.²⁰ Classic clinical and radiographic changes of OA in the metacarpophalangeal joints of seven manual laborers who gripped with their hands repeatedly and intensively for prolonged periods also have been reported,²¹ as has a case of severe OA of the metacarpophalangeal joints and elbow in a 62-year-old man who worked 27 years as a jackhammer operator.²² In a study of 20 pianists averaging 33.9 years of age who had practiced piano at least 2 hours a day for at least 5 years, radiographic evidence of OA at the third, fourth, or fifth metacarpophalangeal joints was noted in eight (40%).²³ However, a report of 16 patients with OA of the elbow who were not exposed to repetitive elbow trauma underscores the need for controlled studies.²⁴ In a large series of patients undergoing shoulder arthroscopy, a significant association between type III and IV superior labrum anterior posterior (SLAP) lesions and a high-demand occupation was found.²⁵

In summary, there is growing evidence over the past decades that repetitive loading of joints in occupational settings leads to OA in joints rarely affected by idiopathic OA. Repetitive trauma is associated with an increased risk of OA in the knee and hip.

Clinical features

OA is generally classified as idiopathic or secondary. Secondary OA results from metabolic, infectious, and inflammatory diseases; acute trauma; epiphyseal diseases; congenital hip dysplasia; and other conditions. Idiopathic

OA is age related, with a striking prevalence for particular joints, including the distal interphalangeal joints of the hand, and the knee, hip, lumbar spine, and feet. Some joints are less frequently involved in idiopathic OA, including the metacarpophalangeal joints of the hand, and the elbow, shoulder, and ankle. Involvement at these sites should raise concern of secondary OA, including an occupational association.

Symptoms of OA usually progress insidiously. Patients experience dull aching pain in the affected joint(s) that is generally exacerbated by prolonged use and improved by resting the joint. As noted above, morning stiffness usually lasts less than 30 minutes; stiffness that lasts longer suggests inflammatory arthritis. Physical examination reveals bony enlargement of the joint, limitation in range of motion variable, joint line tenderness, and, in advanced disease, crepitus and joint deformity. Radiographs reveal characteristic joint space narrowing, subchondral sclerosis, cysts adjacent to the joint, marginal osteophytes, and other degenerative changes.

Treatment

Symptomatic relief can usually be obtained by resting affected weight-bearing joints or splinting other joints, such as the first carpal metacarpal. Pharmacologically, non-steroidal anti-inflammatory drugs (NSAIDs) are the first-line treatment of choice, although gastric irritation, including gastrointestinal bleeding, is a concern, as well as renal insufficiency with chronic administration. Cyclooxygenase (COX)-2 inhibitors show promise for their decreased risk of gastrointestinal bleeding, though renal insufficiency remains a concern. A recent randomized double-blind trial, conducted in 29 clinical centers in the US, found that rofecoxib, 25 mg/day, provided advantages over acetaminophen, 4000 mg/day, celecoxib, 200 mg/day, and rofecoxib, 12.5 mg/day, for symptomatic knee OA.²⁶ Intra-articular injections of corticosteroids and/or hyaluronic acid can be useful in refractory cases.²⁷ Use of some herbal preparations in the treatment of OA has been reported in a recent review.²⁸ A Cochrane review found the evidence for the use of avocado-soybean unsaponifiables in the treatment of OA convincing, but found the evidence for other herbal interventions insufficient to either recommend or discourage their use.²⁹ Many patients take intensively advertised and unregulated supplements such as glucosamine and chondroitin sulfate. Advocates of these alternative modalities cite reports of progressive and gradual decline of joint pain and tenderness, improved mobility, sustained improvement after drug withdrawal, and a lack of significant toxicity associated with short-term use. Critics point out that in the great majority of the relevant clinical trials, sample sizes were small, and follow-up was short term.³⁰ In advanced disease, many joints can be approached surgically, with arthroplasty or arthrodesis. Surgical modalities under investigation also include autologous chondrocyte transplantation.³¹

RHEUMATOID ARTHRITIS

RA is a chronic, systemic inflammatory disorder characterized by symmetric polyarthritis and, occasionally, extra-articular manifestations.

Epidemiology

The prevalence of RA is approximately 1%, with women affected two to three times more frequently than men; the peak incidence occurs between the fourth and sixth decades. An estimated 2.1 million US adults have RA,³² with medical costs of approximately \$8.7 billion annually.³³

The literature on the association between specific occupations and RA is conflicting. Studies that do not use standard classification criteria for RA further limit interpretation. Major studies from the National Center for Health Statistics and others³⁴ have demonstrated no statistically significant correlation between occupation and the onset of RA. Other investigators have suggested that RA in males is associated with agricultural work.³⁵ A Swedish registry-based cohort study found an increased risk of RA in farmers, upholsterers, lacquerers, concrete workers, and hairdressers, as well as in several 'white-collar' trades.³⁶ Substantial handling of organic solvents was also associated with an increased relative risk for RA.

Exposure to silica and established silicosis have been associated with extrapulmonary conditions, including scleroderma and RA. Rheumatoid pneumoconiosis (Caplan's syndrome) is a syndrome of nodular fibrosis of the lung and RA in coal workers.³⁷ In an early population-based study of an entire community in South Wales, there was no increased prevalence of RA among miners and ex-miners.³⁸ A Finnish cohort of 1026 granite workers hired between 1940 and 1971 was followed until the end of 1981.³⁹ The incidence of awards for disability related to RA, the prevalence of RA, and the prevalence of individuals receiving medication for RA were significantly higher among granite workers than in the general male population of the same age. A retrospective analysis of all patient records was used to verify diagnoses according to standardized criteria and showed a predominance of severe seropositive erosive RA, especially when the onset of the disease occurred after 50 years of age or older. None of the patients had Caplan's syndrome, and only a few had evidence of silicosis at the onset of RA.

The pathophysiologic basis for the association between RA and occupational exposure to dust such as silica remains unclear. Exposure to silica may facilitate entry of infectious agents, or increase an individual's susceptibility to them. Pulmonary silicosis and RA share some immunochemical features, such as the serologic findings of rheumatoid factor and ANA, circulating immune complexes, and decreased resistance to infectious diseases.

Clinical features

Clinically, RA is characterized primarily by symmetric polyarthritis most commonly involving the metacarpophalangeal and proximal interphalangeal joints, wrists, neck, hips, knees, elbows, and metatarsophalangeal joints. With continued synovitis, cartilage and, ultimately, bony destruction may occur, resulting in deformity and disability.

Extra-articular manifestations may include subcutaneous nodules, pleuritis, pericarditis, interstitial lung disease, mononeuritis multiplex, compression neuropathies such as the carpal or tarsal tunnel syndromes, Sjögren's syndrome, and episcleritis. Laboratory features include anemia of chronic disease, elevated sedimentation rate, and, in about two-thirds of patients, positive rheumatoid factors, which are antibodies to the Fc portion of IgG. Radiographs reveal periarticular osteopenia and soft tissue swelling early in the disease, with characteristic joint space narrowing and bony erosions with progressive disease.

The diagnosis of RA is made clinically. The most important step in the diagnosis is to exclude other causes of inflammatory polyarthritis. The revised classification criteria for RA that were published in 1987 were found by a large academic rheumatology practice to have a diagnostic sensitivity of 95% and a specificity of 73%.⁴⁰

Treatment is usually initiated with an NSAID. If these drugs fail to relieve the pain and inflammation, disease-modifying antirheumatic drugs (DMARDs) are generally offered, such as hydroxychloroquine, oral or intramuscular gold, sulfasalazine, and methotrexate. Promising advances in the treatment of RA using various biologic therapies have been made.⁴¹ Clinical trials testing the transfer of anti-arthritic protein coding genes to the synovial lining of human joints are in progress.⁴²

SYSTEMIC LUPUS ERYTHEMATOSUS

SLE is a chronic inflammatory disease of unknown etiology with protean manifestations. The prevalence of SLE varies greatly among populations. In the US, the prevalence in women is 1 in 700, and among black women, 1 in 250. There is a marked female predominance of approximately 9:1.

Occupational epidemiology

A variety of drugs can cause a lupus syndrome, autoantibodies, or both, which suggests that environmental and occupational etiologies may exist for this disorder. The two most thoroughly studied medications associated with SLE are procainamide and hydralazine, which contain aromatic amino and hydrazine groups, respectively. Slow or rapid acetylation of these drugs is genetically determined; and a person of the slow-acetylator phenotype is more likely to develop autoantibodies and a lupus-like syndrome from exposure to these drugs. Procainamide-induced SLE can remit when *N*-acetylprocainamide is substituted for

procainamide, providing presumptive evidence of the etiologic role of the amino group.

At the present time, however, associations between environmental agents and SLE are speculative, based only on case reports. In the US, hydrazine use exceeds 30 million pounds a year. Hydrazine and its derivatives are used in the synthesis of such diverse products as plastics, anticorrosives, rubber products, herbicides, pesticides, photographic supplies, rocket fuel, preservatives, textiles, dyes, and pharmaceuticals. Hydrazine sulfate has additionally been investigated as an anticancer and anticachexia agent, with unconvincing results, and is marketed in the US as an unregulated dietary supplement.⁴³ Hydrazine itself occurs naturally in tobacco and tobacco smoke, and a number of aromatic hydrazines are present in mushrooms. A laboratory worker exposed to hydrazine sulfate developed fatigue, photosensitive rash, a positive ANA, arthralgias, photosensitivity, and periungual telangiectasias, which resolved with cessation of the exposure.⁴⁴ When evaluated, it was determined that she had a slow-acetylator phenotype, and many of her healthy family members also had antibodies to nuclear constituents. Tartrazine (FD&C yellow #5) is an azo dye present in thousands of foods and drugs which can be broken down to hydrazine compounds and has been implicated in one case of pruritus, photosensitivity, arthralgia, and myalgia.^{45,46} Alfalfa sprouts, which contain a highly basic amine, canavanine,⁴⁷ have caused a lupus-like disease in monkeys.⁴⁸ A case report described a hairdresser with acute exacerbations of SLE which coincided with periods of intense work with aromatic coloring agents.⁴⁹ The disorder disappeared completely after a period of 4 years following a change of occupation.

A case-control study was completed in a small four-county area in Southeast Georgia to identify risk factors for SLE and other connective tissue diseases.⁵⁰ The investigators found that a family history of connective tissue diseases and the use of hair dyes were associated with connective tissue disorders.

After a cluster of three cases of SLE were noted in workers at one US Army ammunition plant, a cross-sectional study was performed to determine whether or not there was an excess of autoimmune disease.⁵¹ Using serologic criteria only, however, no rheumatologic, hepatic, or renal abnormalities were noted in employees with 8-hour time-weighted exposures to cyclotrimethalintrinitamine (RDX) of up to 1.57 mg/m³.

Clinical features

Arthritis occurs in over 90% of patients with SLE and is generally non-destructive. Skin lesions, including the typical erythematous malar rash, occur in about 50% of patients, as do pleuritis and pericarditis. Renal disease, central nervous system involvement, and hematologic abnormalities occur frequently, and may complicate management of these patients.

The etiology of SLE is unknown, but appears to involve both genetic and environmental factors. The disease is characterized by autoantibodies, including ANA, which

likely have a role in pathogenesis. Pathologically, involvement in most organs relates to vasculitis or mononuclear cell infiltrates. Diagnosis is made on the basis of clinical features. The treatment of SLE is complex and has undergone major advances, which are reviewed elsewhere.⁵²

SYSTEMIC SCLEROSIS

Systemic sclerosis, or scleroderma, is a systemic disorder characterized by fibrosis of the skin, blood vessels, and internal organs. The incidence is estimated at 4–12 cases per million annually, with peak onset in the fourth through sixth decades, and a female-to-male ratio of approximately three to one. A variety of occupational and environmental exposures have been associated with the development of scleroderma or related fibrosing conditions.⁵³

Occupational epidemiology

Exposure to silica has been associated with increased risk of systemic sclerosis. A case-control study revealed that South African gold miners with systemic sclerosis had significantly greater exposure to silica dust than age-matched miner referent groups.⁵⁴ In a study conducted in Pittsburgh, 47% of patients admitted to the hospital with systemic sclerosis had heavy exposure to silica dust from local coal mines, whereas just 19% of hospitalized controls were similarly exposed.⁵⁵ Although case reports of scleroderma-like syndromes arising in the setting of silicone implantations (such as in cosmetic augmentation mammoplasty) have suggested an etiologic association,⁵⁶ a recently convened National Science Panel found no evidence to support an association between silicone breast implants and connective tissue diseases.⁵⁷ The pathogenesis of silica-associated scleroderma is unknown. Interestingly, the clinical findings in this syndrome are indistinguishable from idiopathic systemic sclerosis, except for a male predominance and earlier age of onset.

Clinical features

Systemic sclerosis is generally characterized as limited or diffuse, based on the extent of skin involvement. In limited cutaneous scleroderma, skin involvement is confined to the distal extremities and face. The CREST syndrome (Calcinosis, Raynaud's phenomenon, Esophageal dysmotility, Sclerodactyly, and Telangiectasias) is common in this group. Visceral involvement generally does not occur until after a decade of skin disease in limited systemic sclerosis, and renal disease occurs in just 1% of individuals. Diffuse cutaneous systemic sclerosis is characterized by the rapid progression of skin thickening, including the proximal extremities and trunk. Raynaud's phenomenon, arthritis, tendon contractures, esophageal disease, and interstitial lung disease are common. Sclerodermal renal crisis, characterized by hypertension and azotemia, may occur in 15% of patients.

The diagnosis of systemic sclerosis generally is made on the basis of the history and physical examination. A

useful physical finding is dilation of periungual vessels on capillary microscopy. Hand radiographs may reveal lesions of the distal tufts later in the course of disease.

Advances in organ-specific therapy, particularly calcium channel antagonists in Raynaud's phenomenon, proton pump inhibitors in esophageal reflux, intravenous iloprost and endothelin receptor antagonists in pulmonary hypertension, and angiotensin-converting enzyme (ACE) inhibitors in renal crisis, have decreased morbidity and mortality in patients with scleroderma.⁵⁸

Scleroderma-like disorders

A scleroderma-like syndrome has been well documented in workers exposed to vinyl chloride.⁵⁹ Polyvinyl chloride is widely used in the plastics industry and is produced by polymerization of gaseous monomeric vinyl chloride. Between 1% and 3% of workers exposed to vinyl chloride monomer at concentrations of 300 to 500 ppm have been affected. The syndrome consists of Raynaud's phenomenon, thickening of the skin over the dorsum of the hand and distal forearm, acro-osteolysis, and other derangements of internal organs, including fibrosis of the lung and liver, splenomegaly, and thrombocytopenia. Angiosarcoma of the liver has been noted in isolated reports.⁶⁰ The diagnosis is made on the basis of an individual's medical history, occupational history, and physical examination. Capillary microscopy of the nail beds may reveal dilated or deformed capillary vessels, as seen in systemic sclerosis. Angiography reveals tortuosities and obstruction of digital arteries, reflecting the primary vascular pathophysiology of the hand lesions.

The bony lesion of vinyl chloride disease, acro-osteolysis, begins with small erosions, which progress to transverse defects in the distal phalanges (Fig. 23.5.1).⁶¹ Bony resorption is also seen in approximately half of patients with idiopathic systemic sclerosis; however, in these patients, resorption is primarily in the distal tuft, whereas in vinyl chloride disease, the central shaft of the distal phalanx is involved. Other sites of bony resorption in vinyl chloride disease include the metatarsals, sacroiliac joints, distal clavicles, and mandible. Lesions may heal when the exposure to vinyl chloride is discontinued. The differential diagnosis of acquired acro-osteolysis in workers includes vinyl chloride toxicity, thermal injury, and trauma,⁶² in addition to non-occupational etiologies, such as mixed connective tissue disease, sarcoidosis, and hyperparathyroidism.⁶³

The etiology and pathogenesis of vinyl chloride disease are obscure. Some evidence suggests that metabolites of vinyl chloride may represent the toxic intermediates, and that genetic susceptibility and immunologic mechanisms may be involved.⁶⁴

Management involves symptomatic treatment and, most importantly, elimination of exposure. Since recognition of this syndrome in the 1960s, regulatory levels of monomeric vinyl chloride have been reduced to 5 ppm or less in most settings, with a resulting decline in the incidence of this disorder. Although many patients have

Figure 23.5.1: A: X-ray views of hands of long-term vinyl chloride worker showing loss of bone in distal phalanges. B: Finger shortening and pseudoclubbing associated with acro-osteolysis. (Courtesy of Ruth Lilis, MD.)

improved or recovered completely upon removal from the exposure, disabling symptoms may persist.

Scleroderma-like syndromes have also been reported with exposure to epoxy resins and organic solvents. Six patients engaged in the polymerization of epoxy resins developed sclerodermatous skin changes, muscle weakness, and fatigue.⁶⁵ Visceral involvement was not observed. The syndrome was characterized by rapid onset within months of exposure, as compared with many years of exposure in cases of vinyl chloride disease. Interestingly, the chlorinated alkene solvents trichloroethylene and perchloroethylene, which are structurally similar to vinyl chloride, have been associated with the development of scleroderma-like syndromes.^{66,67} Scleroderma-like skin induration has been reported in therapy with bleomycin, and with the abuse of pentazocine and cocaine.⁶⁸

Two epidemics in the 1980s identified other chemicals associated with scleroderma-like disorders. In 1981, toxic oil syndrome (TOS) affected thousands of previously healthy Spaniards, who developed a syndrome of acute and often fulminant pneumonitis followed by chronic sclerodermatous skin changes, myopathy, and sicca syndrome. Extensive investigation revealed that the offending agent was contained in rapeseed oil, denatured with aromatic amines, and sold as inexpensive cooking oil.⁶⁹ In 1989, the eosinophilia–myalgia syndrome (EMS), including eosinophilia, severe myalgia, sclerodermatous skin changes, fasciitis, and myopathy and neuropathy, was recognized in users of certain lots of L-tryptophan;⁷⁰ this syndrome appeared to be caused by one or more contaminants formed during the preparation of L-tryptophan by one company in Japan.⁷¹ Removal of the contaminated preparation from circulation ended the epidemic.

The mechanisms by which contaminated oil and L-tryptophan led to clinical syndromes similar to scleroderma and eosinophilic fasciitis are not known, although a common aniline-derived or related indole ring-containing compound is suspected (Fig. 23.5.2). The initial manifestations of TOS included fever, headaches, cough, dyspnea, skin eruptions, intense myalgias, and eosinophilia. Edematous skin changes gave way to sclerodermatous lesions, neuropathy, and chronic neuromuscular disability. The presentation and evolution of EMS were strikingly

Figure 23.5.2: Chemical structures of (A) aniline, the parent compound of contaminants found in toxic oil syndrome, and (B) L-tryptophan, the parent compound associated with the eosinophilia–myalgia syndrome.

similar to those of TOS, as were the histopathologic features. In both epidemics, most patients had complete resolution of symptoms following exposure but some were left with chronic disability; a mortality rate of approximately 1% was observed for TOS and about 0.1% for EMS. No therapy, including corticosteroids, was of proven efficacy in these syndromes.

FIBROMYALGIA

Fibromyalgia syndrome (FMS) is a common disorder of unknown etiology, characterized by diffuse and chronic musculoskeletal pain, discrete tender points on physical examination, profound fatigue, and sleep disorder. Fibromyalgia is estimated to affect from 1% to 5% of the population of industrialized societies.⁷²⁻⁷⁴ There is considerable overlap between FMS, chronic fatigue syndrome (CFS), and certain psychiatric disorders, which continues to engender controversy.⁷⁴⁻⁷⁷

Epidemiology

Trauma through 'overuse' or 'repetitive strain' has been reported to be associated with the development of FMS.^{78,79} The prevalence of trauma as an initiating event in FMS has been reported to range from 11% to 24%; however, no formal studies have adequately examined this relationship.⁷⁴ Etiologic associations between occupational exposure and FMS therefore remain speculative.⁸⁰

Clinical features

The clinical picture is dominated by pain, which is diffuse and primarily affects the axial skeleton, shoulder, and pelvic girdles, as well as soft tissues.⁸¹ Patients with FMS may have a biologic predisposition to more sensitive pain perception than people without FMS.⁸² Stiffness is also common, lasting up to 1 to 2 hours daily. Fatigue is one of the most debilitating symptoms of fibromyalgia, and it seems to be closely related to non-restorative sleep. It is estimated that 70% of patients have a sleep disorder.⁸³ Symptoms occurring in at least 25% of patients include paresthesias, arthralgias and subjective stiffness, headaches, irritable bowel syndrome, Raynaud's syndrome, sicca syndrome, palpitations, dizziness, and psychologic disturbances. The disease may be exacerbated by weather, temperature, exercise, stress, and acute trauma.

The clinical examination of the patient with fibromyalgia is remarkable only for tender points (Fig. 23.5.3). These are symmetrically distributed in characteristic locations, including the intertransverse or interspinous ligaments of C4 to C6, the upper border of the trapezius, the inner scapula, the origin of the supraspinatus, the upper outer quadrant of the buttocks, the lateral epicondyle, and the medial fat pad of the knee. Laboratory examinations are generally unremarkable except for sleep studies, which reveal an 8 to 10 cycle/sec interference pattern superimposed on the usual 1 to 2 cycle/sec wave pattern characteristic of stage IV non-rapid eye movement sleep.

Figure 23.5.3: Location of typical tender points in patients with fibromyalgia.

The diagnosis of fibromyalgia is made on the basis of a characteristic history, with physical examination revealing tender points, and the absence of other notable physical or laboratory findings. A variety of other disorders, including systemic rheumatic diseases, must be excluded. The pathogenesis of fibromyalgia is largely unknown. Possible mechanisms, including post-traumatic neurologic changes, which have been demonstrated in animal models, as well as psychological etiologies, wherein minor trauma triggers FMS, have been posited.⁷⁴ The adjudicative difficulties inherent in the trauma-FMS-disability association have been summarized in a consensus report.⁸⁴ Classification criteria for fibromyalgia⁸⁵ are listed in Table 23.5.2.

The treatment of FMS should ideally entail a multidisciplinary program. Treatment should address physical fitness, work and other functional activities, mental health, and other commonly associated conditions such as irritable bowel syndrome, interstitial cystitis, migraine headaches, and temporomandibular joint dysfunction.⁸⁶ Tricyclic antidepressants such as amitriptyline have been used successfully to treat pain associated with FMS; NSAIDs and systemic corticosteroids have typically been ineffective. Promising medications include 5-HT₃ receptor antagonists such as odansetron⁸⁷ and the serotonin/dopamine receptor antagonist olanzapine.⁸⁸ The avoidance of dietary monosodium glutamate and aspartame has been beneficial in some patients.⁸⁹

GOUT

Gout has been described since antiquity. The prevalence of gouty arthritis is 2-2.6 per 1000 persons and increases

1. History of widespread pain.
Definition: Pain is considered widespread when all of the following are present: pain in the left and right side of the body, above and below the waist. In addition, axial skeletal pain must be present. Shoulder and buttock pain is considered as pain for each involved side. Low back pain is considered lower segment pain.
2. Pain in 11 of 18 tender point sites on digital palpation.
Occiput: bilateral, at the suboccipital muscle insertions.
Low cervical: bilateral, at the anterior aspects of the intertransverse spaces at C5–C7.
Trapezius: bilateral, at the midpoint of the upper border.
Supraspinatus: bilateral, at origins, above the scapula spine near the medial border.
Second rib: bilateral, at the second costochondral junctions, just lateral to the junctions of upper surfaces.
Lateral epicondyle: bilateral, 2 cm distal to the epicondyles.
Gluteal: bilateral, in upper outer quadrants of buttocks in anterior fold of muscle.
Greater trochanter: bilateral, posterior to the trochanteric prominence.
Knee: bilateral, at the medial fat pad proximal to the joint line.

Digital palpation should be performed with an approximate force of 4 kg.

* For classification purposes, patients are said to have fibromyalgia if both criteria are satisfied. Widespread pain must have been present for at least 3 months. The presence of a second clinical disorder does not exclude the diagnosis of fibromyalgia.

Table 23.5.2 The American College of Rheumatology 1990 criteria for the classification of fibromyalgia*

steadily with age and serum uric acid concentration. It is predominantly a condition of males, but also occurs in elderly women with renal dysfunction, diuretic use, or both. Gout is an important disorder in occupational medicine because of its association with lead intoxication.

Occupational epidemiology

The association between lead ingestion and gout has been recognized for over two centuries. Lead toxicity may result from inhalation of fumes from radiator recycling operations or ingestion of lead-containing materials such as paints, water from lead pipes, and historically, with the use of illicit alcohol (moonshine) distilled in lead-containing car radiator stills.⁹⁰ Patients with saturnine gout may exhibit other symptoms of lead toxicity for months or years before developing gouty arthritis.⁹¹ Classic findings, as well as the diagnosis and treatment of lead intoxication, are discussed in Chapter 39.7.

The occurrence of gout in lead-intoxicated individuals also suggests that prior lead exposure at a subclinical dose may explain some of the renal disease commonly observed in patients with gout.⁹² However, it has also been shown that patients with gout, renal impairment, and a history of lead exposure may have normal EDTA chelation tests, indicating that concurrent disease entities (e.g., hypertension, diabetes) may explain the renal insufficiency observed in gouty patients with moonshine exposure.⁹³ Chronic low-level environmental lead exposure may interfere with urate excretion in patients with renal insufficiency. This inhibition may be markedly improved by lead-chelating therapies.⁹⁴

Clinical manifestations

Acute gouty arthritis is characterized by episodes of exquisitely painful monoarthritis with a predilection for lower extremity joints, particularly the first metatarsophalangeal joint (podagra). Untreated attacks last up to 2 weeks but usually resolve completely. Attacks become more frequent and prolonged over time, often involving multiple joints. Chronic tophaceous gout generally occurs after many years of untreated disease and is characterized by deposits of uric acid in the helix of the ear, extensor surfaces of the forearm, olecranon bursa, and other sites.

Gouty arthritis results from an inflammatory response to monosodium urate crystals deposited in joints and peri-articular structures. Monosodium urate crystals may form when the serum urate concentration exceeds the solubility threshold of approximately 7 mg/dl. Hyperuricemia occasionally arises from overproduction due to enzymatic defects in purine metabolism. Over 80% of cases, however, are due to undersecretion of urate because of proximal tubular dysfunction, likely representing the pathophysiologic process in saturnine gout.

The clinical features of saturnine gout do not differ substantially from idiopathic gout. A greater predilection for knee involvement, as well as polyarticular disease, has been observed. Treatment of acute saturnine gout is the same as for idiopathic gout, including NSAIDs or colchicine in acute cases and urate-lowering agents on a chronic basis. Because renal dysfunction is often present in saturnine gout, doses of colchicine and allopurinol should be reduced. Uricosurics are less effective in the setting of renal dysfunction. Removal of the affected individual from exposure to lead is imperative, but the role of chelation is uncertain if signs of acute intoxication are absent.

ANKYLOSING SPONDYLITIS AND THE SPONDYLOARTHROPATHIES

As discussed in Chapter 23.4, millions of workers in the US are evaluated annually for low back complaints. Although most low back syndromes are mechanical in nature, inflammatory back disease occurs in 0.1% to 1% of the population and, therefore, must be considered in the differential diagnosis. The spondyloarthropathies are related disorders characterized by inflammation of the spine, sacroiliac joints, peripheral joints, and, variably, the eye, skin, and other organs. Specific spondyloarthropathies include ankylosing spondylitis (AS); Reiter's syndrome and other reactive arthritides; psoriatic arthritis; and enteropathic arthritis, including Crohn's disease and ulcerative colitis. These diseases have no known occupational associations, although Reiter's syndrome and other reactive arthritides have been reported in outbreaks of enteritis in settings such as military camps. Patients with AS who have physically demanding jobs are more likely to experience permanent or temporary work disability, or require accom-

modation than those with less physically demanding jobs.⁹⁵

Spondylitis can usually be distinguished from mechanical back pain by history. Patients with AS have the insidious onset of back discomfort before age 40, generally in the late teens or twenties. Mechanical pain seldom starts in the teens and generally has an acute or subacute rather than insidious onset. Spondylitis also is associated with morning stiffness, usually lasting for more than 30 to 60 minutes, which is improved with exercise. Mechanical back pain usually causes just a few minutes of stiffness, which worsens with exercise. The physical examination is generally unrewarding in distinguishing early spondylitis from mechanical back pain. Although sacroiliitis and ligamentous calcification are characteristic radiographic findings in spondylitis, they generally do not appear in the initial years of disease.

Mechanical back pain has an excellent prognosis, with 90% of patients being symptom free 3 months following an episode. Spondylitis, particularly AS, has a less favorable natural history. Spontaneous remissions are uncommon, and progressive disability with deforming spine fusion may occur. For this reason, it is critical to diagnose spondylitis early, and institute a physical therapy program directed at maintaining lumbar and cervical extension, preventing fusion in a stooped posture. NSAID therapy is appropriate, especially to improve exercise tolerance and physical capacity. Recently, clinical responses have been reported with tumor necrosis factor (TNF)-alpha antagonists such as etanercept and infliximab.^{96,97} The risk of activating an occult infection with these agents, however, demands that they be used with great care.

INFECTIOUS DISEASES

Rheumatic conditions caused by infectious diseases (see Chapter 22) may be acquired in occupational settings,⁹⁸ and include the following common conditions.

Septic bursitis

Bursae are synovia-lined cavities. The prepatellar and olecranon bursae are superficial and frequently traumatized. Resultant skin lesions provide a portal of entry for purulent organisms, particularly *Staphylococcus aureus*, which is involved in 80% of cases of septic bursitis. Workers exposed to repeated knee or elbow trauma, including carpenters, carpet layers, and other laborers, are at risk for septic bursitis.⁹⁹

Symptoms include pain, swelling, and diminished range of motion. Associated cellulitis is common. Systemic symptoms and fever occur occasionally. Diagnostic aspiration should be performed and appropriate antibiotics initiated. Hospitalization and intravenous antibiotics are advisable in patients with systemic features or impaired host defenses. In many patients, outpatient oral antibiotic therapy (e.g., penicillinase-resistant penicillins) is adequate, because the olecranon and prepatellar bursae do not communicate with the joint space.

Brucellosis

Brucella are non-encapsulated gram-negative aerobic bacilli. There are four species: *B. melitensis* found in goats, sheep, and camels; *B. abortus* in cattle; *B. suis* in hogs; and *B. canis* in dogs. The organisms may cause infection by direct contact (through abraded skin or exposed conjunctivae), inhalation, or ingestion. Thus, workers in contact with dogs, sheep, or cattle, such as farmers, slaughterhouse workers, and veterinarians, are at risk. Brucellosis also may be acquired through ingestion of unpasteurized milk. There were 82 cases of brucellosis reported in the US for 1999. The usual incubation period is 10 to 21 days. The characteristic tissue reaction to *Brucella* is the formation of a non-caseating granuloma.

The most common clinical features are fever, fatigue, anorexia, and weight loss. Arthritis and spondylitis may occur, particularly in association with *B. melitensis* and *B. suis* infections. Arthritis is generally polyarticular and migratory, affecting the knees, sacroiliac joints, shoulders, hips, sternoclavicular joints, elbows, ankles, and manubriosternal joints. Arthritis develops in 10% to 20% of acute, self-limited cases of brucellosis and in 50% to 65% of patients with chronic infections.¹⁰⁰

Lyme disease

Lyme disease was initially described in 1977 and has become a significant source of morbidity in endemic areas.¹⁰¹ The initial cluster was located in Lyme and surrounding towns at the mouth of the Connecticut River. Currently, the disease is endemic in the northeastern, mid-Atlantic, and north-central regions of the US, as well as in portions of the West Coast states. From 1991 to 2000, the annual incidence has nearly doubled to an all-time high of nearly 18,000 cases, with a bimodal age distribution peaking at 5 to 9 and 50 to 59 years of age.¹⁰²

Among workers studied in an endemic area of southeastern New York, most of whom were employed outdoors, 6% were seropositive, compared with 1.1% of 362 New York blood donors.¹⁰³ Outdoor leisure activity was a significant risk factor (odds ratio [95% confidence interval (CI)] = 2.5 [1.2, 5.2]); while outdoor employment was associated with increased risk (odds ratio [95% CI] = 2.0 [0.3, 12.0]), this was not statistically significant. In multivariate analyses of outdoor workers in New Jersey, adjusting for age, sex, and recreational activities, a history of tick bites on the job conferred a significant risk of seropositivity (odds ratio [95% CI] = 5.1 [1.1, 23.6]).¹⁰⁴ Another study found an incidence of Lyme disease of 3.8 per 100,000 persons in Monmouth County, New Jersey, from 1980 to 1982, and 0.5 per 100,000 persons in the rest of the state.¹⁰⁵ The incidence at the Naval Weapons Military Reserve was over 1000 per 100,000 persons. Outdoor workers had a fivefold higher risk than indoor workers of contracting disease. These data point to substantial occupational risk.¹⁰⁶

The infectious agent in Lyme disease is the spirochete *Borrelia burgdorferi*. *Borrelia* are transmitted by *Ixodes* ticks. The ticks feed on white-footed mice in the larval and

nymph stages, allowing for horizontal transmission from nymphal to larval generations and consequent perpetuation of *Borrelia* infection. Adult ticks feed on white-tailed deer and a variety of other wild animals and birds. The disease is transmitted to humans by nymphal and, occasionally, adult forms. When the nymph feeds, the organism migrates from the tick midgut to the salivary glands and is transmitted in saliva. The tick must remain attached to its host for as long as 24 hours for migration and transmission to occur.

Clinical features of Lyme disease generally are classified in three stages. Stage I, or localized Lyme disease, occurs within 3 to 30 days of infection and consists of erythema migrans, an enlarging erythematous circular lesion with a clearing center, often accompanied by mild constitutional symptoms and regional lymphadenopathy. Of note, 20% to 35% of patients with Lyme disease do not experience erythema migrans, and only a minority of patients actually remember a tick bite. Stage II, disseminated infection, occurs weeks to months after the initial infection. Although multiple organ systems may be involved, the most common manifestations are neurologic, which occur in 10% to 20% of cases and include meningoencephalitis, cranial neuritis, radiculoneuritis, and myelitis. Cardiac involvement, including abnormal conduction and other arrhythmias, occurs in up to 10% of patients. Stage III, chronic persistent infection, may occur months to years following the initial infection and generally involves arthritis, nervous system involvement, or both. The knee is the most commonly involved site, followed by the shoulder, ankle, and elbow.

The diagnosis of Lyme disease is based on clinical features and supporting serologic tests. The serologic diagnosis of Lyme disease is a two-stage process in which a positive or equivocal result by an enzyme-linked immunosorbent assay (ELISA) or immunofluorescent assay is then followed by Western blot; a rapid assay has also been reported.¹⁰⁷ Sensitive techniques such as the polymerase chain reaction are also available, though no single diagnostic modality is suitable for detection of *Borrelia burgdorferi* in every patient with erythema migrans.¹⁰⁸ Negative results from US laboratories should be interpreted cautiously when tick exposure occurred in Europe or other regions of the world. Better recognition of two emerging tick-borne zoonoses (babesiosis and human granulocytic ehrlichiosis) that can also be co-transmitted with Lyme disease is changing the approach to diagnosis and treatment of Lyme disease.¹⁰⁹

The treatment of Lyme disease really begins with prevention of infestation through proper use of protective clothing and repellants, followed by careful body inspection and removal of any attached ticks with tweezers, grasping only the head. A tick bite should not be treated with antibiotics, but cleansed and observed. Erythema migrans should be treated with oral amoxicillin, doxycycline, or cefuroxime. The treatment algorithm for various stages of disease is complex and beyond the scope of this text. These and further detailed treatment guidelines have been published recently by the Infectious Diseases Society of America.¹¹⁰

OSTEONECROSIS

Osteonecrosis, ischemic necrosis of bone, and avascular necrosis are terms used interchangeably to denote a painful disorder associated with inadequate vascular supply to bone. Numerous conditions may impair circulation to bone, causing osteonecrosis. For example, dislocation or fracture of the hip may disrupt blood supply to the femoral head. Corticosteroids and alcohol use appear to cause hypertrophy of intramedullary fat cells with consequent impairment of intramedullary fat metabolism. Sick cell disease may cause sludging in bony sinusoids with attendant ischemic necrosis. Exposure to deep-sea pressures and compressed air are important occupational exposures that may also predispose an individual to osteonecrosis. Approximately 20% of cases are idiopathic.

Occupational epidemiology

Osteonecrosis is a significant occupational hazard in workers exposed to compressed air, such as tunnel workers,¹¹¹ or elevated ambient pressures, such as deep-sea divers (see Chapter 36).¹¹² A report from the British Decompression Sickness Central Registry and Radiological Panel indicates that the prevalence of dysbaric osteonecrosis among commercial divers is 4.2%.¹¹³ Gaseous nitrogen solubilizes and accumulates in vascular tissues, including bone, during exposure to elevated pressure. When workers return to normal ambient pressures, nitrogen becomes insoluble, forming gaseous bubbles. These nitrogen bubbles may occlude osseous capillary flow, increase intramedullary pressure, and exert a direct toxic effect on osteocytes.

Dysbaric osteonecrosis involves two distinct syndromes: juxta-articular lesions, which involve the humeral and femoral heads, and shaft lesions, which typically involve the distal femoral shaft.¹¹⁴ Juxta-articular lesions are much more important because they can lead to joint destruction and significant disability. Shaft lesions, in contrast, are generally asymptomatic. The presence of shaft lesions, however, has been used to disqualify workers from further hyperbaric exposures.¹¹⁵

Several risk factors have been identified for the development of dysbaric osteonecrosis. The duration of an episode of diving is strongly associated with osteonecrosis. Radiologic osteonecrosis occurs in 0.7% of divers with less than 4 years of experience and in 10.7% of divers with 12 or more years of experience. The depth of diving also is a strong risk factor; osteonecrosis rarely occurs in divers at a maximum depth of less than 30 meters, compared with a 15.8% prevalence at a maximum depth greater than 200 meters. The rate of decompression also is a strong risk factor; gradual adjustment is much safer than abrupt exposure to normal atmospheric pressure. Age and obesity also appear to be independent risk factors (see Chapter 36).¹¹⁶

Clinical features

Divers and compressed air workers may experience decompression sickness on return to ambient pressures. The char-

acteristic symptom is limb pain, which may be relieved by bending the extremity – thus, the colloquial term, ‘the bends’. More severe symptoms of decompression sickness include pulmonary edema and neurologic symptoms. It is presumed that these acute symptoms of decompression also result from the formation of nitrogen bubbles in the microcirculation.

Physical examination is non-specific until actual joint destruction occurs, at which point, range of motion is limited. Radiographs are generally normal until late in the disease process, when areas of sclerosis appear. The collapse of subchondral bone is evidenced by a lucency or crescent sign (Fig. 23.5.4). Flattening of the articular surface appears subsequently, followed by secondary degenerative changes. Radionuclide bone scanning is much more sensitive than routine radiography, showing increased activity, which reflects the initial repair phase. Magnetic resonance imaging (MRI) is the most sensitive test for osteonecrosis (Fig. 23.5.5), showing changes due to necrosis of bone before sclerotic changes are evident.

Management

Despite increased recognition of the problem over the last two decades, and continued attempts to improve decom-

Figure 23.5.4: Plain X-ray study of the hip in a patient with osteonecrosis, revealing a crescent sign, indicating bone infarction without collapse of subchondral bone.

Figure 23.5.5: MRI of the hip, showing osteonecrosis in a patient with a normal plain radiograph. It demonstrates areas of lucency (arrows) in both femoral heads, corresponding to necrotic bone. The left hip has a moderate effusion, which appears as a bright signal in this T₂-weighted scan.

pression protocols, dysbaric osteonecrosis remains a significant hazard among compressed air workers. Multinational experience over many years indicates that all current air decompression schedules for caisson and compressed air tunnel workers are inadequate to prevent osteonecrosis.¹¹⁷ Hyperbaric oxygen decompression seems to be the only viable method for safely decompressing tunnel workers. This technique has been successfully used in Germany, where only hyperbaric oxygen decompression of compressed air workers is permitted, as well as in France and Brazil. Once osteonecrosis has occurred, hyperbaric oxygen therapy has been demonstrated to limit bony destruction in animal studies.¹¹⁸ Elimination of weight bearing on joints offers symptomatic relief and may retard progression of joint destruction. NSAIDs are of modest value. Aggressive surgical approaches, including arthroplasty, are effective but involve considerable rehabilitation. Many surgeons recommend core decompression for the treatment of osteonecrosis in the early stages of hip and knee involvement.¹¹⁹ The rationale is that early ischemic changes result in elevated pressures within the affected bone, which further compromise the vascular supply. The procedure allows histologic confirmation of osteonecrosis, measurement of pressure within the affected bone, and therapeutic decompression. The efficacy and safety of the procedure are debatable.¹²⁰ Affected workers require long-term follow-up, as lesions can develop in previously normal areas and progression of previously identified lesions may occur, even in the absence of further exposure to hyperbaric pressures.¹²¹

FLUOROSIS

Musculoskeletal manifestations from exposure to fluoride were initially described by Moller and Gudjonsson in 1932.¹²² During the winter of 1931 to 1932, these authors

investigated employees of a factory that processed cryolite, which contains sodium, fluoride, and aluminum, and which is frequently mixed with quartz. The investigators were struck by the abnormal appearance of the thoracic vertebrae, clavicles, and ribs on chest X-ray studies of these exposed workers. The bone appeared peculiarly dense and coarse. Moller and Gunjonsson performed skeletal surveys of 78 workers and found that among 30 (38%), there were distinct osseous changes. The workers also complained of acute nausea, vomiting, and anorexia with cryolite dust exposure, which predictably disappeared when the exposure was removed.

Seventy years later, the spectrum of fluorosis has been recognized in other industries and with other environmental exposures, but the clinical syndrome remains essentially as that described by Moller and Gudjonsson.¹²³ Significant fluoride exposure may occur in the mining and processing of cryolite, fluorspar, and apatite, which occur in sedimentary rock. Fluorides are used in the processing and manufacture of aluminum, nickel, copper, gold, and silver.^{124,125} Fluoride also is used as a preservative and a bleaching agent, and is a component of certain pesticides.

Epidemiology

At the present time, the most common exposures include fluoridated drinking water and the manufacture of aluminum, fertilizer, and glass. It is estimated that around 350,000 workers in the US are exposed to fluoride. The number of individuals exposed to fluoride in drinking water is more difficult to estimate. However, excessive levels have been noted in parts of India, China, Africa, and South America.¹²⁶ Because fluoride intake is related to both the concentration and the amount of water consumed daily, environmental fluorosis occurs more commonly in hot climates, with increased water consumption. Fluorosis has been noted in 3000-year-old human mandibles from the Arabian Gulf region.¹²⁷ In China, the risk of fluorosis is elevated in areas where high-fluoride coal is burned indoors.^{128,129}

Metabolism and pathogenesis

Fluoride may be inhaled or ingested. Ninety percent of fluoride taken by mouth is absorbed through the gastrointestinal tract. Systemic absorption of inhaled fluoride depends largely on the particle size. Of absorbed fluoride, 50% is excreted in the urine within 24 hours. Of the remainder, 99% is taken up by the bones. The half-life of fluoride in bone may reach 8 years. In bone, fluoride displaces hydroxy residues from apatite, forming fluorohydroxyapatite.

The mechanism of fluoride's toxic effect is not well understood. Recently, hyperparathyroidism was correlated with an increase in fluoride ingestion, and the severity of skeletal fluorosis was observed to parallel an increase in parathyroid hormone (PTH) concentration.¹³⁰ Fluoride has been observed to stimulate osteoblasts, resulting in new bone formation. With increasing concentrations of fluo-

Daily exposure	Sequelae
1 to 2 mg	None
2 to 4 mg	Tooth mottling No skeletal changes
8 mg	Skeletal changes rare
20 to 80 mg	Crippling skeletal disease

Table 23.5.3 Sequelae of increasing exposure to fluoride

ride, the new bone is woven rather than lamellar. At 1 to 2 mg/day, a typical dose achieved in water fluoridation programs, no adverse effects are seen. At 2 to 4 mg/day, the dental enamel becomes mottled, but no skeletal changes are observed. At approximately 8 mg/day, osteosclerosis has been observed in a small fraction of exposed individuals. Crippling fluorosis with advanced bony changes has been observed following exposure to 20 to 80 mg/day of fluoride for 10 to 20 years. Workers exposed to less than 8 mg/day of fluoride have had no skeletal changes following as much as 14 years of observation. The Occupational Safety and Health Administration (OSHA) has established a limit of 2.5 mg of fluoride per cubic meter of air averaged over an 8-hour shift (Table 23.5.3).

Clinical manifestations

Early diagnosis of fluorosis is made on the basis of history of exposure, with concomitant musculoskeletal and, often, gastrointestinal symptoms. Musculoskeletal symptoms include vague joint pains and restriction of movement. Pain in the heel, hand, and other sites may arise from bony exostoses at the sites of ligamentous or muscular attachments. Bone pain may become diffuse. Gastrointestinal symptoms include nausea, loss of appetite, and vomiting, which occur acutely on exposure to fluoride. Some adaptation to these effects has been noted over time. Short-term exposure also may cause irritation of the eyes and respiratory tract. Advanced cases may be accompanied by kyphosis, limitation of chest expansion, and severe contractures of joints, including the knee and hips. Spinal stenosis may result from impingement of the spinal cord and roots by exostoses in the spinal canal. Radiographic changes occur after significant exposure and are less useful in diagnosing early disease. Characteristic findings include sclerosis and coarsened trabeculae of the vertebrae, along with vertebral fusion (Fig. 23.5.6). Bony exostoses are noted at the attachments of muscles, ligaments, and tendons. Bony overgrowths also may be noted in joint capsules and interosseous membranes. The differential diagnosis of these radiographic findings include AS and other spondyloarthropathies, diffuse idiopathic skeletal hyperostosis, and vitamin A intoxication.

Prompt removal from exposure is mandatory for workers with fluorosis and was until recently the only available treatment. A double-blind, controlled trial was conducted to examine the effect of a combination of calcium, vitamin D3, and ascorbic acid supplementation in fluorosis-affected children.¹³¹ A significant improvement in dental

Figure 23.5.6: A: Cervical spine: 12-year-old child affected by endemic osteofluorosis. Note increased sclerosis of vertebral bodies and base of skull, with abnormal bone formation evidenced by decreased height of vertebral bodies. B: Pelvis: note unusual trabecular pattern and early sclerosis of pubic and ischial bones. The sacroiliac joints and Y cartilages are prominent, and the lumbar bones are of decreased height in this young child affected by endemic osteofluorosis. (A and B courtesy of David Christie, MD.)

and skeletal fluorosis was noted in these children. This study suggests that fluorosis may be somewhat reversible, at least in children. Further studies are needed in adults. Gradual improvement in symptoms has been noted in some exposed workers upon retirement.

MUSCLE DISORDERS

Muscle may be the target of inflammatory, infectious, metabolic, traumatic, and toxic insults, including environmental exposures. Most muscle disorders are associated with weakness, pain, or clinical evidence of muscle damage. Inflammatory muscle disease is termed polymyositis if there is no evidence of characteristic skin lesions over the hands and extensor surfaces, and dermatomyositis if such lesions are present. These disorders are generally idiopathic. However, cimetidine and D-penicillamine may induce a polymyositis syndrome, suggesting that environmental agents may do likewise, although specific evidence is currently lacking. A variety of drugs cause myopathy associated with myalgia and weakness, including chloroquine, colchicine, and the HMG-CoA reductase inhibitors, particularly when combined with lipid-lowering therapy.

Rhabdomyolysis refers to acute destruction of muscle cells, leading to weakness and marked elevation of creatine kinase. Rhabdomyolysis may occur in response to a variety of agents, including alcohol, drugs, prominent overexertion, thermal stress and infection. The urine is characteristically darkened by myoglobin. Treatment consists of removing the offending agent, hydrating, alkalinizing the urine, and providing supportive care.

Malignant hyperthermia is a group of inherited disorders that are characterized by rapid increases in core temperature from 39°C to 42°C in response to inhalation anesthetics such as halothane, methoxyflurane, cyclopropane, and diethyl ether; or muscle relaxants, most commonly succinylcholine. In the autosomal dominant variety, individuals are normal between attacks, but 50% of patients may have an elevation in creatine phosphokinase and 90% experience muscle contractions following exposure to concentrations of caffeine, halothane, or hexamethonium that would not normally cause symptoms. A recessive form of the disease is associated with a number of congenital musculoskeletal abnormalities. It is believed that this disorder results from the release of calcium from muscle endoplasmic reticulum on exposure to the triggering agents. The endoplasmic reticulum is believed to be defective in storing the calcium ion. The result is a sudden increase in myoplasmic calcium, which activates myosin ATPase, which, in turn, converts adenosine triphosphate to adenosine diphosphate, phosphate, and heat. This disorder is exceedingly rare but may arise in occupational settings. Denborough and associates reported a case of a worker involved in the production of fire extinguishers who complained of malaise, stiffness, and weakness in his forearms and hands during the work week which improved on weekends.¹³² His serum creatine kinase was markedly elevated. The plant used bromochlorodifluoromethane, which has a structure similar to halothane. The worker had rhabdomyolysis due to recurrent exposures to this agent. Avoiding occupational exposure to halogenated hydrocarbons resulted in improvement in symptoms.

Metallic poison from lead, arsenic, and antimony produces two types of striated muscle lesions. One is muscular atrophy secondary to neuritis, and the other is a fibrous

pattern of degeneration. No proliferation of sarcolemmal nuclei or other reactive changes have been observed, even in the most chronic stages of lead poisoning, and the significance of these changes and their clinical importance are not clear.

Chapter 24

Cardiovascular Disorders

Lawrence J Fine, Linda Rosenstock

Despite the marked decline between 1985 and 1997 of about 30% in the age-adjusted death from coronary heart disease in white men and women, coronary artery disease (CAD) remains the leading cause of death in the United States.¹ Although identification and modification of cardiovascular risk factors is an ongoing area of intense investigation, the contribution of known major risk factors (advanced age, male gender, hypertension, low serum HDL-cholesterol and high serum LDL-cholesterol, smoking, physical inactivity, and type II diabetes mellitus) does not explain a significant fraction of the cases of coronary artery disease.² There is active research on a variety of other risk factors from socioeconomic status to genetic factors.³ Research during the last 50 years has established that a limited number of chemical exposures directly cause or substantially contribute to coronary artery disease.

In the last two decades, there has been increased interest in the possibility that other aspects of work play a role in causing heart disease. The psychosocial or work organization characteristics of work are examples of non-chemical exposures that are the focus of research studies. In some of the research the significant relative risks are modest in magnitude, but because these psychosocial exposures are common, from a public health perspective, they may still be important. With common conditions like CAD, modest additional increases in risk may lead to a substantial number of potentially preventable cases. One of the complexities of investigating a common disease of multifactorial causation is that the suspected occupational risk factor can either directly or indirectly contribute by affecting one of the causal factors. Lead, for example, may cause systolic arterial hypertension even at low levels of exposure and, thus, indirectly contribute to CAD.

Several occupational exposures have been definitively linked to cardiovascular conditions, including CAD and dysrhythmias. A larger number of occupational exposures have been implicated in at least one investigation as causally related to a wide range of cardiovascular conditions such as hypertension, and it is possible that with further study additional occupational and environmental exposures may be similarly implicated. Cohort studies have found modest elevations in the rate of coronary artery disease in workers very highly exposed to 2,3,7,8-tetrachlorodibenzo-p-dioxin and very modest elevations for some groups of cardiovascular diseases in workers from mercury mining and refining facilities.^{6,7} Several agents are definite cardiac toxins at high levels of exposure, such as carbon monoxide or fluorocarbons, but their effects at more typical levels of industrial use are less clear.

Suggestions about occupational risk for CAD also come from studies which either (1) examined a wide range of occupations in order to identify occupations associated with elevated rates of cardiovascular diseases, or (2) were primarily undertaken to study the relationship between cancer and occupation and observed significant increases in cardiovascular mortality. In European studies of the latter type the occupation with the most consistent elevated risk for CAD not explained by traditional risk factors is urban professional drivers such as truck drivers or bus drivers.⁴ Occupational psychosocial stressors may explain this association.⁵ Consideration of psychosocial stressors at work is increasingly being integrated with the large body of research on heart disease and the social determinants of health such as education, socioeconomic status, gender and ethnicity. Investigators in Denmark postulated that 16% of the premature cardiovascular mortality in men and 22% in women in Denmark might be related to occupational factors. The three most common suspected factors were monotonous high-paced work, shift work, and passive smoking.⁸ A similar estimate was adopted by The European Heart Network in July 1998.⁹

CLINICAL EVALUATION

History

The medical history will usually direct the clinician to suspect correctly the presence of heart disease in the symptomatic patient. A careful history should include a search for symptoms suggesting myocardial ischemia, especially exertional chest pain (angina). Cardiac dysrhythmias are often asymptomatic but may be associated with palpitations and, if cardiac output is compromised, dyspnea, light-headedness, and syncope. Right, left, or biventricular dysfunction, regardless of cause, will often produce symptoms of fatigue and dyspnea. Non-coronary vascular disease secondary to atherosclerosis is suggested by symptoms consistent with end-organ ischemia, such as claudication or transient cerebral ischemia (TIA).

The occupational history should focus on eliciting possible exposures to known or suspected occupational cardiovascular toxins or risk factors. This aspect of the history should identify any changes in symptoms relative to variations in time at work or type of work. A foundry worker, for example, who is exposed to carbon monoxide and heat might complain of angina at the end of a workday at the time when his carboxyhemoglobin levels would be highest.

Any clues in the history that are reliable indicators about the level of exposure are important. In terms of chronic effects, a careful determination not only of the intensity but the duration of exposure is particularly important.

Examination

A routine, comprehensive cardiovascular examination should be performed, including a thorough evaluation of the peripheral vascular system with a description of the presence, strength, symmetry, and auscultatory findings of peripheral pulses. A search for end-organ effects should include a careful fundoscopic evaluation of retinal blood vessels. The physical examination should also include evaluation of other organ systems that may explain the patient's symptoms, such as the respiratory system, or that may in turn show evidence of the sequelae of cardiovascular dysfunction, such as hepatic enlargement in congestive cardiomyopathy. Rarely, findings in other organ systems may also implicate an occupational etiology; for example, the presence of polyneuropathy in a worker who has been heavily exposed to carbon disulfide and who has symptoms of coronary heart disease.

Laboratory evaluation

The laboratory evaluation, as is the case for cardiovascular disease of any cause, should be a directed one and based on symptoms and signs and suspected or known physiologic abnormalities. The resting electrocardiogram (ECG) may be helpful in evaluating ischemia, dysrhythmias, and hypertension. Continuous ambulatory rhythm monitoring may identify abnormalities not seen on the resting ECG and may allow for an assessment of the relationship among exposures, symptoms, and dysrhythmias. Chest radiography aids in the evaluation of heart chamber size and other anatomic abnormalities, such as valvular calcification or enlarged pulmonary arteries. Cardiac imaging techniques and catheterization play important roles in the assessment of cardiac function and the evaluation of coronary artery disease. In seeking evidence of current exposure, specific tests, such as carbon disulfide metabolites (2-thiothiazolidine-4-carboxylic acid), carboxyhemoglobin levels, or carbon monoxide in exhaled air, should be undertaken based on the exposure history and degree of suspicion about its relation to the identified abnormalities.

CLASSIFICATION

The following is a classification of occupational cardiovascular disorders. These disorders are discussed in detail throughout the rest of this chapter.

1. Coronary artery disease.
2. Dysrhythmias.
3. Hypertension.
4. Cardiomyopathy.
5. Peripheral vascular disease.
6. ECG abnormalities.
7. Cor pulmonale.

CORONARY ARTERY DISEASE

Cardiac ischemia, which results from an imbalance between the heart's demand for oxygen and the delivery of oxygen to the myocardium, most often is caused by CAD. Causes of cardiac ischemia may be either acute, which transiently result in increased demands for oxygen (such as during vigorous work in a hot humid climate), or chronic, which contribute directly or indirectly to the development of CAD. Among occupational exposures, only carbon disulfide (CS₂), carbon monoxide, methylene chloride, nitrate esters, and physical inactivity at work have been definitely linked to acute cardiac ischemia or CAD, with strong causal associations established for CS₂ and physical inactivity at work. There is substantial scientific evidence that non-occupational exposure to sidestream smoke from cigarettes is causally related to a moderate increase in the risk of dying from CAD among spouses of cigarette smokers, and there is some evidence that occupational exposures to sidestream smoke have been higher than home exposures.

Other occupational factors for which there is considerable evidence for a relationship are adult social class linked to occupation and possibly psychosocial stressors, such as monotonous high-paced work where the employees also have little control over the pace or methods of work. For a much larger group of exposures there is either less evidence, or they simply have been proposed as possible causes of cardiac ischemia, either by their acute effects or by contributing to the development of CAD. This group of occupational exposures includes arsenic, cobalt, inorganic mercury, high temperature, shift work, standing at work, and low-frequency noise. The occupational factors most strongly associated with cardiac ischemia are discussed separately.

CS₂

A solvent and chemical intermediate known to be neurotoxic for more than a century, CS₂ has been implicated as the cause of chronic cardiovascular disease since the 1940s. An increase in CAD mortality has often been observed in a number of CS₂-exposed populations from different countries; however, the findings of these studies are sometimes in conflict. Overall, the trend over time has been a declining risk for exposed workers because levels of exposure have declined from earlier levels. For example, a 10-year prospective Finnish study found a two- to five-fold greater relative risk of dying from CAD in workers exposed to CS₂ before 1970. This increased risk was noted by age 50 years in workers with 15 years of exposure.¹⁰ A Japanese study found no evidence of increases in CAD, but a substantial increase in the frequency of retinal microaneurysms was observed.¹¹ This marked difference between the Japanese and Finnish studies led to an interesting collaborative research effort. Joint teams of Japanese and Finnish investigators studied workers from their respective countries. They confirmed that Japanese CS₂ workers have a high rate (25%) of retinal microaneurysms; their Finnish counterparts have a low rate (4%) of such hemorrhages. The

reason for this disparate result may reflect the interaction between such factors as exposure, diet, and the difference in the prevalence of CAD or hypertension between the countries and other lifestyle variables.

Since the publication of the first mortality studies, several of the earlier cohorts have been updated, and other cohorts have been reported, including a large American cohort.^{12,13} Together these studies confirmed the definite association between exposure to CS₂ in the production of rayon and excess mortality from CAD. The follow-up of the Finnish cohort documents the success of their intervention program, instituted after 1972, which included substantial reductions in the level of exposure to CS₂. This is an example of the effectiveness of primary and secondary prevention triggered by a research study and effective implementation of a control program.¹⁴

Several important questions remain inadequately answered. The precise shape of the relationship between exposure and effect and the mechanism of the action of CS₂ are unknown. There is a difference of opinion whether long-term exposure below the TLV-TWA (threshold limit value/time-weighted average) (31 mg/m³) may cause increased mortality from CAD.¹⁵⁻¹⁷ More precise elucidation of the exposure-response relationship for cardiovascular mortality will require studies with more detailed characterization of lifetime exposures at the lower (current levels) of exposure. Another important issue is whether CS₂ exposure contributes to atherosclerosis at locations other than the coronary arteries; the potential to do so is suggested by the elevated rate of retinal microaneurysms in the studies from Japan. The largest American mortality study, however, did not find an increase in the mortality rate from cerebrovascular disease, suggesting that, if there is a general atherosclerotic effect in US workers, it is not marked at the average duration and level of exposure studied.⁸

In addition to mortality from CAD, several studies have addressed the possible mechanisms, pathways, and cardiovascular morbidity from CS₂ including changes in blood lipids, heart rate, diastolic blood pressure, and carotid artery distensibility. While the results of the studies are not consistent, a few investigations identified absence of mortality effects below the TLV-TWA. Some findings indirectly support the validity of the older NIOSH recommendation, an exposure one-tenth of the TLV-TWA, of 1 mg/m³.¹⁸ One study found in a population with geometric mean exposures in the range of less than 2.2 to 13.0 mg/m³ that CS₂ may have caused significant decrement in carotid artery wall distensibility and an increase in heart rate but no changes in level of blood pressure or blood lipids.¹⁹ Another study in the United States found a significant and positive linear trend between low density lipoprotein cholesterol (LDL) and exposure after adjustment for confounders.²⁰ In this study the low exposed workers had median CS₂ exposures of 3.1 mg/m³, moderate exposed had exposures of 13 mg/m³, and high exposed had exposures of 24 mg/m³.

A large Japanese study found no differences in blood lipids, blood pressure, or carotid artery wall stiffness, but did find the prevalence of microaneurysm of the retinal artery was significantly higher in workers exposed to CS₂.²¹

The median current exposure was 13 mg/m³ for CS₂ and 1.5 mg/g Cr for 2-thiothiazolidine-4-carboxylic acid (TTCA) levels in the urine post-shift. Overall the research on CS₂ shows that exposures have been reduced over the last few decades, with a resulting reduction in the level of risk for mortality from work-related CAD in Europe and United States. Nevertheless at current levels of exposure, which in general seem to be below the TLV of 31 mg/m³, there is some evidence of exposure-related abnormalities or dysfunction which may be harbingers of a possible remaining low level of risk for work-related cardiovascular disease in long-term exposed workers at current levels of exposure. There are also few animal studies of the adverse toxic effects of exposures above and below the TLV level.^{22,23} These animal studies confirm that CS₂ interacts with a diet high in saturated fat to accelerate the arteriosclerotic process at levels of exposure similar to those found in epidemiological studies. Animal studies suggest that the interaction between non-work-related and work-related factors is substantial. Like lead, CS₂ appears to operate by several pathways or mechanisms by which damage or dysfunction occur.

Diagnosis and treatment

The diagnosis of CS₂-related CAD rests on the documentation of exposure by the work history and, when available, biologic monitoring of exposed workers through direct measurements of CS₂ in the blood or urine or by urine metabolites. The duration of exposure probably needs to be at least several years before adverse cardiovascular effects occur, and the adverse effects are dependent on the intensity of the exposure. Treatment does not differ from the usual treatment of CAD, although further exposure should be eliminated. TTCA measurements in the urine are an effective method of biomonitoring and have been used in the United States.^{24,25} Whether elimination of further exposure halts progression is unclear. Prevention generally can best be accomplished by engineering means, with complete enclosure of any operation using CS₂ to minimize human exposure. The NIOSH recommends an exposure limit of 1 ppm or 3.1 mg/m³; the exposure limit set by the Occupational Safety and Health Administration (OSHA) is 10 ppm or 31 mg/m³. There are diverse views about whether the present exposure standard in the United States is sufficiently protective.^{12,13}

Nitrate esters

Nitrate esters, of which nitroglycerin (NTG) is the most well known, have a long history of use both as pharmaceuticals and explosives. Exposures to NTG and ethylene glycol dinitrate (EGDN) in the explosives industry are the most extensively studied. In addition to their oxidant properties and potential to induce methemoglobinemia, nitrates have acute effects of variable onset and duration as arterial vasodilators. Among regularly exposed workers, these vasodilatory effects may result in headaches. Commonly, a tolerance develops so that the headaches occur only after re-exposure after several days away from

work. Sufficiently high acute exposures can also cause systemic hypotension and confusion.

In older studies, the association between episodes of anginal pain, myocardial infarction, and cardiovascular death and acute occupational exposures to nitrate esters in the manufacture of explosives was convincing.^{26,27} Nevertheless, these studies have provided conflicting evidence about whether, in addition to these acute effects, there are additional chronic sequelae. Hogstedt and colleagues studied two cohorts of Swedish workers exposed to NTG and EGDN.^{28,29} Both cohorts had significantly increased death rates of about two-fold from CAD; the elevated rate continued even after exposure had ceased, suggesting a delayed chronic effect. Because these exposures were in the past, they most likely were higher than current exposures, although a precise determination of levels of exposure is difficult to obtain because EGDN and NTG can be absorbed through the skin.

However, an epidemiologic study in the United States involving exposure to NTG and dinitrotoluene found no evidence for a delayed chronic effect of NTG exposure on the risk for mortality from cardiovascular disease, but it did find a three-fold increased risk in younger men for acute cardiac deaths. However, after the start of a more comprehensive screening program for CAD in this workforce, no more excessive cardiac deaths were observed.³⁰ Most of these deaths occurred in men with current exposure. It is possible that a chronic effect on cardiovascular disease is restricted to exposures involving EGDN but not NTG. Earlier clinical reports had suggested that sudden death in exposed workers could occur in workers without pre-existing clinical CAD. The findings of the US cohort may not be consistent with this observation.

When, after 1970, exposed members of the cohort were screened every 6 months for hypertension, resting ECG abnormalities and treadmill ECG, the risk of death from CAD declined to normal. Although the association between exposure to NTG and EGDN or other nitrates in the explosives industry and death from adverse cardiac effects is convincing, prospective studies are needed of currently exposed workers who would likely have substantially lower exposures to determine whether excess cardiac deaths are still occurring, and whether there are chronic persistent effects from low-level exposures. Nevertheless, convincing case reports suggest some current exposures are hazardous.³¹

Pathogenesis

While the specific pathogenic mechanism of nitrate-induced cardiac ischemia is unknown, two types of acute cardiac effects have been described. The first is rebound vasospasm. This may occur up to several days following cessation of exposure. Coronary artery spasm induced in this fashion can result in myocardial ischemia and necrosis, dysrhythmias, and sudden death. The second acute effect of exposure to nitrates is the paradoxical occurrence of dysrhythmias after re-exposure to nitrates after a period away from work, typically on Monday or after vacations.

Diagnosis

The diagnosis of the nitrate-induced ischemic disease depends on the patient's history and, in particular, the timing of exposures in relation to symptoms. The cases in the scientific literature have been reported only from the explosives industry.

Prevention

Prevention of acute and postulated chronic effects of nitrates depends on the reduction of all exposures. Although some explosives producers have attempted to eliminate all at-risk workers from exposed areas by identifying all workers with evidence of CAD with medical screening, this may not identify all susceptible workers. It is not known whether workers with stable CAD are at elevated risk from exposure to nitrate esters. Neither is it clear how to mitigate routinely the effects of exposure-re-exposure transitions. It is possible that workers without CAD also may be at elevated risk. Non-lethal symptoms, like headache, should alert all to the potential for more serious sequelae.

Carbon monoxide

In contrast to CS₂ or nitrate esters, carbon monoxide exposure is more common. It exerts its primary adverse health effects through its avid binding to hemoglobin, with a resultant decrease in tissue oxygen delivery. Carbon monoxide also binds to the cytochrome oxidase system in the mitochondria of cardiac muscle and may, thereby, directly decrease myocardial contractility. The potential effects of single excessive exposures include myocardial ischemia or infarction, dysrhythmias, and sudden death. It is not until higher levels of carboxyhemoglobin are reached, usually above 25%, that manifestations of ischemia, dysrhythmias, and ECG abnormalities are likely to be observed in otherwise healthy workers. Most of these acute high exposures will occur from combustion sources, such as during firefighting.^{32,33}

The consequences of repeated low-dose exposures are not completely understood. Two types of studies have been conducted, i.e., experimental studies in which patients with CAD are exposed to low levels of carbon monoxide and epidemiologic studies of cohorts of exposed workers. Workers exposed on a continuous basis to levels of carbon monoxide within current OSHA-allowable limits (50 ppm) may achieve carboxyhemoglobin levels of 5% or more, levels comparable to those achieved by moderate to heavy cigarette smokers. Levels of non-exposed non-smokers will generally be below 1%. The most common source of exposure is the exhaust from gasoline engines.³⁴ The current OSHA permissible exposure limit (PEL) for CO is 50 ppm as an 8-hour time-weighted average (TWA). The NIOSH recommended exposure limit (REL) for CO is 35 ppm as an 8-hour TWA and a ceiling limit (CL) of 200 ppm. The American Conference of Governmental Industrial Hygienists (ACGIH) has adopted a threshold limit value (TLV) for CO of 25 ppm as an 8-hour TWA.³⁰

NIOSH recommended immediately dangerous to life and health concentration (IDLH) for CO is 1200 ppm. The IDLH is the concentration that could result in death or irreversible health effects, or prevent escape from the contaminated environment within 30 minutes.

The acute cardiac effects of carbon monoxide are likely to be principally dependent on the ability of coronary arteries to increase blood flow to the myocardium in response to the hypoxic stress of carbon monoxide. As a result, the effects of relatively low-level exposure to carbon monoxide may be substantially different in individuals with CAD than in those without CAD. Experiential studies in patients with CAD who are exposed to low levels of carbon monoxide during exercise have identified acute adverse effects at elevated carboxyhemoglobin levels of 2–6%; these adverse effects include limitations of exercise capacity as indicated by ST-segment depression, development of angina, or increase in the frequency of multiple ventricular premature depolarizations.^{35–38}

Overall, mortality studies of workers exposed to carbon monoxide provide some evidence to support the hypothesis that the adverse effect of chronic carbon monoxide exposure is acute or subacute only and does not persist many years after exposure ceases. Cohort mortality studies of two groups of workers with intermittent exposure have been reported, i.e., iron foundry workers, and tunnel workers. The carbon monoxide exposures in iron foundries are highest in the furnace and pouring areas. Most mortality studies of foundry workers focus on non-malignant respiratory disease or cancer. Several, however, also examined cardiovascular mortality in the furnace and pouring operations, where the carbon monoxide levels are likely to be the highest. Four of these latter studies demonstrate increased risk for either CAD or total cardiovascular mortality for workers in the furnace, melting or pouring operations,^{39–42} with one of the positive studies documenting carbon monoxide levels in the range of 85–110 mg/m³ (75–96 ppm).³⁵

In an earlier morbidity study of this cohort, there was suggestive evidence of an interaction between smoking and carbon monoxide exposure in causing angina.⁴³ In another of the positive foundry studies, the median levels were from 20 ppm to over 100 ppm.³⁶ One of the few additional studies with more detailed information on exposure is a study of New York tunnel workers who collect tolls and walk the tunnels. This study found a significant increase of 35% in the mortality rate from CAD in the tunnel workers.⁴⁴ The excess appeared to decline after 1970, when the carbon monoxide levels were reduced by improved ventilation. Prior to 1970, the levels averaged more than 50 ppm, with some peaks above 400 ppm. The study noted that the excess mortality was limited to the first few years after employment; as a result, the authors concluded that the risk declined after cessation of employment (i.e., a cessation of occupational exposures). In a more recent investigation of this cohort, the exposure levels for carbon monoxide were very low and therefore it is not surprising that there was also no carbon monoxide exposure disease relationship in active workers.⁴⁵

If older study findings such as the Stern investigation of tunnel workers are correct, that the increased risk from carbon monoxide exposure is moderate, it is not surprising that the other mortality investigations of other occupations with intermittent exposures have not detected the increased risk. The Stern study was more likely to detect an effect because it used an internal comparison group (i.e., the bridge workers who were hired in a similar manner to the tunnel workers). This study also may have had less misclassification of exposure with a higher fraction of those who were considered exposed by the investigators actually being exposed. In summary, the Stern study and the two foundry studies provide evidence that exposures to carbon monoxide above 50 ppm are associated with an increased risk of death from CAD. The effect most likely involves acute or subacute mechanisms. However, the acute effects in experimental studies in patients with CAD at lower levels of exposure to carbon monoxide suggest caution in assuming that there are no effects at low levels for workers with CAD and ischemic-related arrhythmias or angina.

Pathogenesis

The two most likely mechanisms for the acute effects of carbon monoxide involve the indirect effect of reducing the oxygen-carrying capacity of hemoglobin by the formation of carboxyhemoglobin, as well as the direct effect on cellular metabolism.

Diagnosis and treatment

Recognition of carbon monoxide-induced cardiovascular toxicity relies on the exposure history and clinical setting. Acute exposures that produce carboxyhemoglobin levels above 25% may pose a cardiac hazard even for individuals with a normal cardiovascular system; lower levels pose primarily a cardiac hazard for individuals with significant CAD. This is presumably because workers with normal coronary arteries can increase the oxygenated blood supply to the heart to compensate for the reduced capacity related to the carboxyhemoglobin level. It is likely that exposure to low levels of carbon monoxide, such as 35 ppm, causes a reduced exercise tolerance and reduced threshold for angina. Many cigarette smokers have a carboxyhemoglobin level of 5%, which is the level that a non-smoker would reach if exposed to 35 ppm for 8 hours a day.

Acute cardiac events occurring under circumstances in which carbon monoxide exposure is suspected, such as smoke inhalation or work in an enclosed space with an operating fuel-burning engine or furnace, could be causally related: carboxyhemoglobin levels should be obtained, and oxygen therapy immediately begun. With very high level of exposure, treatment with hyperbaric oxygen may be indicated⁴⁶ (see Chapter 36).

Patients with new-onset angina or exacerbations of angina at work should be closely questioned regarding possible exposure. Checking a carboxyhemoglobin level after a typical work shift may be helpful. Treatment is the prevention or reduction of exposure.

Methylene chloride

A solvent in common use, methylene chloride (dichloromethane) has cardiotoxicity because of its metabolic conversion to carbon monoxide. The biologic half-life of carbon monoxide from this source is longer than that of the inhaled gas. Methylene chloride exposure should be considered in any individual with a clinical presentation consistent with carbon monoxide toxicity, such as anginal symptoms worsening at work, and should be recognized as additive to other occupational and environmental sources of exposure to carbon monoxide. Stewart and colleagues described an individual who had three myocardial infarctions, each following an exposure to methylene chloride in a confined space.⁴⁷

Exposed workers in a triacetate fiber production process had average values of COHb ranging from 1.77% to 4% in the non-smoking group, and between 4.95% and 6.35% in a smoking group, with individually measured methylene chloride exposures averaging up to 99 ppm (8-hour TWA).⁴⁸ While there was no simple relationship between the workers who were smokers and their COHb levels, there was a linear relationship between exposure and COHb level in the non-smokers that were not influenced by exposures on the previous day.⁴⁹ NIOSH and OSHA have documented high exposures to methylene chloride in the furniture-stripping industry and other industries.^{50,51} Several epidemiologic studies have not found an association between mortality from heart disease and methylene chloride in the chemical industry.⁵²⁻⁵⁴ The clinical evaluation needs to focus on the intensity and duration of the exposure, as well as on the carboxyhemoglobin level of an acutely exposed employee.

Passive smoking

There is substantial epidemiologic evidence that exposure to environmental tobacco smoke (ETS) is an important public health factor in deaths from CAD.⁵⁵ Most studies have found that non-smokers living with smokers have about a 30% increased risk of death from CAD. While there is some difference of opinion about the strength of the epidemiological evidence for the risk of cardiovascular disease from occupational passive smoking exposure, a meta-analysis of eight studies yields a significant relative risk of 1.21.^{56,57} While the median levels of workplace concentrations of nicotine in areas where smoking is allowed are lower than in homes where smoking occurs, the range of level of exposures is larger in workplaces (with some having very high levels of exposure).^{58,59} According to the NHANES III study (1988–1991), a representative sample indicated that nearly 40% of US workers report being exposed to ETS in the workplace.

The 1999 data from NHANES suggest that for the entire US population there has been a 75% reduction in the average level of exposure to ETS based on serum cotinine levels. Some of this reduction may be the result of changes in workplace smoking policies. There are a variety of possible biologically plausible explanations for the effect of ETS,

ranging from effects on platelet aggregation to small increases in the level of blood carboxyhemoglobin.⁶⁰ In summary, environmental tobacco smoke is likely one of the most common workplace exposures to a potential occupational cardiac toxin. In 1999, Steenland estimated that approximately 1700 deaths from CAD per year may be related to occupational ETS exposure among non-smoking US workers 35–69 years of age.⁵²

Arsenic

Arsenic exposure during the manufacture of pesticides and smelting of copper has been associated with an increased risk of developing lung cancer. In one of these mortality studies there was also an increase in the exposure-related risk of dying from cardiovascular disease, although additional follow-up of this Swedish cohort did not demonstrate an exposure-‘heart’ disease relationship, despite a strong relationship between arsenic and lung cancer.⁶¹ Current levels of exposure are substantially lower than the levels to which these Swedish workers were exposed formerly. One of two recent re-analyses of United States copper smelters cohorts also found evidence of exposure-related excess mortality for cardiovascular but not cerebrovascular disease.^{62,63} It seems possible that the high levels of exposure to arsenic during the smelting of copper in the past may have been associated with an increased rate of cardiovascular disease. This premise is supported by the observed acute toxic effect of arsenic compounds on the heart in patients treated with arsenic trioxide and cardiovascular diseases, and also seen in populations chronically exposed to drinking water with high levels of arsenic contamination.^{64,65} It also has been proposed that arsenic at current exposure levels may increase the risk of cardiovascular disease by increasing blood glucose levels.⁶⁶

Air particle pollution and cardiovascular disease

There is increasing evidence that links intermittent increases in the level of fine particulate air pollution to acute increases in the risk of mortality or morbidity from cardiovascular disease in the general population. One recent study concluded that elevated concentrations of fine particles may transiently elevate the risk of myocardial infarctions within a few hours to one day after exposure.⁶⁷ In a Swedish case referent investigation of myocardial infarction and occupational exposure to motor exhaust and other organic combustion products, a significant and dose-related risk for myocardial infarction was observed.⁶⁸ The relative risk was 2.1 among those who were highly exposed after adjustment for a variety of other risk factors such as tobacco smoking, obesity, and physical inactivity in leisure time. Since exposure to combustion products is common, this research study warrants follow-up, particularly since the levels of fine particle exposure are likely higher in some occupational groups than in the urban population.

Stress: physical, thermal and psychologic

Physical and thermal stresses have been implicated in aggravating myocardial ischemia, with or without concomitant clinical CAD. Among physical stress factors, although regular high levels of physical activity mostly likely reduce the risk of dying from CAD, unusually heavy exertional activities, particularly episodic ones, may increase the risk of acute ischemic events among those with underlying CAD.^{69,70} The risk of sudden death in individuals free from clinical CAD, however, was very low at about one sudden death per 1.51 million episodes of exertion. Routine vigorous exercise reduced the risk further but did not eliminate it.⁶⁵ Epidemiologic studies support both the detrimental effect of the lack of physical activity at work (sedentary) and the protective effect of moderate to very high levels of physical activity at work or at leisure (such as brisk walking for 30 minutes each day of the week).^{64,71,72} It is clear that benefits of physical activity clearly outweigh the small risks of transient increase in sudden death associated with vigorous physical activity.

Thermal stress

In the last decade there has been increased interest in the modest acute elevations in mortality rates for CAD in middle-aged and elderly populations associated with ambient temperatures below 18 degrees C.⁷³ The transient increased peak for CAD occurred 2 days after the temperature change and is postulated to be partially related to thrombosis, due to hemoconcentration in the cold, and from other consequences of cardiovascular reflexes that are acutely induced by cold.⁶⁹ These elevations interestingly are greater in regions with warm winters like Greece rather than in cold ones like Finland. In fact, in the coldest city in Siberia, Yakutsk, there was no winter increase in CAD mortality.⁷⁴

The risk seems higher in populations who wear less protective clothing and are less active outdoors and with cooler homes. These population-based studies, which show a relationship between exposure to cold ambient temperatures and mortality from CAD, raise the issue of whether occupational exposures to cold temperatures less than -18 degrees C, particularly when sedentary or inadequately clothed, might increase the transient risk for middle-aged workers with some degree of clinically silent coronary atherosclerosis or clinically evident CAD. Two studies suggest that this may be a useful question to investigate for occupationally exposed workers. A study in Pennsylvania found significant transient increases in the death rate from CAD in men aged 35-49 for either low temperature less than 7 degrees C (RR 2.08) and further increases on cold days with snow fall of more than 3 cm (RR 3.54).⁷⁵ The latter observation could be a combined effect of the cold weather and unusual exertion.

In the CORDIS study, significant increases in the rate of asymptomatic ST-segment depressions during ambulatory electrocardiac monitoring were found among women

workers working at ambient temperatures lower than 20 degrees C after adjusting for traditional CAD risk factors.⁷⁶ Cold temperatures may also aggravate angina, presumably by inducing an increase in peripheral vascular resistance at the same time that myocardial oxygen demand is increased. The cold effect is likely a transient risk factor for CAD mortality. The magnitude of effect in the European studies is very modest and only detectable with very large samples; however, the magnitude noted in the Pennsylvania study is larger.⁷¹

Rarely, acute myocardial infarction may occur after severe heat stroke in young individuals.⁷⁷ In periods of extreme hot weather, the mortality from cardiovascular disease increases; however, compared to cold weather the increases are more clearly linked to those with definite pre-existing risk factors such as old age, pre-existing heart disease, living alone, and being confined to bed.⁷⁸ Two of the three epidemiological studies of heat-exposed workers provide evidence that the longer the duration of exposure to hot working environments, the lower the CAD mortality, presumably because of worker selection or the benefits of physical conditioning.^{79,80} One of the studies did observe an increase in the risk for CAD mortality with increasing duration of employment in a hot mining environment.⁸¹ One new physical factor has been proposed: in one investigation, standing at work was related to the progression of carotid atherosclerosis, particularly in men with CAD or carotid stenosis.⁸² In summary, with regard to the thermal association with CAD mortality, because the impact of colder temperatures on CAD mortality occurs over a broader range of temperatures, it may be a more important issue than occupational exposures to hot environments.

Psychosocial stress

The interplay between socioeconomic factors and work environment in the pathogenesis of CAD has been actively explored by a number of investigators. This body of research divides into two principal areas. The first investigates the role of factors such as income, education, and other socioeconomic determinants in the traditional risk factors for CAD and the mortality from CAD. The second examines the psychosocial occupational environment and the development of CAD. The association between CAD or heart disease mortality and socioeconomic measurements has been investigated. Since two-thirds of all heart disease deaths result from CAD, the socioeconomic pattern for total heart disease mortality is likely similar to CAD mortality.⁸³ In 1997 in the United States for working age men (25-64), persons with incomes under \$10,000 had death rates from heart disease 2.5 times higher than persons with incomes over \$25,000.⁷⁹

Gradients of similar magnitude were observed for most of the other gender, race and ethnic groups in the United States. In the United Kingdom, Ireland, and Nordic countries manual workers compared to non-manual workers have higher mortality from CAD, while in France, Switzerland, and Southern Europe the manual workers had

similar or lower rates than the non-manual workers.⁸⁴ In the United States compared to Northern Europe, differences were smaller for US manual workers aged 30–44 years old, but as large for older American manual workers (aged 45–64).⁸⁰ In both England and United States, while the prevalence of CAD risk factors is higher in lower socioeconomic (SES) groups, the SES gradient for risk factors may not be increasing or fully explain the SES gradient in CAD mortality.^{85,86} In addition to the importance of these SES studies because of their public health significance, from a research perspective they suggest that SES factors must be addressed carefully in studies of the psychosocial characteristics of work and CAD.

There are two common hypotheses that have been proposed for psychosocial characteristics of work that may contribute substantially to an increased risk for CAD. The first, proposed by Robert Karasek in 1979 and later modified by Johnson and Hall, is that the incidence of CAD will be elevated in occupations characterized by low levels of social support (workplace isolation), by jobs with low control or decision latitude (little influence over work methods and opportunities to use skills or learn new skills), and by jobs with high levels of psychological demands (such as deadlines or high work pace).^{87,88} This model is called the job strain or demand–control–support model (DCS) (see Chapter 38).⁸⁹ In many of these studies, the job characteristics are defined based on questionnaire responses from employees (Table 24.1). In this model, the highest risk jobs will be those with low social support, low control, and high demands (job strain).

The second model, proposed by Johannes Siegrist, has three key components. It is called the effort–reward–imbalance (ERI) model. The first component is the rewards of a job. Rewards are measured by level of financial rewards, esteem (similar to prestige and social support), and job security and promotion opportunities.⁹⁰ The second component is job efforts that are related to the level of physical and mental workload. The third component is the

individual's response (personal pattern of coping) to the balance between the effort and reward of his or her jobs. The psychological stress of a job that is related to the imbalance between high demands and low rewards is increased if an individual uses a coping strategy called 'overcommitment'. This strategy involves attitudes, behaviors, and emotions involving excessive effort and a strong need for approval and support from the work situation.⁸⁶ The most adverse or stressful situations thus involve jobs with high demands and low rewards for workers who exhibit the coping strategy of overcommitment. Siegrist believes this model may be particularly useful during difficult economic periods, when some workers may have few alternatives to jobs with low rewards, job security and other job benefits, including downward mobility. Each of these models focuses on identifying common work-related conditions (exposures) that may elicit chronically stressful reactions in workers.

Although the DCS model is sometimes measured subjectively based on workers' questionnaires, theoretically its focus is the objective conditions of work and does not address directly the issue of job security or pay. The ERI model differs in that it addresses the subjective reactions and coping strategy of the worker to the psychosocial working conditions, the level of job insecurity, and salary.

More epidemiological studies have been performed to evaluate the DCS than the ERI model. There are several European studies that have found that either jobs with high demands and low control or jobs with low control regardless of the level of demands are associated with higher rates of CAD morbidity.⁹¹ The earliest European studies had the highest relative risks, and generally provide stronger support for low job control in association with CAD rather than the job strain hypothesis (low control/high demands).⁸⁷ However, findings of only one of the five studies conducted in the United States are clearly supportive of the hypothesis.^{87,92} Most of the earlier European and United States studies involved only male working populations. Three of the largest and most recent European studies of men, which also adjusted for traditional CAD risk factors and socioeconomic status, reported significant relative risks for low job control or job strain in range of 1.3–2.5, depending on the health endpoint and subsample of the population examined.^{93–95}

Two of these European studies also examined the job control or job strain aspect of the DCS model in women workers. They found significant relative risk for job control or job strain in the range of 1.5–1.7, with adjustment for some of the traditional CAD risk factors.^{90–96} While over 20 investigations have examined the DCS model and some measure of CAD, many fewer studies have examined the ERI model.^{83,87} The three prospective studies of this model also adjusted for traditional risk factors, and found significant relative risks between 2 and 4.5.^{83,97} One of these studies compared the relative risks between the alternative job stress models in both women and men. This report also adjusted the relative risks by employment grade, a measure of socioeconomic status, and by traditional CAD risk factors. The significant resulting relative risks for new CAD when both

Job demands scale (0 = yes, 1 = no)

Could talk to coworkers during breaks?
Could leave their job to talk with coworkers?
Could interact with coworkers as part of their work?
Met with coworkers outside of the workplace?
Had met with a coworker during last 6 months?

Table 24.1 Questions used to measure job strain and work support

job stress measures were simultaneously included in the analysis were 2.15 for ERI model and 2.38 for low job control (self measured) and 1.56 for low job control (externally assessed by supervisors).⁸³ The authors suggested that future studies need to further understand the overlapping and unique features of each model. The implication of this study is that a model that focuses both on workers' reactions and the 'objective assessment' of the psychosocial characteristics of jobs, and considers additional factors such as job insecurity, may be a superior model.

Other researchers have also described the important relationship between 'occupational exposure' and subsequent onset of disease. Non-occupational factors affecting this relationship include earlier events in childhood or adult life (life course perspective), the interaction between genetic and environmental factors, the interaction between non-occupational and occupational exposures like social support at work or outside work, personal health habits and ties, and a wide variety of community and societal factors.^{98,99} Because of the complex nature of the interaction with these factors and earlier mentioned socioeconomic and cultural factors, generalizations across groups that vary substantially in socioeconomic or cultural attributes may not hold for either the DCS or ERI model. While some occupational factors may be associated with the development of CAD, others likely will be associated with the promotion of health and possibly reduction of the risk for CAD. While childhood socioeconomic determinants may be related to the subsequent risk of developing CAD, adult exposures including occupational factors appear more important with CAD.^{100,101}

In summary, several reviewers and investigators have concluded that the European studies provide support for the hypothesis that psychosocial aspects of work are related to the risk of developing CAD.^{83,84,88,93} Although this is a potentially important hypothesis from a public health perspective, for this hypothesis to gain more support, particularly in the United States, several additional factors or questions will need to be addressed. Studies in the United States similar to the European studies would add more weight and acceptance of the evidence if they confirmed the findings of the European studies. A basic question is whether there is selection of individuals at high risk into high-strain jobs or selection of individuals at low risk into other jobs. This selection might be the result of a variety of factors, such as educational level. Individuals in these high-risk jobs, for example, might have different access to medical care, or different levels of non-work social support. Because socioeconomic status is associated with cigarette smoking, in some studies the investigators have examined these traditional CAD risk factors as potential confounders, and in general, have concluded that they are not the principal explanation for the differences in CAD mortality or morbidity between high- and low-strain occupations.^{83,91,92}

Another major issue is that the exposure variable in these studies is usually the current job, not an individual's entire occupational experience. Another possible limitation of many of these studies is that the exposure classifi-

cation is based on questionnaire data rather than direct observation of the workplace by the investigators. Finally, the application of these concepts to clinical decision making remains difficult because of the complex interaction between the individual, culture, and work.

Pathogenesis

The mechanism for the potential adverse cardiac effects of psychologic stress is an area of active investigation. Several mechanisms have been proposed.¹⁰² First, specific working conditions, such as time pressure, could cause activation of the hypothalamic-pituitary-adrenal (HPA) axis leading to elevation of hormones such as catecholamines. Second, increased activity in the sympathetic nervous system together with alterations in the regulation of the HPA axis could result either in elevated blood pressure or more frequent dysrhythmias. Third, the work stresses could lead to adverse lifestyle behaviors, such as increased cigarette smoking or obesity. Fourth, work stress may change the rate of progression of precursors of CAD. For example, psychosocial stress in monkeys causes exacerbation of diet-related atherosclerosis, with activation of the sympathetic nervous system; stress also induces endothelial injury mediated by beta-1-adrenoceptor activation, even without an atherogenic diet.¹⁰³ The interaction between the acute and chronic effects of psychosocial stress, and the endocrine, endothelial, and nervous systems, is likely to be complex. Nevertheless, these animal studies suggest biologically plausible mechanisms by which chronic exposure to adverse psychosocial factors could be related to CAD.¹⁰⁴

The diagnosis of stress-related ischemia should be limited to circumstances in which the stressors are clearly identifiable and for which there is strong scientific evidence. Acute events, especially myocardial infarction and sudden death, occurring in the setting of unaccustomed and severe thermal stress associated with heat stroke can be work related. In individuals without clinical CAD, one study estimated the occurrence of one sudden death per 1.51 million episodes of substantial physical exertion, and that routine vigorous exercise reduced the risk further but did not eliminate it.⁶⁵ Anginal patterns temporally related to certain work activities also suggest stress as a precipitant, but chemical factors like carbon monoxide must first be excluded.

Management and prevention

Patients with severe or unstable CAD should avoid episodic, severe unaccustomed work stresses. Cardiac rehabilitation programs and enhancing fitness may be valuable for such workers.

Shift work

Shift work is work occurring outside the normal daytime shift, particularly work between midnight and 6am. The evidence for a possible link between shift work and CAD was recently reviewed; however, findings were inconsistent.¹⁰⁵ One of the most recent prospective studies did not find evidence of a relationship between shift work and mortality from CAD after adjustment for socioeconomic

status.¹⁰⁶ Despite the large number of workers who regularly perform shift work, a clearer picture of whether shift work is related indirectly or directly to the risk of CAD will require further investigation.

DYSRHYTHMIAS

Abnormal cardiac rhythms secondary to ischemia may result from the agents discussed previously. In addition, a number of chemicals have been associated with atrial and ventricular dysrhythmias by mechanisms largely unrelated to ischemia. Such events may occur even in individuals with anatomically normal coronary vessels; however, they are rarely fatal. The levels of exposure that preceded these deaths were not well documented but likely were high. The agents of concern are organic solvents, with both halogenated (particularly fluorocarbons) and non-halogenated chemicals. Evidence for the association between these chemicals and dysrhythmias comes from compelling case reports, clinical studies, and experimental animal investigations.^{107–110} Many of the case reports have been of intentional overexposures, such as glue sniffing (toluene), but a few have also come from occupational settings, including chlorofluorocarbon.^{111,112} With very high levels of exposure, the animal studies and case reports of human inhalant abuse suggest that a wide range of solvents are cardiac toxins.¹¹³ In addition to the association of acute exposure to high levels of non-halogenated and halogenated solvents and acute dysrhythmias, there is more limited and inconsistent evidence for a chronic effect or an effect at lower levels of exposure.^{113–115}

Several epidemiologic studies have been conducted of solvent-exposed workers, principally in rubber, chemical, and dry-cleaning industries. Each of these studies has limitations for evaluating the association between acute intense solvent exposure and CAD mortality. Most of these studies had limited information on the fluctuating level of acute exposures and were designed as cancer mortality studies, not as studies of heart disease. A review of the literature showed no consistent association between solvents with the exception of CS₂ and CAD.¹⁰⁵ One study of trichloroethylene found a modest significant increase in mortality for CAD (SMR of 108) but this association was not dose related and has not been consistently found in other studies.^{116,117} In summary, there is considerable evidence that after high levels of exposure, some non-halogenated and halogenated industrial solvents cause serious dysrhythmias in some individuals. The results of the older studies of moderate levels of exposure to fluorocarbons are in conflict with those of newer studies, which include better measurements of exposure and the finding of no effect. In contrast to the acute effects of high-level exposure, most of the epidemiologic studies on cohorts of workers exposed to industrial solvents have not found evidence of an increased risk of death from heart disease.

Pathogenesis

The pathogenesis of solvent-related dysrhythmias is likely to involve the sensitization of the myocardium to endoge-

nously secreted catecholamines. Direct effects of some of these substances on myocardial contractility may also play a role. In addition, it is possible that with high exposure hypoxia also plays a role because these agents, in general, are also respiratory depressants in animals. The greatest risk for dysrhythmias occurs in situations of overexposures. Other factors that may increase the risk for occurrence of these events include those associated with increased catecholamine production, including physical, psychologic, and thermal stress, or the use of sympatho-mimetic medication. It is plausible that, if these co-factors are present, the level of exposure that would trigger a dysrhythmia may be lower.

Diagnosis

An evaluation should be undertaken for any patient presenting with cardiac dysrhythmias without a known cardiac cause and a history of high levels of exposure to suspected toxic agents. The role of solvents should also be considered in patients with known or suspected rhythm disturbances who experience palpitations or syncope temporally related to exposure. Ambulatory rhythm monitoring may be used to document the presence of dysrhythmias and assess their relation to time at work. If dysrhythmias are present, re-assessment several days after cessation of exposure can provide additional evidence implicating the role of solvents. The role of other possible workplace factors that may be contributing to dysrhythmias should also be assessed.

Management

When workplace exposures are considered to be contributing to observed dysrhythmias, all efforts to reduce exposures should be made. Removal from all further exposure should be recommended when exposure reduction measures fail or the dysrhythmias cause substantial symptoms or hemodynamic effects.

Prevention

Patients with known serious ventricular rhythm disorders should be cautioned about substantial solvent exposure, either occupational or non-occupational (e.g., hobbies). Advising patients who have myocardial disease and are at risk for such disturbances must be done on a case-by-case basis.

HYPERTENSION

A number of occupational factors may play a role in the development of hypertension. These include workplace psychosocial stress, physical factors, such as noise, and chemical exposures, including lead and CS₂. The most extensively studied exposure is lead. Although blood pressure effects may occur at low levels of exposure, the specific effect of lead on blood pressure is still not clearly defined.¹¹⁸ It is not clear if the lead-related effect is only on systolic or diastolic pressure or both, or whether it is an acute or chronic effect. The distinction between acute or chronic effect is complicated because up to 95% of total

body lead burden accumulates in the skeleton with a constant influence on the levels of serum and plasma blood lead. The plasma lead, which constitutes less than 1% of whole blood lead level, may be the biologically relevant lead for effects on the vascular system.¹¹⁴ Overall the evidence suggests a modest increase in either systolic or diastolic blood pressure.

The increase in blood pressure probably occurs at lower levels of environmental or occupational exposure, and the rate of increase may be non-linear with the principal effect occurring at low exposure levels.^{119,120} The increases in blood pressure have been associated with blood lead levels between 7 and 35 µg/dL and bone lead levels of 10 to 50 µg/g.¹²¹ These levels are common in occupationally exposed workers. The potential public health importance of the blood pressure and lead relationship is illustrated by the results of one prospective study of hypertension, a community study of the elderly which found a significant rate ratio of 1.7 for new hypertension cases in highly exposed versus low exposed subjects based on bone lead levels.¹¹⁴ The high exposed group had a mean patellar lead level of 53 µg/g and no subject had a blood lead above 35 µg/dL. Based on animal studies, two mechanisms have been proposed.¹¹⁴ One involves action on arterial smooth muscle, and the other on the renin-angiotensin axis. In contrast to lead, there is little evidence that current exposures to CS₂ are a significant factor in hypertension. At exposures below the TLV value for CS₂ there does not appear to be an acute or subacute effect on blood pressure, although there still may be an effect on carotid artery distensibility.^{9,15}

The relation between chronic exposure to noise and hypertension remains an active area of research. In the last 10 years, studies have yielded inconsistent results for a relation between exposures above 90 dB and increased risk of hypertension or an elevation in either the systolic or diastolic blood pressure, generally after many years of exposure.¹²²⁻¹²⁷ An interesting recent study of chronic noise exposure reported transient increases in systolic and diastolic pressures and heart rate in exposed workers less than age 50. This increase in blood pressure persisted for several hours after exposure; it is postulated that these changes over time might lead to more permanent changes in blood pressure.¹²⁸ Studies of chronic noise exposure and the risk for increased blood pressure are difficult because they require careful prospective assessment of blood pressure and cumulative assessment of noise exposures in a large number of subjects.

The same models of psychosocial stress and job strain that have been used in studies of CAD also have been applied to blood pressure and psychosocial working conditions. Interestingly, ambulatory blood pressure measurements generally are higher on work days compared to non-work days.¹²⁹ In a review of the studies examining the relationship between blood pressure and job strain model, the reviewers concluded that studies using measures of ambulatory blood pressure were more useful than studies of routine blood pressure measured in clinical settings.⁸⁷ These reviewers also concluded that there is substantial

evidence to support the association between psychosocial stress or job strain and significant elevation of blood pressure; however, since the strongest US studies have largely been done by one group, confirmatory studies by other investigators would reinforce their hypothesis.

One of the most interesting studies found a three-fold increased risk for job strain and hypertension during routine screening. In this case-control study, it was possible to consider several potential confounders, including 'type A' behavior, 24-hour sodium excretion, physical activity level of the job, educational level, and smoking. None of these variables explained the relationship between job strain and hypertension. Age, body mass index, and regular drinking of alcoholic beverages were additional risk factors assessed in this study. The possible relation between job strain and hypertension was supported by two additional findings from this group of researchers. One study found both ambulatory monitoring of diastolic pressure and left ventricular mass measured by echocardiography were related adversely to job strain.¹³⁰ A later longitudinal study found that interval changes in blood pressure were significantly related to job strain.¹³¹ The possible mechanisms for the elevation of blood pressure by job strain include stimulation of the sympathetic nervous system, as well as the hypothalamic-pituitary-adrenal and renin-angiotensin systems.¹²²

The ERI model has also begun to be applied to studies of blood pressure and psychosocial characteristics with some positive cross-sectional associations.⁹² A recent study of the coping strategy used by workers who perceived that they had been treated unfairly found a complex relation between coping strategies, psychosocial working conditions, gender, age and hypertension.¹³² Although the diagnostic importance of these factors in an individual patient with hypertension is unclear, if additional studies confirm these findings, then preventive action may be warranted. Current research also seems to be increasingly focused on the interaction among personality, psychologic coping strategy, psychosocial work stressors, gender, and blood pressure. The nature of these inter-relationships is not clear and may be quite complex. As a result, translating the results into effective prevention strategies will be challenging.^{132,133}

CARDIOMYOPATHY

Only one environmental exposure (cobalt) has been linked directly to the development of cardiomyopathy. The association with cobalt, observed in heavy consumers of beer (for a period in the late 1960s, cobalt was added to beer to stabilize foam formation), may be confounded by other factors, such as alcohol and diet. However, only subclinical cardiac muscle dysfunction has been reported after cobalt exposure in industrial settings, and these changes could be related to hard metal lung disease.¹³⁴ A recent epidemiological study of men exposed to hard metal which consists of tungsten carbide and cobalt powders found no excess mortality from heart disease.¹³⁵ Antimony has also been anecdotally linked with the development of cardiomyopa-

thy and ECG abnormalities. One of two epidemiologic studies of exposed workers provides equivocal evidence of risk of increased mortality from heart disease.^{136,137} Similarly, there are several case reports of cardiomyopathy following intense exposure to solvents. Other occupational factors to be considered are those associated with the development of CAD, such as CS₂, which in turn can result in ischemic cardiomyopathy.

PERIPHERAL VASCULAR DISEASE

There is very limited evidence that occupational factors may be related to peripheral vascular disease. In countries where there are high levels of arsenic in the drinking water, there have been reports of an association between 'black foot disease' and environmental arsenic exposure but no reports of an elevated prevalence of peripheral vascular in occupationally exposed workers.¹³⁸ There is one study of peripheral vascular disease in young workers exposed to CS₂, which found evidence of damage to retinal vessels but little evidence for damage to peripheral vessels at current levels of exposure.¹³⁹

ECG ABNORMALITIES

Abnormalities found on the resting ECG are neither sensitive nor specific for diagnosing many cardiovascular diseases. In most cases in which occupational exposures have been associated with ECG abnormalities, these findings simply reflect the underlying disease problem, such as that between CS₂ and CAD or that between some high-level solvent exposures and premature ventricular contractions.¹⁴⁰ Arsine, for example, in addition to its hemolytic effect, may have a detrimental effect on the myocardium after a high level of exposure. Temporary ECG abnormalities were noted in all survivors of an arsine poisoning episode in 1949. These changes resolved within 10 months, and they were characterized by large T waves in the V₂ through V₅ leads.¹⁴¹ Overexposure to arsine, and perhaps arsenic, may cause the prolongation of the Q-T interval.¹⁴² In each case, removal from exposure is indicated; the role of chelation is less clear.

COR PULMONALE AND OCCUPATIONS AND OTHER CARDIOVASCULAR DISEASES

The effects of respiratory insufficiency on pulmonary arterial pressures and subsequent right-sided ventricular failure are well recognized. As discussed in Chapter 19, a wide range of occupational exposures may cause severe respiratory dysfunction, which may be associated with this secondary effect on the heart.

Chapter 25

Renal and Bladder Disorders

Caroline S Rhoads, William E Daniell

Toxins that gain access to the circulation have the potential to cause significant damage to the urinary tract. The kidneys provide a major route for the excretion of these substances, and normal renal function (glomerular ultrafiltration of blood, proximal tubular secretion and reabsorption, and medullary tubular concentration) can produce intracellular, interstitial, and intratubular concentrations of chemicals that exceed those found in the blood and other tissues. Some chemicals, particularly low molecular weight compounds of neutral pH, may accumulate within the renal interstitium in a manner analogous to urea. Other chemicals, such as cadmium, may be concentrated intracellularly through sequestration and molecular binding. The kidneys are also a site for enzymatic detoxification of a wide variety of chemical classes, and the generation of reactive intermediate compounds with increased toxicity poses an additional risk. At the distal end of the urinary tract, concentrated and excreted chemicals may rest for hours in contact with bladder mucosa.

While the risk for urinary tract injury from exogenous chemicals is theoretically high, the actual incidence and prevalence of occupational renal disease are not known. About 20% of acute renal failure is attributable to the toxic effects of chemicals but most of these cases involve the adverse effects of pharmaceutical agents administered for clinical purposes. At the present time, the United States Renal Data System does not include nephrotoxicity as a distinct category in its listing of causes of end-stage renal disease. It is thus equally difficult to estimate the prevalence of chronic occupational renal disease. The infrequent recognition of nephrotoxicity, particularly that attributable to occupational or environmental chemicals, is unlikely to reflect the true rate of occurrence.

Clinical recognition of occupational renal disease is challenging. Clinicians may have a low index of suspicion for chemical causes of disease in general, and patients may lack symptoms and signs that would alert the clinician to the presence of early renal disease. Normal kidneys have a large functional reserve and the glomerular filtration rate (GFR) may be preserved during early renal damage. Once the GFR begins to decline, adult patients may remain asymptomatic despite having GFRs as low as 30 mL/minute. An individual can thus sustain substantial acute or chronic renal injury without associated symptoms or changes detectable by laboratory tests and can subsequently have progressive renal dysfunction long after exposure to an injurious factor ceases.

When chemical toxicity is suspected and renal damage detected, it may be difficult to prove chemical causation. The available assays for direct measurement of industrial chemicals in body fluids and tissues commonly have little utility in ascertaining the clinical relevance of historically remote, temporally variable, or mixed chemical exposures. In addition, early histopathologic changes of renal disorders attributable to workplace chemicals typically have no pathognomonic features, and the pathologic features of renal diseases in general become increasingly non-specific with disease progression.

Finally, there may be little incentive for a clinician to identify a specific chemical cause for a patient's renal disease as this usually has little therapeutic benefit beyond ensuring that the exposure has ceased. There are few workplace chemicals for which there are known to be effective antidotal treatments, and identification of historically remote exposures may allow no meaningful opportunity for exposure prevention or modification.

Epidemiologic investigation of occupational renal disorders and other disorders of the urinary tract has been subject to the same limitations faced at the clinical level, principally the lack of tests to detect dysfunction prior to advanced stages of disease. As a consequence, there have been relatively few studies in this area, with most having concentrated on a limited spectrum of occupational exposures, chiefly certain metals and organic solvents. However, the continuing development of new and increasingly sensitive assays for markers of nephrotoxicity, such as plasma and renal proteins in urine, offers increasing potential for epidemiologic identification of possible nephrotoxic effects of occupational chemical exposures, particularly those involving the renal tubules.

The personal and social costs of urinary tract disorders are high. In the United States the annual cost of providing healthcare for individuals with end-stage renal disease is estimated to exceed 13 billion dollars, and the costs in terms of reduced quality of life are incalculable. While it is likely that occupational urinary tract disorders do not account for a major proportion of these overall costs, the absence of incidence and prevalence data does not allow an assessment of their contributions to these disorders. The personal risk and social costs for workers exposed to chemicals with potential but yet uncharacterized toxicity for the urinary tract could still be substantial. Clinical and epidemiologic investigations are needed to define the extent of occupational urinary tract disorders.

CLINICAL EVALUATION

Clinical history and physical examination

The medical and exposure histories are critical to the evaluation of patients suspected of having occupational urinary tract disease. Virtually every component of the urinary tract has been found to be susceptible to injury following acute or chronic exposures to specific toxic chemicals, particularly if consideration is extended to pharmacologic agents. Therefore, in the evaluation of unexplained disorders at any level of the urinary tract, any recent or remote chemical exposures that fall outside the range of usual population experience should be given consideration as possible causative or contributory factors. It is critical that consideration not be restricted to lists of chemicals with known potential to injure the urinary tract. Currently identified urotoxins should be regarded as exemplifying pathophysiologic mechanisms that, at least theoretically, might also be inducible by other chemicals with yet unrecognized potential for urinary tract toxicity.

The key feature to be determined in the exposure history; beyond the qualitative assessment of exposure dose, is the temporal relationship between the exposure and the probable onset of the condition under evaluation. For acute conditions (such as acute renal failure) or for conditions with relatively abrupt onsets (such as rapidly progressive glomerulonephritis), exposures occurring within hours to days or possibly weeks are more likely to be of clinical significance than are exposures that occurred remotely in time. In contrast, for chronic conditions with relatively indolent onsets (such as chronic renal failure), recent exposures may have minimal relevance in comparison to historically remote or cumulative longer-term exposures. Substantial exposures that occurred and ended early in a working career should still be considered as potential causative or contributing factors in the development of chronic urinary tract disorders that occur in older persons. Finally, general statements such as these should be treated as guides and not as absolute rules because remote exposures may serve as predisposing factors for acute conditions, and recent short-term exposures may precipitate the clinical manifestation of an otherwise slowly progressive disorder.

Information regarding the frequency and usual intensity of exposure to suspected occupational toxins, and the degree of personal protection, allows some estimate of the relative dose in comparison with the range of occupational, domestic, and general environmental experience. Exposure patterns characterized by variability or intermittent high peaks across a workshift may potentially have greater biologic significance than would uniform exposure to the comparable cumulative amount. In addition, consideration should be given to the potential for skin exposure; for some agents, such as organic solvents, dermal absorption can potentially contribute more to the total dose received than the associated inhalation exposure.

The possibility of a chemical etiology should be considered for any patient with renal dysfunction, even in the presence of other presumptive pathogenic processes.

Clinical experience with drug-induced nephrotoxicity shows that numerous factors (e.g., age, genetic predisposition, hypertension, diabetes, gout, pre-existing chronic renal disease, and transient factors such as intravascular fluid depletion or co-administered drugs) can enhance a drug's intrinsic nephrotoxicity. Such factors are likely also to influence any acute or chronic renal effects of workplace chemicals, and conversely, exogenous chemicals might worsen pre-existing renal disease of non-toxic etiology.

The physical examination is unlikely to reveal information that is directly pertinent to the urinary tract, but associated findings involving other organ systems including skin and mucous membrane changes associated with metals (see heavy metals) and neurologic changes associated with organic solvents may be helpful in identifying an etiologic factor.

Laboratory testing

Laboratory tests are essential for characterizing the nature and severity of renal dysfunction. However, most clinical tests have limited utility in the consideration of occupational factors, either in etiologic evaluation of renal disease or in screening or surveillance for renal dysfunction. Measurements of serum electrolyte concentrations or osmolality generally contribute little to these occupational goals. While the serum creatinine level and to a lesser degree the blood urea nitrogen (BUN) level are the conventional clinical tools used to screen for and monitor reductions in GFR, these tests are insensitive to mild renal dysfunction. Dynamic tests of renal concentrating ability after fluid deprivation potentially provide a sensitive measure of distal tubular function; however, these tests have limited applicability outside of a clinical research setting.

In general, urinary sediment examination is an insensitive and non-specific indicator of suspected occupational urinary tract disease or injury, and has little applicability outside of situations involving known or suspected risk for urinary tract tumor (see Chapters 30.3 and 30.4). Imaging studies and tissue examination can provide anatomic and pathologic classification, and can lead to diagnoses that reduce the likelihood of occupational contribution, but these studies do not commonly yield information that is otherwise helpful in identifying an occupational etiology. Tissue findings are rarely pathognomonic for the effects of chemical toxins or other occupational factors. In addition, kidney biopsy is invasive and expensive. In contrast to the limited clinical utility of the tests noted above, measurements of plasma and renal proteins in the urine offer broad potential for occupational epidemiologic studies and surveillance programs to detect the subclinical renal effects of chemical exposures.

A variety of factors determine the applicability of laboratory tests to clinical, screening, or surveillance situations, and the limitations of a test must be considered accordingly when ordering a test or interpreting its result in relation to an individual or group. Tests that lack normal reference ranges based on appropriate comparison populations or have substantial degrees of interindividual variability will

have little diagnostic value in the non-serial evaluation of an individual and should be interpreted cautiously. However, tests that have limited degrees of interindividual variability but low degrees of intraindividual variability, such as the serum creatinine level, can provide useful information regarding an individual even when small changes are found on serial measurements or in comparison to a previous value. The potential for chronologic variability (e.g., diurnal or seasonal effects and temporal variation in laboratory methods) should always be considered when screening groups or serially monitoring individuals. The influence of urine flow rate on a urine test result may be at least partially controlled by standardization relative to an indirect measure of urine concentration, such as urine creatinine, specific gravity or osmolality. The practice of urine concentration adjustment, however, is based largely on convention and has undergone only limited scrutiny for most specific urine analytes; unadjusted urine analyte values should always be considered and reported concurrently.

Glomerular filtration rate

Invasive functional studies (such as intravenous injection of inulin or *p*-aminohippurate [PAH] to measure GFR or renal plasma flow, respectively) may allow definitive characterization of exposure-related reductions in renal excretory function. Such studies have been used to describe functional decrements in association with occupational carbon disulfide exposure and hypertension; however, the logistic difficulties of these procedures normally limit their use to clinical research settings. Creatinine clearance is potentially useful as an alternative measure, but the necessity for timed collection of blood and urine specimens limits its applicability in surveillance programs. Serum measurements of creatinine and BUN levels are the most commonly used alternatives to provide indirect estimates of GFR.

Serum creatinine level measurements, unfortunately, have little value in the detection of early stages of chronic renal injury because of the large functional reserve of the kidneys. Serum creatinine levels show an inverse, hyperbolic relationship with GFR, such that small increases in creatinine above normal can represent major functional loss. An individual's serum creatinine level may not convincingly exceed the upper normal reference range until up to one half of renal function is lost.

While there is little reassurance to be gained from a normal serum creatinine level, the detection of an elevated creatinine level (or even a small mean increment when evaluated among exposed workers and non-exposed controls) is strong evidence of renal dysfunction. Furthermore, because the degree of intraindividual variability in the serum creatinine level is normally much less than interindividual variability, small increases in an individual's creatinine level over time should be regarded as potentially significant.

Urine proteins

Urine contains proteins of plasma and renal origin. Normally, no more than 150 mg of protein are excreted

each day. The glomerulus presents a charge and size selective barrier to the filtration of plasma proteins that excludes the majority from the ultrafiltrate. Both high molecular weight (HMW) proteins such as albumin (about 65,000 daltons) and low molecular weight (LMW) proteins such as β -2-microglobulin (<40,000 daltons) are able to cross the glomerulus to varying degrees. Reabsorption of the two predominant LMW proteins, β -2-microglobulin (β 2M) and retinol binding protein (RBP), is nearly complete, with a fractional reabsorption of 99.97%. LMW proteins normally account for about 20% of the daily protein excretion. Reabsorption of albumin and other HMW proteins is less complete, with a fractional reabsorption of between 90 and 99%. HMW proteins normally account for about 40% of the daily protein excretion. Renally derived glycoproteins (including Tamm-Horsfall protein) which are secreted by the renal tubular epithelial cells during the course of tubular work constitute another 40% of the normal daily protein excretion. Against this background, changes in the level of excretion of HMW and LMW plasma proteins can serve as approximate markers of glomerular and tubular dysfunction, respectively.

In the absence of acute illness or unusually intense activity, protein excretion in excess of 150 mg per day is a reliable indicator of kidney damage. Excessive excretion of albumin and other HMW proteins such as transferrin is indicative of glomerular damage. In this setting there is increased filtration of HMW plasma proteins without any accompanying change in the normally total filtration of LMW plasma proteins. The relatively low affinity of HMW proteins for tubular reabsorption sites is aggravated by the filtrate overload, and the HMW protein excess appears to provide little competition for LMW protein reabsorption. Consequently, HMW protein excretion increases without substantial increase in the urinary LMW protein concentration.

In contrast, the proteinuria associated with proximal tubular damage and dysfunction (with preservation of glomerular function) is characterized by absolute increases in excretion of both LMW and HMW plasma proteins, but with markedly greater relative increase in LMW protein excretion. LMW proteins provide the better indicator of tubular proteinuria because, although HMW proteins still comprise the major proportion of total urine protein, the increases in concentrations of LMW proteins are more readily detectable in comparison to their low normal concentrations than are the increases in HMW proteins.

A wide variety of urine proteins have been investigated as markers for occupational renal disease (Table 25.1).¹ Urine proteins can potentially serve as markers of renal injury from low or short-term chemical exposures, but toxin-induced proteinuria is most likely to be persistent after long-term exposures and to be most representative of a cumulative exposure effect. At the earliest stages of renal damage, the specific proteins present may localize the site of damage to either the glomerulus or the tubule. When more advanced disease is present, however, multiple classes of proteins may be present, reflecting more widespread damage. Patterns of proteinuria may suggest a

Markers of effects at the glomerular level

High molecular weight plasma proteins (>40,000 D) in urine:
albumin, transferrin, IgG

Components of glomerular structure in urine or plasma:

fibronectin, laminin, sialic acids, anti-glomerular basement
membrane antibodies; prostanoids: thromboxane B₂, 6-keto-
prostaglandin F_{1α}

Markers of early effects at the proximal tubule

Low-molecular weight proteins in urine:

β-2-microglobulin, retinol binding protein, α-1-
microglobulin

Enzymes:

N-acetylglucosaminidase (NAG), total non-specific alkaline
phosphatase (TNAP), human intestinal alkaline phosphatase
(HIAP), gamma glutamyl transferase (GGT), alanine
aminopeptidase (AAP)

Kidney antigens:

Brush border BB-50

Marker of the distal tubule

Kallikrein

Marker of the loop of Henle

Tamm-Horsfall glycoprotein

Markers of the collecting tubule and interstitium

Prostaglandin_{2α} prostaglandin E₂

Site-unrelated markers

Glycosaminoglycans

* Adapted from Mutti¹

Table 25.1 Site selectivity of biomarkers of early renal effects*

specific toxin but are not pathognomonic; the causative agent is usually inferred from the exposure history and further documented by direct measurement in blood or urine. The sensitivity of urinary markers for detecting renal damage varies widely and it is possible that urine protein abnormalities may not be detected until a cumulative dose threshold or period of latency has occurred. In addition, both intersubject and intrasubject variations can be substantial, further complicating the interpretation of these tests.² Nonetheless, these markers allow for the detection of early renal damage and are useful for surveillance, monitoring, and risk reduction in the industrial setting, and there is some evidence that low level LMW proteinuria may be reversible when workers reduce their exposure to occupational toxins.³

High molecular weight plasma proteins

Albumin is the most abundant high molecular weight (HMW) plasma protein in urine, and it is the urine protein that is measured most commonly to assess proteinuria. It is stable in urine, even with prolonged frozen storage, and can be quantified readily across the full range of concentrations found in urine. Complicating its role as a marker of possible nephrotoxicity is the fact that albuminuria also can result from chemically unrelated, non-disease factors, such as heavy exercise, severe heat stress, and orthostatic postural influences. Mild degrees of albuminuria (less than 0.5 g/day) can arise with either glomerular or tubular damage, and the site of dysfunction can potentially be distinguished by the absence or presence, respectively, of low molecular weight proteinuria. Higher degrees of albuminuria are generally attributable to a predominantly glomerular defect, particularly when albuminuria reaches the nephrotic range

(urine total protein more than 3.5 g/day). Nephrotic syndrome has only rarely been described in association with occupational chemicals, most notably with mercury exposure (discussed later in this chapter).

Other HMW plasma proteins have been used or suggested for characterization of proteinuria. Transferrin has been reported to be more sensitive than albumin in the early detection of glomerular defects in diabetic and cadmium nephropathies. It is less stable than albumin, however, and urine samples can be stored reliably only for short periods before analysis.

Low molecular weight plasma proteins

The protein β₂M (molecular weight, 12 kD) appears in the urine when tubular absorption of protein is impaired. It has been used extensively in epidemiologic investigations and ongoing surveillance of workers with selected chemical exposures, most notably cadmium. In workers chronically exposed to cadmium, an increase of urine β₂M concentration to critical threshold levels can signal an irreversible cadmium effect on the kidney before any remarkable changes appear in other clinical test parameters (discussed later in this chapter). The widespread use of β₂M reflects its historically early use as a renal marker, more than its suitability for occupational exposure surveillance, because β₂M is unstable at acid pH or with prolonged storage. Even with neutralization of the urine at the time of sample collection, the degree of degradation in the bladder can be significant. Retinol binding protein RBP (21 kD) is a practical substitute for β₂M, in view of its comparable renal handling, its relative stability, and the existence of reliable assays for its quantification. Increases in RBP excretion have been reported among workers with chronic exposure to cadmium and chromium. α-1-microglobulin (30 kD) has also been considered as a marker of tubular dysfunction, primarily because of its higher concentration in urine (and consequently greater technical ease of quantification). However, the available evidence indicates that it may be a less accurate marker of tubular function than β₂M or RBP.

Proteins of renal origin

Enzymes. A number of enzymes found in renal (and non-renal) cells have been suggested as urine protein markers of renal injury. These enzymes are all HMW proteins, and it is assumed that, in the absence of evidence for glomerular dysfunction, their increased presence in urine reflects release from damaged tubular tissue. Examples include the lysosomal enzyme, N-acetylglucosaminidase (NAG), and the luminal brush border enzyme, human intestinal alkaline phosphatase (HIAP). These assays have been used increasingly in studies of occupational exposures, and both NAG and HIAP have been found to be sensitive markers of early renal damage.⁴

Increases in urine NAG and HIAP have been detected in workers chronically exposed to cadmium and mercury. Urine NAG may also be elevated in workers exposed to lead. The initial evidence suggested that urine NAG and other enzyme activities were less sensitive indicators of

renal tubulotoxicity than the LMW proteins β 2M and RBP, but more recent studies have variably described comparable or improved sensitivity. Furthermore, in contrast to β 2M, the enzyme NAG is unstable only in alkaline conditions (pH greater than 8), which are not usually found in urine, and there exists an automated assay for urine NAG activity. Day to day differences in enzyme excretion may be significant and thus it is critical that serial specimens be collected under the same conditions. Age, sex, body mass index, blood pressure, and smoking and drinking habits all impact measurements between individuals.²

The onset and persistence of enzymuria will vary with the nephrotoxin, the exposure pattern, and the specific enzyme. There is generally limited understanding of the temporal relationships between these markers and the renal injury that may occur in occupational exposure situations, particularly in the absence of ongoing exposure. In general, acute renal injury will produce detectable increases in these markers within hours or days, with increases that last only several days or 1 week with limited injury. Enzymuria may even normalize during short-term nephrotoxin exposures, and it has been speculated that tissue stores of enzyme may become depleted or that tissue regeneration may lead to some degree of resistance. Enzymuria has been reported to become persistently abnormal after chronic or high-level acute exposures to nephrotoxic drugs.

Antigens. Renal tubular antigens have also proven to be sensitive indicators of tubular damage in workers exposed to heavy metals. For example, a monoclonal antibody for a proximal tubular brush border protein (BB-50) detected increased antigen excretion in the urine of chromium-exposed workers and patients with cancer who were receiving cisplatin. Drug-related increases have also been reported for other renal tubular antigens in urine; however, antigen assays are not yet standardized and their utility for the clinical evaluation of workers is yet to be established.

Circulating immune markers

Antiglomerular basement membrane (anti-GBM) antibodies occur in association with one class of immune-mediated glomerulonephritis. The etiology of this uncommon condition is unknown, although epidemiologic evidence indicates organic solvent exposures may increase the risk for this and other types of glomerulonephritis (discussed later in this chapter). Other than the use of anti-GBM antibody titers in case studies of solvent-associated glomerulonephritis, this assay has had limited application in occupational investigations. Another assay for circulating antibody directed against renal tissue (antilaminin antibody) was used to demonstrate an increased prevalence of antibody among hydrocarbon-exposed refinery workers and cadmium-exposed, but not lead-exposed, workers. The presence of antibody in these studies showed no correlation with renal dysfunction. The utility of circulating immune markers for occupational studies is generally not established.

DISORDERS OF THE KIDNEY AND URINARY TRACT

Acute renal disorders

A broad array of industrial toxins has been associated with acute renal failure, typically in the setting of severe short-term overexposure. It is likely that acute nephrotoxic exposures can produce any degree of excretory insufficiency, but the cases that ultimately come to clinical recognition usually involve acute renal failure, either of an oliguric or non-oliguric nature. Chemically induced acute renal failure may be produced either through direct toxic actions on renal tissue, or indirectly through systemic, prerenal mechanisms.

Postrenal or obstructive mechanisms have generally not been described in association with acutely toxic exposures. However, for example, the acute renal dysfunction associated with ethylene glycol poisoning is at least partially attributable to the obstructive effects produced by intratubular crystallization of calcium oxalate, a major metabolite of ethylene glycol. In addition, certain other chemicals, notably cadmium, place chronically exposed workers at increased risk for urolithiasis; affected workers face at least the theoretic possibility of obstructive renal dysfunction, particularly in the context of anatomic anomalies, such as a solitary kidney.

Only a small proportion of chemicals associated with acute renal failure have their primary or most severe toxic effects directly on the kidneys. Chemically induced acute renal failure commonly occurs in the context of multiple organ system dysfunction, and it can be difficult or impossible in an acute poisoning to ascertain whether renal dysfunction is a direct or indirect consequence of the toxin involved. Fortunately, the issue is more of general toxicologic interest than clinical concern. Clinical management of acute renal dysfunction in such settings is generally supportive. Selection of toxin-specific treatments (in the limited number of situations where antidotal or chelation regimens, or facilitated toxin removal through extracorporeal technologies are known to be efficacious) is generally dictated by the overall severity of systemic illness rather than the primacy or degree of renal dysfunction.

Pigment nephropathy

Chemical and physical factors with no inherent potential to cause renal cell injury through direct toxic action may indirectly cause acute renal insufficiency through pigmenturias generated by chemically induced rhabdomyolysis or hemolysis (Table 25.2). Myoglobin and, to a lesser degree, hemoglobin have toxic effects on the renal tubular epithelium.

Rhabdomyolysis. Most cases of toxin-induced rhabdomyolysis occur in the setting of intentional ingestion or abuse of a variety of drugs and chemicals and thus have limited pertinence to industrial exposures.⁵ Many of the reported cases, however, involve chemicals that are used in industry and are capable of producing, or are known to have produced, some degree of systemic toxicity with skin

or inhalation exposure. Chemical ingestions that are severe enough to produce rhabdomyolysis are frequently accompanied by severe metabolic derangements, seizures, and prolonged immobilization, all of which may themselves produce muscle injury and exacerbate rhabdomyolysis. In a given case it is frequently difficult to determine whether the rhabdomyolysis is primarily due to a direct effect of the toxin or whether it is primarily due to systemic illness induced by the toxin.

Non-chemical factors have generally been identified more commonly than have chemical substances as occupational causes of rhabdomyolysis and acute renal failure. Rhabdomyolysis is a well-recognized possible consequence of electrical and crush injuries and has also been seen with lesser degrees of trauma, such as repeated impact trauma

experienced during the operation of jackhammers or other physical impact tools. Vigorous physical exertion, particularly in relatively hot environments, can also be a cause. The risk for exertional rhabdomyolysis has not shown any clear association with the degree of premorbid physical fitness, but it has been speculated that fitter individuals may be at greater risk because of their greater muscle mass and potentially greater willingness to attempt extreme exertion. In severe cases, heat stroke can produce rhabdomyolysis (or hemolysis), and these factors and the usually concomitant hemodynamic insufficiency can lead to renal failure. Systemic infections (e.g., viral syndromes) can also result in varying degrees of rhabdomyolysis, with associated renal failure. Finally, it should be noted that the venoms of certain snakes, spiders, and hymenoptera are capable of causing acute renal failure along with rhabdomyolysis and/or hemolysis, and in some instances, direct nephrotoxicity.⁶

Hemolysis. Although free myoglobin is inherently more nephrotoxic than free hemoglobin, hemolysis and resultant acute renal failure have been more clearly linked with occupational chemical exposures than has rhabdomyolysis. Arsine (AsH_3) is a dense, colorless, non-irritating gas with a faint garlicky odor that causes hemolysis during both acute and chronic exposure. It may be generated incidentally as a refining byproduct from arsenic-contaminated non-ferrous metals, including the common and usually benign practice of spraying water on metal dross. Arsine is also used routinely as a source material for arsenic dopant in semiconductor manufacturing, in which even with appropriate precautions, the potential remains for accidental release of large quantities of arsine during use or transport. Acute exposure to very high levels of arsine may cause massive acute hemolysis, acute tubular necrosis, and even death. Arsine exposures and their clinical manifestations may be abrupt or insidious. The severity and rapidity of the onset of arsine poisoning manifestations show some correlation with the concentration and duration of exposure.⁷

Milder cases may not be apparent until 24 hours after exposure, and the initial presentation may be non-specific, with headache, weakness, and abdominal complaints. With severe poisoning, however, the symptoms may appear within 2 hours, followed by hemoglobinuria within 4–6 hours, jaundice at 24–48 hours, and anuria or oliguria within 2–3 days. Acute renal failure is the most common cause of death in fatal arsine poisonings. The renal failure has been attributed to acute tubular necrosis induced indirectly by hemolysis and mediated through tubular accumulation of hemoglobin casts or through anemia, hemodynamic insufficiency, and consequent renal tubular ischemic injury. However, there are reports of severe tubular necrosis occurring out of proportion to the degree of hemolysis and hemoglobinuria, and even mild cases may show evidence of tubular dysfunction. Experimental evidence further indicates that arsine, or arsenic complexed with hemoglobin, has directly nephrotoxic properties.

Survivors of arsine-induced renal failure commonly have persistent abnormalities of renal function for months and up to 1 year afterward. Hypertension and chronic interstitial

nephritis have been reported as long-term outcomes. Delayed recovery may reflect sequestration of hemoglobin-arsenic complex in renal lysosomes with subsequent slow release and prolonged nephrotoxicity. Consequently, although chelating agents such as dimercaprol (BAL) have generally not been effective in modifying the course of arsine-induced hemolysis and acute renal failure, it has been speculated that BAL or another appropriate chelating agent may have a longer-term benefit in reducing residual renal dysfunction. Exchange transfusion has also been reported to be beneficial in managing acute arsine hemolysis.⁸

Arsine is probably the most potent hemolytic substance found in industrial settings, but other industrial chemicals are also known or suspected to cause hemolysis. Two other gaseous hydrides of Group V elements (phosphine, PH_3 , and stibine, SbH_3) have acute toxic properties that are similar to, although less severe than, those of arsine. Arsenic trioxide, or white arsenic, typically has minimal hematologic effects with acute or chronic poisoning, but has been reported in isolated cases of acute ingestion to cause hemolysis with associated renal dysfunction. Hemoglobinuric renal failure has also been reported with cresol skin burns in industrial accidents. Table 25.2 lists examples of other commercial and industrial chemicals that have been associated with hemoglobinuric renal failure, primarily in cases involving chemical ingestion.

Methemoglobinemia. Certain chemicals that either bind to or oxidize hemoglobin may produce hemolysis with acute overexposure, and they have at least the potential to cause secondary acute renal insufficiency. Although this is not a common phenomenon with carbon monoxide poisoning and carboxyhemoglobinemia, it has been reported in a limited number of cases. Methemoglobinemia also is typically not associated with hemolysis. However, some industrial chemicals that can generate methemoglobinemia with overexposure have been reported either experimentally, or in case reports of poisonings, to produce oxidative hemolysis, and poisonings, with certain of these chemicals also have been associated with renal failure. Chlorate salts produce prominent intravascular hemolysis and an extracellular methemoglobinemia, and acute hemoglobinuric renal failure has been reported to occur with poisoning by a sodium chlorate weed killer. Methemoglobinemia is a central feature of poisoning with aniline and its homologues, many of which are used extensively as synthetic precursors in the chemical industry. Hemolysis is not a common feature of poisoning with these aromatic nitro and amine compounds (See Chapter 42), but it has been described in association with acute renal failure following poisonings.

Dinitrophenol, which is used as an herbicide, and trinitrophenol (picric acid), which is used in the explosives industry, each produce methemoglobinemia with intoxication, and trinitrophenol can cause intravascular hemolysis. These agents are highly toxic and may cause multiple organ system failure, including renal failure; however, the relative contribution of the methemoglobinemia and hemolysis cannot be distinguished from broad systemic effects associ-

ated with poisonings. Ethylene glycol dinitrate, another explosives agent, also has been reported to cause methemoglobinemia and acute renal failure.

Genetic deficiencies. Individuals with certain genetic enzyme deficiencies, such as glucose-6-phosphate dehydrogenase (G6PD) deficiency, may experience acute hemolysis and secondary renal dysfunction with exposure to specific chemical substances that, for the general population, may not be toxic (e.g., fava bean ingestion) or are toxic at much higher levels of exposure. While this has been described infrequently in industrial settings, the potential for unrecognized predisposition to hematologic toxicity exists.

Phenylhydrazine is an oily, relatively non-volatile liquid used as a precursor in the manufacture of dyes and pharmaceuticals; it is also a reagent in chemical analysis. It can produce marked hemolysis, anemia, and decreased urinary output in experimentally poisoned rabbits and guinea pigs, and it produces a low-grade hemolytic anemia when used medically in humans for the treatment of polycythemia vera. There are no reports of fatalities or acute renal failure from industrial exposures. However, phenylhydrazine is absorbed readily across the skin, and the potential exists for such occupational toxicity. Another aromatic nitro compound, trinitrotoluene, has produced acute hemolytic episodes in explosives workers with G6PD deficiency and no prior history of hemolytic anemia, although no renal dysfunction was reported in the described cases.⁹ The polyaromatic compound naphthalene can induce hemolysis after metabolism to naphthol and naphthoquinone intermediates, and subsequent metabolic detoxification can be slowed by deficiency of G6PD or glutathione. Ingestion of naphthalene has led to hemolytic anemia and renal dysfunction.

It is at least a realistic consideration that genetic deficiency traits or disorders, such as G6PD deficiency, might place affected individuals at increased risk for hemolytic (or rhabdomyolytic) effects of specific industrial chemical exposures. In general, however, this is a rare mechanism, and the human experience is based on isolated case reports. Despite the broad prevalence of certain genetic enzyme deficiencies, such as the 15% prevalence of G6PD deficiency among African-Americans, no identified genetic deficiencies have been linked to any predictable or significant risk for occupational renal toxicity. There is presently no need to restrict selected individuals from specific chemical exposures on the basis of isolated genetic enzyme deficiencies.

Acute interstitial nephritis

Certain pharmacologic agents may cause an acute hypersensitivity nephritis characterized by renal enlargement, diffuse interstitial infiltration by mononuclear cells, relative non-prominence of tubular or glomerular necrosis, and frequent coexistence of non-renal signs of hypersensitivity. The drug-induced form generally follows a second or later administration of the causative drug, and the degree of dysfunction shows little correlation with the recent or cumulative drug dose. This phenomenon has

not been reported as a consequence of occupational chemical exposures, but it is theoretically feasible that the operative mechanism could occur in the context of occupational chemical exposure. Occupational exposures should at least be considered when evaluating individuals with no readily apparent cause for either acute interstitial nephritis or acute nephropathy in the setting of an allergic reaction.

Nephrotoxic acute renal injury and renal failure

The predominant pathogenic mechanism in most cases of acute renal failure induced by chemicals is tubular injury, and the most prevalent pathologic appearance is tubulointerstitial nephritis with associated inflammation or necrosis. While primary nephrotoxic action at the level of the glomerulus is less common, as the clinical course of tubulointerstitial injury progresses, there develops an increasing degree of histologic change or necrosis involving non-tubular renal structures, including the glomerulus. With some noteworthy exceptions, such as lead and oxalate-producing toxins, the histologic appearance of nephrotoxic acute renal failure is relatively non-specific. The extent of histologic change and the clinical pattern do, however, show some correlation with the toxin dose. Most patients have some degree of oliguria beginning within hours to days of exposure. With higher doses, the poisoned individual is more likely to be anuric.

Milder cases may have little or no decrease in urinary output and may show only minimal or selective changes in renal excretory pattern, such as aminoaciduria. Many of these mild cases might easily escape detection. Most of the published clinical and experimental experience with nephrotoxic acute renal injury pertains to heavy metals and organic solvents, particularly the halogenated hydrocarbon solvents, but a wide variety of chemicals have been identified or suspected as having potential to produce acute nephrotoxicity (Table 25.3). Similar to the acute pigment nephropathies, however, it is sometimes difficult to characterize the relative nephrotoxicity of many of the individual chemicals for which there is only limited clinical evidence because of the frequent simultaneous toxic effects on other organs.

Metals and other elements

Arsenic. Acute arsenic intoxication, which may occur with ingestion or through inhalation of dusts or fumes, produces a potentially severe multisystem disorder. Trivalent arsenic (e.g., arsenic trioxide) and the generally less toxic pentavalent forms (e.g., arsenates) have limited inherent toxicity for the proximal renal tubules. Acute tubular and cortical necrosis have been observed with acute poisoning, and one case report describes the development of an acute exacerbation of chronic interstitial nephritis with ongoing arsenic ingestion, but in general, nephrotoxicity is not a central feature.¹⁰ Treatment is dictated by the severity of the poisoning. The high potential for inhalation of arsine gas to cause acute renal injury is described above.

Table 25.3 Reported nephrotoxic causes of acute renal failure

Cadmium Acute cadmium toxicity, which may occur occupationally with inhalation of fumes produced by welding or burning cadmium-containing metals, primarily and most severely affects the lungs. However, absorbed cadmium rapidly and preferentially accumulates in the liver and kidneys, and renal injury also may occur with acute intoxication, potentially resulting in marked proteinuria or acute tubular or cortical necrosis with renal failure. Use of the chelating agent BAL is contraindicated for acute cadmium toxicity because of its tendency to increase renal cadmium concentrations after acute overexposure and because of the apparent greater nephrotoxicity of the cadmium-BAL complex than of cadmium alone. Other currently available chelating agents either have no ability to extract cadmium from intracellular sites (e.g., ethylenediaminetetra-acetic acid, EDTA) or have been principally studied in animal models of cadmium intoxication (dimercaptosuccinic acid, DMSA, and 2,3-dimercapto-1-propanesulfonic acid, DMPS).¹¹ Treatment should be supportive.

Chromium. Chromium, particularly in the form of potassium dichromate, is a potent proximal tubular toxin in animal models. In humans, acute renal failure has been produced by ingestion of hexavalent chromium compounds and also through skin burns caused by accidental contact with chromic acid, covering as little as 10% of body surface area.¹² Chromium is dialyzable, and dialysis is recommended for treatment of acute chromium poisoning. Both hemodialysis and continuous peritoneal dialysis have been reported to enhance chances of survival without residual renal dysfunction. Chelating agents have no demonstrated efficacy in chromium intoxication.

Lead. Severe lead poisoning in children is commonly accompanied by transient toxic nephropathy, particularly when blood lead levels exceed 60 µg/dL, and acute encephalopathy. The primary functional abnormality is a proximal tubule reabsorptive defect, which manifests clinically with a Fanconi-like syndrome (generalized aminoaciduria, phosphaturia, glycosuria, increased fractional excretion of urate resulting in hypouricemia, and various degrees of bicarbonate wasting [renal tubular acidosis]). The Fanconi syndrome induced by lead, in contrast to the primary and other secondary forms, also is associated with fructosuria and citraturia. The phosphaturia can be sufficient to cause rickets.

Pathologic evaluation of affected kidneys typically reveals non-specific cytomegaly, mitochondrial morphologic changes, and a relatively characteristic abnormality, acid-fast intranuclear inclusion bodies in the proximal tubule epithelial cells. The glomeruli are generally unaffected or show only minimal, non-specific changes. The inclusion bodies, which consist of a lead-protein complex, can also be demonstrated in urinary sediment and in other non-renal tissues. Both the tubular histologic changes and the reabsorptive defects have been produced experimentally in rats fed dietary lead. Similar intranuclear inclusions have also been described in the kidneys of occupationally lead-exposed workers with evidence of mild renal insuffi-

ciency, but they are generally not seen with more advanced stages of chronic lead nephropathy. While the inclusion bodies of acute lead nephropathy resolve during and after the course of chelation treatment and exposure cessation, recent evidence suggests that the proximal tubule reabsorptive defect can persist for years after the acute exposure.¹³ The clinical significance of this persistent reabsorptive defect remains unclear as it has not been associated with reduced renal function.

Acute lead nephropathy may require specific therapy in the form of electrolyte or bicarbonate replacement to restore metabolic balance, but otherwise, therapy is generally dictated by the severity of manifestations in other organs, which typically present greater acute clinical significance than the nephropathy. Treatment for clinically significant lead intoxication with or without acute nephropathy should include a chelating agent, usually EDTA. When lead nephropathy is present, EDTA therapy should not be withheld because of concern about possible additional nephrotoxicity from EDTA. Although it has not been demonstrated consistently in clinical follow-up investigations, repeated episodes of acute lead intoxication in children may result in a chronic nephropathy and, ultimately, renal failure (discussed in Chronic Renal Disorders Section).

Mercury. The potential for mercury to produce acute nephrotoxicity depends on its chemical form and the nature of the exposure. Mercury poisoning in occupational settings most commonly involves inhalation of elemental mercury, which is highly volatile. Elemental mercury has its primary effects on the lungs and nervous system, and although it is preferentially accumulated in the kidneys, it rarely produces significant renal injury. A variety of organic mercury compounds are used widely as fungicides, and in general, they may be absorbed readily by any route of exposure. While their primary toxic effect is also on the central nervous system, they may also affect the kidneys. It is speculated that the nephrotoxic potential of organic mercury compounds correlates with their tendency to undergo metabolic transformation to inorganic mercury. The phenyl and methoxymethyl mercuric salts have been described in animal models as having nephrotoxic properties similar to those of mercuric chloride (described below). However, there have been only a small number of reports linking organomercurial agents to nephrotoxic injury in humans, with these reports pertaining to chronic rather than acute manifestations.

The soluble inorganic salts of mercury, which are absorbed best by ingestion and weakly with dermal exposure, rarely cause poisoning in occupational settings. Severe renal injury is a major manifestation of accidental or suicidal ingestions, although such poisonings with these agents are uncommon. The mercurous salt (Hg₂Cl₂) is minimally toxic and has even been used as a medicine in the past, but the mercuric salt (HgCl₂) is extremely nephrotoxic. If an individual survives the corrosive gastrointestinal injury from an acute ingestion, the major systemic toxic effect is acute proximal tubular necrosis. Severe poisonings progress to oliguric renal failure within

several days and generally require dialysis to ensure survival. If a patient survives the initial clinical course, the recovery phase is characterized initially by polyuria and then by progressive resolution of renal impairment toward normal over a course lasting up to several months. Residual renal dysfunction is common, occurring in association with persistent interstitial nephritis, dystrophic calcification of the renal tubules, and end-stage renal disease.

The clinical course of acute poisoning in humans parallels that seen in experimental animal models of acute mercuric chloride nephrotoxicity. In animals, mercury avidly binds to sulfhydryl groups of proteins such as albumin and metallothionein. Within a few hours of exposure, inorganic mercury begins to accumulate in proximal tubular epithelial cells complexed with metallothionein. It is postulated that toxicity occurs when sulfhydryl binding sites on buffering proteins such as metallothionein and glutathione are saturated. At that point mercuric or mercurous ions may bind to more critical cell components and cause dysfunction or damage. When mercury exposure ceases, bound mercury is released slowly with reported half-lives ranging from 10 days to 4 months.¹⁴

A chelating agent should be administered as early as possible after acute mercury poisoning to bind competitively with free mercury and minimize protein binding and tissue accumulation. In the presence of anuric renal failure, BAL can accumulate to toxic levels and, even in the absence of renal failure, it has the potential to increase central nervous system levels of mercury. Thus, DMPS and DMSA, the water-soluble derivatives of BAL, are now more commonly used. Early hemodialysis, in combination with chelation therapy, has been reported to reduce dramatically the acute mortality of mercury poisoning and the risk of subsequent chronic renal failure.¹⁵

Silver. There have been reports of acute renal failure among photographic film developers, with the presumed cause being silver exposure. Injections of silver salts in animals have confirmed the ability of silver to induce tubular degeneration associated with renal interstitial silver deposits and relative glomerular sparing.¹⁶

Uranium. Uranium is a highly potent nephrotoxin, with relatively high specificity for the proximal tubules, and uranyl nitrate injections are used routinely to induce acute tubular necrosis in experimental animals. However, acute renal failure has only rarely been described in humans with overexposure to uranium. One incident involved three workers exposed to a uranium cloud, with each developing transient proteinuria, diminished urine output, and slight increases in BUN levels, but no long-term residual dysfunction. In a case of deliberate overdose, chelation therapy proved ineffective and chronic renal failure with an incomplete Fanconi syndrome resulted from the ingestion.¹⁷ Exposure to low levels of uranium in drinking water was associated with increased urinary excretion of tubular proteins in another study, but no clinical renal disease was detected.¹⁸

Pharmaceutical agents. A number of metals and other elements are recognized as having the potential to cause nephrotoxic side effects when used as pharmaceutical agents. In general, there are limited parallels between the therapeutic administration (or intentional excessive ingestion) of such agents and occupational exposure to the same or related compounds. The former typically involves ingestion or injection of agents at higher doses and, often, as uniquely different chemical compounds relative to those found in industry. However, their adverse clinical effects should at least be recognized in considering occupational exposures to related compounds. Oral use of *bismuth* compounds, which were used formerly as antisyphilitic therapy, frequently caused acute renal failure or nephrotic syndrome. Renal failure was the most common cause of death with bismuth poisoning. However, metallic bismuth and bismuth oxide are poorly soluble in plasma and are rapidly excreted in the urine and have not been associated with occupational nephrotoxicity. Analogous to lead intoxication, bismuth induces the development of distinctive, refractile inclusion bodies in the epithelial cells of the proximal tubules and causes tubular degeneration. Dialysis has been reported to be beneficial in the treatment of acute poisoning.

Lithium carbonate, which is used widely for the treatment of manic-depressive and other psychiatric disorders, interferes with ion transport in both the proximal and distal tubules and is capable of causing nephrogenic diabetes insipidus and an incomplete distal renal tubular acidosis (impaired urinary acidification after an acid challenge). Diabetes insipidus may be produced or precipitated in chronically exposed individuals by acute lithium overdose, which may not be completely reversible. However, other than the strong irritant properties and flammability of lithium hydride, industrial experience with lithium has been relatively benign.

Certain organometallic complexes and their salts commonly have adverse renal effects when used as pharmaceutical agents. These effects may have no relevance for industrial situations involving the same metals, particularly in view of the general lack of any recognized human or experimental nephrotoxicity associated with the metallic or inorganic forms of those metals. Three examples are presented here.

Organic *gold* salts, used for the treatment of rheumatoid arthritis, can cause hematuria and proteinuria to nephrotic proportions. The condition is generally at least partially reversible with cessation of therapy and is rarely fatal. Gold toxicity may involve the renal tubules or the glomeruli, depending on the specific compound involved and the dose and chronicity of exposure; gold toxicity has not been described with industrial exposures.

The primary limitation to the use of the cancer chemotherapeutic drug, *cisplatin*, is its potent and dose-related nephrotoxicity. The primary renal sites of involvement are the distal and collecting tubules. Although platinum binding to cytosolic components in dosed animals is usually maximal within 24 hours and urine abnormalities (casts, enzymuria, and proteinuria) may be

detected soon after a nephrotoxic dose, azotemia develops slowly in association with polyuria and may take more than 1 week to reach peak levels. Industrial exposures to platinum compounds have been associated with irritant and sensitization effects on mucocutaneous barriers and the respiratory tract, but there have been no reports of acute or chronic renal effects.

Organic *antimony* compounds, which have been used to treat helminthic infections, commonly produce cardiac, hepatic, and to a lesser degree, renal adverse effects, and large doses have produced acute renal failure. Acute industrial inhalation exposures to inorganic antimony compounds have generally been associated with mucocutaneous, respiratory, and gastrointestinal irritant conditions, and rarely, sudden death, but there are no reports of significant renal effect. The hemolytic and secondary renal effects of exposure to stibine, the gaseous anhydride of antimony, were described previously.

Accidental or intentional ingestions. Certain metal compounds, such as inorganic mercury, are potentially nephrotoxic at large doses that are generally only achieved through accidental or intentional ingestion and that are relatively unlikely to occur in industrial settings. Acute thallium poisoning, which has occurred historically through ingestion of rat poisons or depilatory agents, usually affects multiple organ systems and may cause albuminuria, diminished renal concentrating ability, or renal failure. Transient albuminuria occurred in each of six workers poisoned while recovering thallium from flue dust at a sulfuric acid plant. Other examples include copper sulfate, iron (as the pharmaceutical preparation, ferrous sulfate), barium chloride, and elemental white phosphorus. Each of these has produced acute renal failure with massive oral ingestion; however, renal impairment is generally only one feature of severe multisystemic poisoning with these agents, and their inherent nephrotoxicity is relatively low, at the exposure levels expected in most industrial processes.

Metal chelation therapy. It should be recognized that some chelating agents used therapeutically for metal intoxications, EDTA and penicillamine (Cuprimine) for example, have intrinsic potential to cause nephrotoxic injury. In general, however, their use is not contraindicated in metal intoxications in which acute renal insufficiency is not prominent. The primary factors in deciding whether or not to initiate chelation therapy should remain the identity of the metal involved and the overall degree of systemic toxicity.

Halogenated hydrocarbons

Carbon tetrachloride. Carbon tetrachloride is historically the most nephrotoxic of the halogenated hydrocarbons. It was formerly used widely as a cleaner and degreaser but has largely been replaced, other than for use as an intermediate in the synthesis of fluorochlorocarbon compounds. Accidental inhalational poisonings were not uncommon in

industrial and domestic settings during previous periods of higher use. Acute overexposure to carbon tetrachloride primarily affects the kidneys and liver, and is accompanied by transient depression of the central nervous system. Kidney damage is relatively more pronounced after inhalation exposure, and liver damage after oral ingestion. Toxicity is mediated by metabolism to a reactive intermediate, probably a free radical, and the kidneys and liver appear to be injured by different mechanisms.

While liver injury is usually maximal within 1–2 days after exposure, renal dysfunction is generally most severe 7–10 days after the exposure, at a time when the liver abnormalities may have nearly resolved. The proximal tubules and loop of Henle are most affected, although the distal tubules also may be involved. In survivors, a subsequent diuretic phase may last for several weeks, and renal function may not return to normal for up to 6 months. Some have suggested that the acute tubular necrosis results from volume depletion during the period of liver injury and that careful volume repletion early in the course may prevent or reverse kidney damage. Despite appropriate treatment with supportive measures and hemodialysis when necessary, carbon tetrachloride poisonings have been fatal in up to 30% of cases. Interestingly, it has been observed clinically and further documented experimentally that acute or chronic ethanol use and acute simultaneous exposure to other alcohols and ketones may worsen the acute toxicity of carbon tetrachloride.¹⁹

Chloroform. Chloroform is also capable of causing liver and renal injury with acute overexposure, but its toxicity for both organs is much less than that of carbon tetrachloride, and its central anesthetic properties are much greater. Despite extensive use of chloroform as an anesthetic in the past, reports of chloroform nephropathy are relatively uncommon in humans. As is the case with carbon tetrachloride, renal toxicity is more pronounced after inhalation and hepatotoxicity after ingestion.

Others. Although many chlorine and bromine derivatives of LMW aliphatic hydrocarbons are known to be nephrotoxic when administered by inhalation or other routes to experimental animals, clinically significant renal injury is less common and occurs generally in settings of high exposure. Acute inhalation overexposures to the chlorinated solvents in common contemporary use, including tetrachloroethylene, trichloroethylene, and 1,1,1-trichloroethane, typically produce transient abnormalities in BUN or creatinine levels. However, renal tubular and hepatic necrosis have been reported in association with occupational use of tetrachloroethylene in a degreasing tank, and abusive inhalation of trichloroethylene has produced hepatic injury and acute renal failure. Workers exposed to tetrachloroethylene in the dry cleaning industry have been found to have increased urinary excretion of tubular proteins and enzymes in a number of studies, but without significant functional impairment.²⁰ Ingestion of ethylene dichloride (EDC), which has been used as a solvent, a fumigant, and a chemical intermediate, has

produced both liver and kidney injury in humans and animals, but the reports of EDC inhalational poisoning through occupational exposure generally have described liver toxicity without prominent renal involvement.

Ethylene dibromide (EDB), which has been used as a gasoline additive and also as a fumigant, is associated with both acute and chronic renal injury. In animal models, EDB was more toxic with acute inhalation or ingestion exposure than was carbon tetrachloride, and resulted in early hepatic injury and a prolonged course of nephrotoxicity. In humans, there is one case report of overexposure to EDB by inhalation in a confined space that resulted in marked liver necrosis and less severe, proximal renal tubular defects.²¹ Other case reports involve suicidal ingestions which are commonly fatal due to liver and renal failure. Treatment is supportive.

Experimental nephrotoxicity. In experimental animal studies, the most acutely toxic halogenated hydrocarbon compound is hexachlorobutadiene (HCBd). Regardless of the route of administration, HCBd exposure results in prominent proximal tubular injury. HCBd has been used as a solvent, a fumigant, and an intermediate in rubber and lubricant production. It is a probable human carcinogen, and its use is now much less than in the past. HCBd is commonly an unwanted byproduct in syntheses of certain chlorinated compounds, and the potential remains for inadequately controlled exposures. HCBd-associated nephrotoxicity has not been documented in humans. In rodents, inhalation of dibromochloropropane (DBCP), a fumigant, primarily affects the testes and kidneys, with single experimental exposures being capable of producing permanent renal injury. DBCP has been established as a human sterilant in both manufacturing and field application settings, but human nephrotoxicity has not been described.

Other halogenated hydrocarbons showing highly potent nephrotoxicity in experimental animals include 1,3-dichloropropene, vinylidene chloride, and allyl chloride (3-chloro-1-propene). The latter is unusual for producing characteristic glomerular changes and interstitial tissue proliferation in addition to tubular injury. Chloroprene is relatively less nephrotoxic in experimental animals but has produced moderate to severe tubular degeneration with single administered doses.

Glycols

Ethylene glycol is classically cited as a severe acute nephrotoxin, and the kidney is in fact the major target organ following ethylene glycol ingestion. However, inhalation or dermal exposures to ethylene glycol are typically limited to mucocutaneous irritation and acute central nervous system intoxication. Consequently, despite common use as a chemical manufacturing substrate, a solvent, and an antifreeze agent, occupational exposures to ethylene glycol have only been associated with acute renal injury in situations of accidental or intentional ingestion. It is theoretically possible, however, that extreme exposure situations such as heating ethylene glycol within a confined space

could produce vapor concentrations sufficient to produce systemic and specifically renal toxicity.

Acute ethylene glycol intoxication manifests clinically in three phases. Initial inebriation with central nervous system depression is followed by cardiovascular dysfunction within about 12 hours. Survivors of the acute phase may then go on to develop proteinuria and acute renal failure within 24–72 hours. Anuria may develop and be relatively prolonged. Although ethylene glycol shows some direct effect on the central nervous system, most of its systemic toxicity is attributable to its metabolites. With clinically significant ethylene glycol intoxication, metabolic disturbance including an osmolar gap and a severe anion gap metabolic acidosis results, with accumulation of lactate and consumption of bicarbonate, as well as production of glycine from glycolate and glyoxalate. The end-metabolite oxalate forms calcium oxalate crystals which may cause tissue injury within multiple organs. Renal injury appears to be primarily attributable to intratubular deposition of crystalline oxalate, which is associated with acute tubular necrosis, interstitial nephritis, and focal cortical hemorrhagic necrosis. Oxalate crystals may be demonstrable in urine microscopically or grossly as precipitates.²²

Early treatment of ethylene glycol intoxication with either ethanol, a competitive inhibitor of the alcohol dehydrogenase enzyme, or 4-methylpyrazole (Fomepizole), a direct inhibitor of the enzyme, may avert the development of acidosis and the need for hemodialysis, though the efficacy of these therapies has not been definitively established. Most patients, however, develop acidosis and renal failure prior to presentation and, for these patients, hemodialysis and aggressive management of acidosis are also critical components of initial treatment. Large cumulative doses of sodium bicarbonate may be necessary to treat the acidosis, and calcium supplementation is often necessary to reverse hypocalcemia. Pyridoxine and thiamine stimulate the metabolism of glyoxalate and have been proposed as additional treatment agents; their use is relatively benign and, therefore, advisable. While dialysis dependence may be prolonged, renal failure frequently reverses.

The derivatives of ethylene glycol include diethylene glycol, dipropylene glycol, the monoalkyl and dialkyl glycol ethers (cellosolves), ethylene glycol diacetate, and dioxane (diethylene dioxide). These derivatives are used in industry, most commonly as solvents, and are known to have analogous and even more severe potential to cause renal injury than ethylene glycol. At least one of these compounds (dioxane) has been linked to deaths related to severe renal and hepatic injury following occupational exposures at relatively high levels for periods of 1 week to 2 months. More commonly, their toxicity is manifested following acute ingestion. The inherent nephrotoxicity of these derivatives may be compounded by the effects of concomitant intravascular hemolysis, particularly with the ether derivatives. It has not been established whether therapy with ethanol or 4-methylpyrazole is efficacious in the management of intoxications with these agents.

Petroleum distillates

Acute tubular necrosis has been produced by short-term exposures to a variety of petroleum distillate fractions. Several case reports have described strong temporal associations between acute oliguric renal failure and short-term exposure to diesel oil. In one case, biopsy-confirmed acute tubular necrosis developed abruptly and then progressively resolved following a several-week period of frequent hand washing with diesel oil. Other cases of acute renal failure with dermal exposure occurred after immersion in seawater contaminated with diesel oil and after hair washing with diesel oil. Isolated reports have described acute nephritic changes and acute renal failure with heavy skin exposure to turpentine and gasoline. One case report described oliguric acute renal failure after exposure to petroleum naphtha, which is widely used as a paint thinner. While renal function returned to normal within 2 weeks, the patient experienced a second episode of acute renal failure several months later after again exposing himself to the same product.²³

Commercially available petroleum distillates may include more than 100 individual solvent compounds in various proportions, and it is impossible to implicate any specific compound as the nephrotoxic agent in cases involving such mixed exposures. In some instances, however, the reported exposure has involved specific petroleum-derived solvent compounds.

Abusive inhalation of glues and other solvent-based consumer substances results in levels of exposure that far exceed the occupational exposure limit. The abused substances commonly include toluene, as the single or predominant solvent compound, or petroleum distillates. While exposure to toluene at levels below the occupational limit has not been associated with renal toxicity, the more intense exposures associated with abuse can induce acute tubular injury with renal tubular acidosis and renal failure.^{24,25} In some but not all reported cases, rhabdomyolysis preceded the renal failure and was undoubtedly a contributing factor.

Bipyridyl herbicides

Poisoning with paraquat, a non-selective herbicide, is most remarkable for the production of profound pulmonary toxicity, including non-cardiogenic pulmonary edema and progressive pulmonary fibrosis. If victims survive the acute systemic and pulmonary effects, proximal tubular dysfunction (including glycosuria, aminoaciduria, and phosphaturia), clinically significant levels of proteinuria, or acute renal failure may develop within 2 to 6 days.²⁶ Poisonings have been reported most often as a consequence of accidental or intentional ingestion but have also resulted after dermal exposures, generally involving sites with skin abrasions or other lesions, and after inhalation exposure. Early hemodialysis, hemoperfusion, or both, have been recommended to expedite removal of paraquat from the blood, enhance chances of survival, and minimize subsequent chronic pulmonary disease. Peritoneal dialysis appears to be ineffective. The renal effects of diquat poisoning are generally more pronounced than those of paraquat, and

the pulmonary toxicity is generally less;²⁷ the treatment is the same. Another bipyridyl herbicide, morfamquat, has been used less extensively, and there is no human experience relating to its toxicity to date; however, it is known to cause renal damage in experimental animals and should be regarded as a likely human nephrotoxin.

Biologic toxins

Exposures to biologic toxins can occur with greater prevalence in some occupations, although these generally do not represent singularly occupational hazards. Environmental factors associated with allergic reactions, including poison ivy, poison oak, hymenoptera (e.g., bees and wasps) stings, certain snake bites, and plant allergens, have produced the nephrotic syndrome, presumably involving an immunologic mechanism. Other environmental factors, including the venoms introduced by the bites or stings of certain arthropods, hymenoptera, and snakes, have direct toxic effects which may produce multisystem injury, in many cases including acute renal failure. Ingestion of certain mushrooms and plants also may produce such clinical pictures. Hemolysis or rhabdomyolysis may be involved. These biologic toxins will not be discussed in further detail.⁶

Acute toxic glomerulonephropathy

Glomerulonephropathies have developed relatively abruptly in the setting of chronic or subchronic exposures to mercury, silica, and mixtures of organic solvents. These are discussed in greater detail subsequently. It is noteworthy that a number of case reports have described the onset of rapidly progressive glomerulonephritis or specifically anti-GBM glomerulonephritis (both with pulmonary involvement [Goodpasture's syndrome] and without) within periods as short as days following short-term exposures to various organic solvent mixtures.²⁸ It has also been reported that individuals with glomerulonephritis may show exacerbations and improvements in renal function, respectively when increasing, resuming, or discontinuing occupational solvent exposures. This temporal association supports a causative or aggravating role for acute solvent exposures or in the clinical manifestations of some glomerulonephritides. The available evidence for an acute solvent-induced glomerulonephritis is limited to case reports at this time. In contrast, a much larger body of epidemiologic evidence indicates there is likely a causal association between chronic occupational solvent exposures and the development of glomerulonephritis (described in the next section).

Chronic renal disorders

Chronic tubulointerstitial nephropathy

Data from experimental exposure situations identify the proximal tubule as the primary target for many occupational nephrotoxins. In the absence of close surveillance, early renal damage from these agents generally escapes detection, however, and by the time a patient presents for

evaluation the primary lesions have usually been obscured by other direct and indirect toxic effects. Histopathologic studies generally reveal only non-specific abnormalities of renal architecture, particularly diffuse interstitial fibrosis.

Cadmium. The kidney is the primary target organ for cadmium toxicity. Cadmium has an exceptionally long half-life in the body of greater than 10 years. After initial accumulation in the liver, chronic, low-level exposure results in up to 50% of the cadmium body burden being concentrated in the kidneys, primarily in the renal cortex bound to metallothionein. Urine cadmium levels serve little purpose in evaluating recent cadmium exposures, but can serve as an indicator of the cumulative body burden, long after cadmium exposures have ceased. Cross-sectional studies of occupationally and environmentally exposed populations, using either historic information or urine cadmium concentrations as measures of long-term exposure, have repeatedly documented cumulative exposure-related increases in serum creatinine concentration and in urinary excretion of tubular proteins.²⁹

A majority of these studies have examined urine β 2M levels, but urine measurements of many other tubular proteins and enzymes such as RBP and NAG have also been utilized to demonstrate the effect of cadmium on renal function. Epidemiologic studies indicate that the relationship between cadmium exposure and tubulotoxic effects follows a threshold pattern, with estimates of the necessary cumulative cadmium exposure ranging between 5 and 20 years at current permissible exposure levels. Findings from animal and in-vivo human investigations support the concept of a critical concentration for cadmium in the renal cortex, and suggest that renal tubular dysfunction is likely to occur when the renal cortical concentration of cadmium reaches 200 μ g/g. Urinary cadmium concentrations generally exceed 10 μ g/g creatinine at this point.²⁹

The most common manifestations in both early and late stages of cadmium nephrotoxicity are deficiencies of proximal tubular reabsorption. The first sign is usually a tubular proteinuria, but glycosuria, phosphaturia, calciuria, and generalized aminoaciduria also may be evident. HMW proteinuria also may occur, although it rarely achieves clinically significant levels. Albuminuria may occur in the absence of significant tubular proteinuria, suggesting that cadmium may have adverse effects at both glomerular and tubular levels of the nephron. It should be noted that the absolute urine concentration of albumin, which is normally present in the urine in measurable levels, will invariably exceed those of smaller molecular weight proteins, even in the context of substantial tubular proteinuria. The relative increase of albumin or total protein in the urine compared with normal values, however, is usually orders of magnitude less than the relative increases in low molecular weight proteins, which may be increased 1000-fold in chronically exposed workers. Therefore, qualitative and quantitative measurements of urine total protein or albumin have little utility in the early or preclinical stages of cadmium nephropathy.

Urine measurements of LMW proteins have proved effective in monitoring cadmium-exposed workers and are routinely employed in industries using cadmium. Urine cadmium can serve as a marker of both cumulative exposure and the presence of renal disease; for an assessment of recent cadmium exposure, blood measurement may be more useful. The biologic standards adopted by the Occupational Safety and Health Administration (OSHA) in 1999 require more intensive monitoring and follow-up of workers who have screening urine cadmium levels > 3 μ g/g creatinine, urine β 2M > 300 μ g/g creatinine, or blood cadmium > 5 μ g/L whole blood. Medical removal of workers may be required when urine cadmium levels are > 7 μ g/g creatinine, β 2M > 750 μ g/g creatinine, or blood cadmium > 10 μ g/L whole blood. The complete OSHA standard and monitoring protocol should be consulted and utilized to guide individual patient care.^{30,31}

Abnormal proteinuria is rarely observed when the urine cadmium concentration is below 5–10 μ g/g creatinine, but urine cadmium levels at or above this threshold are associated with a higher risk for renal tubular dysfunction. The risk of renal involvement increases progressively with higher urine cadmium levels. It has been well established that the nephrotoxic effects of cadmium can be irreversible and can progress even after cessation of exposure. Periods of follow-up extending for 5 or more years after workers have been removed from exposure because of increased urine β 2M levels have demonstrated significant average increases in urine proteins and serum creatinine, as well as progressive nephrocalcinosis. Nevertheless, exposure cessation may delay the development of clinically significant abnormalities in these parameters.

The natural history of cadmium toxicity is characterized by gradual progression of proteinuria with renal failure or osteomalacia described only in isolated cases among occupationally exposed workers. Environmental studies have generally demonstrated progressive but persistent subclinical tubular damage, manifested by increasing excretion of tubular proteins and enzymes. In contrast, urinary calculi are not uncommon among long-term cadmium-exposed workers; the prevalence is undetermined but was reported to be as high as 44% in one series. The dramatic Itai-Itai disease, which affected individuals who consumed food contaminated by cadmium in one region of Japan, is characterized by painful bone disease, osteomalacia, and pseudofractures attributed to disordered calcium, phosphate, and vitamin D metabolism caused or influenced by the cadmium-induced renal damage.

Renal pathologic findings in advanced cases have included frank kidney contraction, tubular atrophy and dilation, interstitial fibrosis, with relative sparing of glomeruli at the microscopic level. Varying degrees of proteinuria occur with some cases progressing to renal failure. The significance of minor signs of renal dysfunction attributable to cadmium may have greater significance in the context of other diseases. For example, one study of individuals residing in areas of Belgium with relatively high levels of environmental cadmium contamination found that those with diabetes were more susceptible to

chronic cadmium nephrotoxicity. Other groups at potentially higher risk include women, the elderly, smokers, and those with iron deficiency.

Historic cohort mortality studies of cadmium-exposed working populations have yielded mixed results in studying end-stage renal disease as a cause of death. At least two studies of worker cohorts have reported greater than expected numbers of deaths from renal disease, with insufficient power to demonstrate statistical significance. Two larger mortality studies found no cadmium-associated risk after adjustment for potential confounding factors, but a nested case-control study conducted within the combined cohorts from those two studies found a two-fold increased risk of death from nephritis and nephrosis among workers with relatively high career exposure to cadmium. Several studies have demonstrated increased all-cause mortality in environmentally exposed subjects, with evidence of cadmium-induced kidney damage at baseline; however, the proportion of these deaths that is attributable to renal disease is not known.^{29,32}

There is no established treatment for cadmium-induced tubular nephropathy beyond removal from further exposure. Reductions in urine protein excretion have been described when individuals with mild and presumably early dysfunction reduce or cease their exposure to cadmium. One retrospective study found that workers whose urine $\beta_2\text{M}$ levels were less than 1000 $\mu\text{g/g}$ creatinine and whose urine cadmium levels never exceeded 20 $\mu\text{g/g}$ creatinine when exposure was reduced or stopped, showed evidence of reversible toxicity.³ The long-term significance of this initial improvement is questionable in light of multiple studies describing slow progression of dysfunction. It has also been reported that calcium and vitamin D replacement can slow the progression of associated osteomalacia, but such treatment is probably contraindicated other than in severe cases because of the risk for nephrocalcinosis. Chelating agents have no demonstrated effectiveness for the condition.¹¹

Lead. Lead remains a widely used metal, and toxic exposures still occur commonly in both occupational and general environments. Chronic renal failure and the pathologic manifestations of end-stage renal disease were identified as late manifestations of chronic occupational lead exposure during the 19th and early 20th centuries, but with improved control of lead exposures in contemporary workplaces in the developed world, chronic lead nephropathy has become a relatively rare clinical diagnosis. The progression from acute and reversible lead nephropathy to the chronic and irreversible form has been demonstrated reproducibly in rodent models, and there are several lines of human evidence that indicate that lead exposure causes or contributes to chronic renal disease.³³

The strongest evidence for the existence of a chronic lead nephropathy comes from clinical and pathologic investigations in Queensland, Australia. At the turn of the last century, chronic nephritis occurred there with excessive frequency among young adults, particularly those with histories of childhood lead poisoning. For at least 10

years before the recognized increase in renal disease, acute lead poisoning had been a problem among children in this region who played on and under wooden verandas that were routinely coated with lead-containing paints. The use of lead paint was prohibited there in 1922, and the occurrence of chronic renal disease progressively declined, approaching the rates seen in other provinces by the 1940s and 1950s. A retrospective follow-up study of children hospitalized for plumbism between 1915 and 1935 established the status of 352 (of 401) former patients in 1954 and found that 165 had died by age 40 years or younger, including 107 who had died with causes of death listed as nephritis variants.

A 1956 autopsy study, which included 67 Queensland natives who died between the ages of 20 and 50 years with chronic nephritis, found the lead content of skull and rib bones to be twice as high among cases of idiopathic renal disease than among cases with non-renal disease or renal disease of other established causes. A follow-up study of childhood lead poisoning victims from the 1920s and 1930s in Boston, however, did not reveal either any significant predilection for renal disease or premature death. It has been hypothesized that chronic renal disease was averted because these children received chelation therapy.³⁴ Other supportive clinical evidence comes from the historically observed cases of chronic renal failure among moonshine drinkers. In addition to having impaired renal function, drinkers of lead-contaminated alcohol had evidence of high total body lead by EDTA lead mobilization testing; renal biopsy specimens revealed intranuclear inclusion bodies in renal epithelial cells, a characteristic of acute lead nephropathy in children.

The other major body of evidence for a chronic lead-induced nephropathy comes from studies of occupationally exposed individuals. One study of 140 deaths among a subcohort of 241 Australian lead smelter workers, who had formerly been acutely lead poisoned, found a five-fold increased risk of death from chronic renal disease in comparison to other lead-exposed, but never acutely poisoned, workers from the same smelter. In addition, three large historic cohort studies of battery or smelter workers exposed to lead demonstrated twice the expected risk for mortality from chronic renal disease (and some hypertension-related diseases), with 20 years of exposure being associated with a four-fold increased risk for death from renal disease. With extended follow-up, however, this excess mortality from non-malignant renal disease became attenuated.^{35,36} Many epidemiologic studies have documented an association between higher blood lead levels (greater than 60 $\mu\text{g/dL}$) and elevated serum creatinine in lead-exposed workers.³⁷ Low level environmental lead exposures have been associated with elevated blood lead levels and increases in serum creatinine as well, although the magnitude of the rise in creatinine is small and the clinical significance uncertain.³⁸

In general, clinical tests have not been valuable in assessing asymptomatic lead-exposed workers. Cross-sectional studies have not found clinical parameters, such as BUN, to be higher than laboratory reference values, or

to correlate with historic or laboratory measures of lead exposure. A number of studies have demonstrated increased excretion of tubular proteins such as NAG by patients with elevated blood lead levels, but the clinical significance of these findings remains unclear.

A comprehensive clinical evaluation of 140 lead-exposed workers (only five of whom were symptomatic) found 57 who had abnormally high lead excretion ($>650 \mu\text{g}$) with EDTA chelation challenge and no other disease. Of these 57 workers, 21 had reduced GFRs (less than $87 \text{ mL/min/1.73m}^2$ body surface area, by iodothalamate clearance) and comparable reductions in effective renal plasma flow (by PAH clearance), with no obvious alternative explanation for renal dysfunction.³⁹ Only three had elevations of serum creatinine or BUN. Six of 12 asymptomatic subjects with abnormal kidney function underwent renal biopsy, with light microscopic changes demonstrating focal tubular atrophy, interstitial disease, and generally normal glomeruli. Two subjects had some evidence of glomerular sclerosis. Fluorescence microscopy revealed various patterns of immunoglobulin deposition in tubular and glomerular basement membranes in the seven cases so studied. Among eight subjects who had reduced GFRs and who underwent thrice weekly EDTA chelation treatment for 6 to 50 months, four showed 20% or greater improvements in GFR (two worsened and two showed no change), with normalization of EDTA-mobilized lead excretion. The authors characterized the observed treatment response as evidence of probable lead causation and as effective reversal of preclinical lead-induced renal dysfunction. They did not, however, recommend EDTA therapy for established lead nephropathy. In another study, the same investigators also found that the degree of EDTA-mobilized lead excretion correlated highly with increases in serum creatinine among 44 men with gout (including 26 with histories of industrial lead or moonshine exposure), a condition that historically has been associated with lead exposure. The investigators speculated that, not only some proportion of non-specific or idiopathic chronic renal disease cases, but also some cases with an identifiable cause, such as gout or hypertension, may be primarily attributable to chronic lead toxicity.⁴⁰

Once diagnosed, the treatment for chronic interstitial nephritis attributed to lead is non-specific, other than elimination of further lead exposure. There is no clear evidence that long-term EDTA chelation therapy improves the course of clinically established chronic lead nephropathy. The possibility exists that long-term EDTA administration in renally compromised patients may itself have an adverse renal effect. Wedeen and coworkers recommend that such treatment only be undertaken with careful follow-up and with a clearly defined endpoint, such as normalization of EDTA-challenge response or improvement in renal excretory function within an *a priori* designated time frame.³⁹

Mercury. Acute poisoning with mercuric salts, described previously, can result in persistent renal impairment characterized primarily by tubular dysfunction. Workers chronically exposed to mercuric salts have been reported to have increased urinary excretion of certain lysosomal enzymes,

particularly NAG, suggesting the presence of proximal tubular dysfunction or injury. Tubular proteinuria also occurs with Minamata disease, a severe neurotoxic disorder that occurred in an outbreak caused by dietary ingestion of seafood contaminated by methyl mercury. However, despite the generally higher affinity of methyl mercury for renal than neurologic tissues, the proteinuria of Minamata disease was not associated with marked azotemia and renal impairment.

Beryllium. Chronic beryllium exposure is well established as a cause of granulomatous pneumoconiosis (berylliosis) or chronic beryllium disease (CBD) and has also been associated with extrapulmonary involvement; skin and, to lesser degrees, liver and lymph nodes are the most commonly described extrapulmonary sites of beryllium deposition and pathologic changes. There have been reports of pathologic changes in other organs, including the kidneys. Renal pathologic changes consistent with old or scarred granulomas (Schaumann bodies associated with local beryllium deposition) have been reported. Most of the reported cases with renal pathologic changes have described hyperemia and intrarenal calculi. Hypercalcemia and hypercalciuria have also been reported frequently with CBD, and nephrolithiasis has been present in as many as 10% to 30% of cases, with passage of calcium oxalate- (and beryllium-) containing urinary stones.⁴¹

Other elements. Cross-sectional epidemiologic studies of chrome platers and of workers with long-term exposures to uranium dust have found slight but statistically significant increases in urine tubular protein excretion. However, no links have been established between chronic exposures to either of these agents and development of clinically significant renal dysfunction. Germanium is sometimes used (in inorganic forms, such as germanium oxide) as a component of folk remedies or health elixirs. There have been at least 13 reported cases of nephropathy associated with regular ingestion of such mixtures over periods spanning 6 to 20 months. The pathologic findings on renal biopsy have uniformly appeared as chronic tubulointerstitial nephritis, typically with proximal or distal tubular degeneration and interstitial fibrosis, and without significant glomerular injury or evidence of immunologic mechanism. The systemic toxicity of germanium in experimental exposures is low, but the kidneys and liver are usually affected.⁴²

Chronic glomerulonephropathy

Mercury. Chronic elemental mercury poisoning primarily affects the central nervous system but also may produce proteinuria. There is human and animal evidence that elemental and inorganic mercury are capable of inducing an immunologically mediated glomerular abnormality and proteinuria that occasionally may reach nephrotic proportions. Young children with exposure to mercury ointment may have acrodynia, an idiosyncratic and presumably allergic reaction whose central features are dermatologic, but

which may be associated with proteinuria. There have also been a number of reports of transient proteinuria and overt nephrotic syndrome occurring idiosyncratically among workers with chronic or subacute exposure to metallic or inorganic mercury. The syndrome has occurred with various degrees of mercury exposure but, typically, without other manifestations of mercury toxicity. Most of the reported cases have resolved completely after cessation of exposure.

The most frequent pathologic pattern on renal biopsy has been a membranous-like glomerulonephropathy, with deposits of immune complex in the glomerular basement membrane, although normal and other immunofluorescent patterns have also been described. An analogous phenomenon can be induced experimentally in rodents by repeated subcutaneous or intramuscular injection of mercuric chloride or by injection or inhalation of a variety of organic mercury compounds, with glomerular deposition of antiglomerular antibodies. A progressive membranous nephropathy with glomerular deposition of immune complexes ensues, followed by resolution of both immunologic and histopathologic changes. Despite consistent reproducibility in selected genetically susceptible experimental animals, it appears that the mercury-induced proteinuric syndrome occurs rarely in humans. Recent cross-sectional studies of exposed workers have found no increase in urinary albumin, anti-GBM antibodies or other autoantibodies.^{43,44}

Other metal exposures have been reported in association with proteinuria of probable glomerulotoxic origin. As discussed earlier, organic gold salts, used for the treatment of rheumatoid arthritis, can cause hematuria and proteinuria up to nephrotic proportions. A pharmacologic preparation of bismuth (bismuth tartrate), which previously also was used in the treatment of rheumatoid arthritis, reportedly caused nephrotic syndrome. Nickel carbonyl inhalation in experimental rats produced proteinuria.

Silica. There is mounting evidence that silica exposure increases the risk for renal disease. Animals exposed to silica under experimental conditions have developed a variety of nephrotoxic effects, including glomerulosclerosis. Three studies have documented subclinical renal dysfunction in silica-exposed workers as evidenced by increased urinary excretion of both glomerular (albumin and transferrin) and tubular (RBP and NAG) proteins. These abnormalities were found independent of silicosis, and with either short- or long-term exposure.

Numerous case reports have described biopsy proven proliferative glomerulonephritis in persons exposed to silica (either with silicosis or without any pulmonary disease), and two recent studies document an increased risk for end-stage renal disease (particularly due to glomerulonephritis) in silica-exposed workers.^{45,46} In addition, two case-control studies of patients with either rapidly progressive glomerulonephritis and antineutrophil cytoplasmic antibodies (ANCA) consistent with Wegener's granulomatosis found an increased incidence of silica exposure in these patients compared with controls.^{47,48} The mechanism

for this putative nephrotoxicity is not well understood and may involve both a direct nephrotoxic effect as well as an immune-mediated mechanism of injury.

Supporting the argument for a direct toxic effect is a case report of acute renal failure following acute overexposure to silica without associated immune deposits on renal biopsy. However, the lack of a clear dose-response relationship and the frequent finding of immune deposits on biopsy specimens argue in favor of an immune-mediated mechanism. In all likelihood, both mechanisms of injury may play a role. Silica-related nephrotoxicity may progress to chronic renal failure and even death, despite steroid treatment and hemodialysis. In one reported case, aggressive immunosuppressive therapy was judged to be helpful.

Organic solvents. Organic solvents have been implicated as either causative or contributing agents in the development of a variety of primary glomerular disorders. While this has not been replicated in studies, a number of investigations have described increased levels of selected urine proteins among groups of workers with chronic exposure to solvents. Cohort mortality studies have not revealed clearly increased risk for death from primary glomerular diseases.

The main evidence in support of there being a causal association between organic solvents and glomerulonephritis comes from an extensive series of case reports and case-control epidemiologic investigations.⁴⁹ The case reports have generally described instances of anti-GBM glomerulonephritis occurring in the context of either chronic, subchronic, or acutely excessive exposures to a variety of organic solvents in both occupational and domestic settings. The predominance of anti-GBM glomerulonephritis among reported cases has indicated an anti-GBM immunopathogenic mechanism, possibly initiated by interactions between inhaled solvent vapors and pulmonary alveolar basement membrane, which share common antigenic properties. However, the findings of case-control studies indicate that the increased risk for glomerulonephritis associated with solvent exposure is greater than can be explained by anti-GBM glomerulonephritis alone, indicating a broader association with many types of primary glomerulonephritis.

At least 15 case-control studies have examined the relationship between solvents and glomerulonephritis, and many have described significantly increased risks, ranging up to nine-fold increases, for solvent exposures that exceed the usual population experience.⁵⁰ The studies have included all types of primary glomerulonephritis, suggesting either that the estimated risk extends to all types or that an even greater risk may be attached to some subgroup of glomerulonephritis. Two studies that examined single categories of glomerular disease, proliferative in one study and membranous in the other, both found substantially increased risks associated with solvent exposure. The case-control studies have been criticized for methodologic limitations, such as the recall bias inherent to retrospective interview studies. However, the credibility of these studies is supported by the consistency and reproducibility of

findings across numerous investigations (each having different types and degrees of methodologic limitation), the high magnitude and statistical significance of the risk estimates, and the evidence for a dose-response relationship in each study that examined subgroups defined by time or intensity of exposure.²⁸

The chemical structural diversity of the associated solvent compounds, the widespread prevalence of solvent use, and the relative rarity of primary glomerulonephritis suggest that any pathogenic mechanism involving organic solvents is probably multifactorial or relatively idiosyncratic. Although the risk for glomerulonephritis may be greater with solvent exposure, solvent exposures appear to be involved in only a small proportion of glomerulonephritis cases. The weight of evidence favors any effect of solvents being non-specific and not limited to specific solvent compounds. Immune mechanisms are probably involved, and it is plausible that there is an immunogenetic predisposition. It may be that potentially glomerulotoxic immune factors arise independently of solvent exposure and that solvents interact with those factors or with renal tissue to precipitate or facilitate the development of glomerulonephritis. For example, when anti-GBM antibodies were injected into rabbits, the antibodies adhered to alveolar basement membrane after intratracheal instillation of gasoline, but not after saline instillation. Other than cessation of further exposures, there is no specific treatment for cases of glomerulonephritis associated with organic solvents. The clinical severity of primary glomerulonephritis has been observed to fluctuate adversely with variations in intensity of continued solvent exposure, and it is prudent to recommend avoidance of non-incident solvent exposure for any individual with glomerulonephritis.

Vascular nephropathy

Chronic exposure to carbon disulfide may accelerate atherosclerosis, and epidemiologic studies of chronically exposed workers have demonstrated significantly increased risks for cardiovascular disease. In addition, an increased prevalence of hypertension has been reported among exposed workers. One study of artificial silk workers reported that half of those with 20 or more years exposure were hypertensive. Carbon disulfide-induced renovascular disease has been invoked to explain this observation. This hypothesis is supported by one clinical study that evaluated 26 carbon disulfide-exposed workers, 16 of whom were hypertensive or had a history of hypertension. The effective renal plasma flow (ERPF, as measured by PAH clearance) was significantly lower on average in the entire group in comparison to eight normotensive and non-exposed control subjects. When creatinine clearance was measured in the five subjects with the lowest ERPFs, four had normal creatinine clearances and relatively high filtration ratios (creatinine clearance/PAH clearance). These findings support the presence of intrarenal vascular changes.

Renal papillary necrosis

Renal papillary necrosis is an uncommon condition that may occur in association with a variety of intrarenal,

urologic, and systemic conditions. In clinical series, it has been associated most often with diabetes mellitus and, in others, with excessive analgesic use. It is particularly strongly associated with excessive use of phenacetin-containing analgesics, although most, if not all, analgesics and non-steroidal anti-inflammatory agents have the potential to cause this condition in humans and animals. Other medical agents also have been incriminated as possible causes, including phenothiazines, cyclophosphamide (Cytoxan), and radiocontrast agents, and it has been speculated that other drugs and chemicals may also contribute to or cause renal papillary necrosis. Although it has not been demonstrated to occur in humans with occupational exposures to many chemicals, it has been produced in experimental animal exposures using a variety of chemicals that either have been used in industry, are structurally related to industrial chemicals, or are recognized as industrial pollutants. These include methylaniline, tetrahydroquinoline, ethylenimine, bromoethanamine, diphenylamine, diphenylmethyl alcohol, phenylanthranilic acid, aminopyrene, dioxin, and PCBs (specifically, Aroclor 1242). In managing cases of renal papillary necrosis, therefore, it is reasonable at least to consider the possible role of antecedent occupational chemical exposures.

Renal cystic disease

Renal cystic disease (RCD) in humans is most often attributable to heritable conditions, particularly autosomal dominant polycystic kidney disease. It is clear, however, from clinical experience and animal experiments that heritable factors are not solely involved in the development of RCD and that cyst development can occur in the absence of heritable factors. For example, RCD occurs in up to 40% of patients undergoing chronic dialysis therapy, including patients with previously non-cystic kidneys. Chemical factors have been considered as possible causes of this acquired condition. Although certain experimental animal species have been identified as having inherited predispositions to renal cyst development, renal cyst formation can be induced reproducibly and in a dose-related manner by experimental exposures to a variety of drugs and chemicals, independent of identifiable predisposition.

Diphenylamine and diphenylthiazole are well characterized experimentally as cystogenic agents. Diphenylamine also produces renal cysts in the offspring of female rats exposed during pregnancy. Cyst formation has also been produced experimentally by lead acetate, diethylhexyl phthalate, dibutyl phthalate, 2,4,5-trichlorophenoxyacetic acid, alloxan, biphenyl, lithium (lithium chloride), and cisplatin, the latter two of which are pharmaceutical agents that have been related adversely to cyst formation in humans. RCD has not been recognized to occur in association with any occupational chemical exposure, but the possibility should be considered in patients with RCD and no family history or obvious alternative explanation.

Radiation nephritis

Renal involvement is generally not a direct feature of ionizing radiation exposure produced either by internal

emitters, which gain entry to the body, or by acute whole-body external radiation (radiation sickness). Renal injury commonly occurs following excessive partial-body external radiation exposure to sites including the retroperitoneum; however, this is described only with therapeutic radiation and usually at cumulative doses exceeding 2300 rads (23 Gy) over a several-week period. Such exposure produces no clinically detectable acute changes other than local skin changes, but it may result in acute radiation nephritis up to 6–12 months later.

The acute nephritis usually manifests with hypertension, which in turn, may produce proteinuria, microhematuria and azotemia. It may occur in the setting of cardiac failure and a relatively refractory anemia. The initial renal pathologic injury includes degenerative changes of the tubular epithelial and glomerular endothelial cells and may progress (as the chronic condition) to include extensive atrophic changes and interstitial fibrosis. The mortality rate is generally high, and survivors often have persistent proteinuria or renal insufficiency. Chronic radiation nephritis may develop years after exposure, with or without acute radiation nephritis in the interim. It is characterized by clinical features similar to the acute condition, although the condition is generally slowly progressive and does not show spontaneous improvement. Malignant hypertension and its complications are common, particularly in the chronic syndrome.

Hypertension

Lead. Chronic lead exposure is associated with subclinical increases in blood pressure and may also increase the risk for developing hypertension. By the early 20th century, it was generally accepted that hypertension was a clinical manifestation of chronic lead poisoning. However, subsequent controlled epidemiologic studies of lead-exposed working populations have generally not demonstrated substantial increases in either hypertension or mortality from hypertensive diseases. Many authorities now question the existence, or at least the clinical significance, of any inherent hypertensive effect of lead beyond that secondarily attributable to lead-associated chronic renal insufficiency. There is, however, evidence indicating that lead exposure has some degree of hypertensive effect. Each of two large population-based studies in the United States and Great Britain found that higher blood lead levels were significant predictors of hypertension, and that the blood lead level showed a statistically significant, although small, positive association with both systolic and diastolic blood pressure.^{51,52} Experimental animal studies have demonstrated that dietary lead can increase blood pressure and that lead, even at low levels, may produce changes in the balance of renin and angiotensin.

Blood lead appears to make a small proportional contribution to blood pressure in the general population, relative to other risk factors. However, in situations that differ from the general population experience, lead may be a more substantial contributor to blood pressure elevation. For example, a study in the west of Scotland, where plumb-

ing systems commonly contain lead parts, found significantly higher blood lead levels among 130 hypertensive subjects than among matched normotensive subjects. Blood lead levels also were higher among normotensive individuals with elevated serum urea levels. Another study that included 20 men with essential hypertension and normal renal function observed significantly higher blood lead levels among hypertensive subjects than the normotensive controls.⁵³ In each study, occult lead exposure was presumed to be a contributing factor to the development of hypertension. Duration of lead exposure may be more strongly associated with blood pressure than elevations in blood lead levels. Because of this, the EDTA lead mobilization test has been suggested as one potentially helpful test for evaluating selected patients with essential hypertension, but it is not broadly accepted as such. In the absence of other manifestations of lead intoxication, there is no indication for chelation treatment for hypertension associated with increased body burden of lead.

Cadmium. Cadmium has also been linked with hypertension. Some, but not all, animal experiments have demonstrated a cadmium hypertensive effect at levels of exposure below those producing evident renal damage. Studies of industrially and environmentally exposed individuals, however, have generally found no substantial increase in hypertension. In summary, the data regarding a possible cadmium hypertensive effect are equivocal, but this issue has not been addressed as closely for cadmium as for lead.⁵⁴

Carbon disulfide. Chronic exposure to carbon disulfide is associated with an increased risk for hypertension and hypertensive diseases. The hypertensive effect is presumed to be the result of vascular nephropathy (discussed earlier).

Non-renal urinary tract disorders

Urolithiasis

The acute toxic nephropathy induced by ethylene glycol is mediated in part by the intratubular concentration and crystallization of calcium oxalate (described earlier). Although it is believed that tubular obstruction by these crystals is the major mechanism by which renal injury is produced, acute oxalate crystal formation is not associated with clinically significant obstruction distally in the urinary tract. There is no reported increase in risk for stone formation among individuals with chronic ethylene glycol exposure in the occupational setting.

Urinary calculi have been reported with high frequency in some studies of long-term cadmium-exposed workers, with prevalence reported as high as 44% in one series involving Swedish workers. This risk for stone formation has not been observed in all series of cadmium-exposed workers, however, and the wide differences in prevalence remain unexplained. Hypercalciuria is usually present with cadmium-associated urolithiasis, and it is believed to play

a primary role in stone formation. Other possible contributory effects of cadmium include its interference with calcium-binding proteins and calcium deposition in bone.

There are a variety of other uncommon or speculative causes of urolithiasis. Chronic beryllium exposure is rarely associated with chronic tubulointerstitial nephritis (described earlier), and this may be accompanied by passage of small calcium oxalate stones, which may contain beryllium. Silica stones are common in domestic grazing animals, particularly in regions where the amount of silicon in forage is high. However, although silicon is a common component of calcium oxalate, uric acid, and phosphate stones in humans, silica-predominant stones occur rarely in humans and are only known to occur with chronic magnesium trisilicate antacid use. It should be noted that, although primary gout may lead to urate nephrolithiasis, there is no identified risk for stone formation with saturnine (lead-induced) gout, even though it may produce hyperuricemia and hyperuricosuria. There is also no evidence that manganese causes urolithiasis, but it may be noteworthy that manganese can interfere with the synthesis of glycosaminoglycans, which have been hypothesized to play inhibitory roles in calcium oxalate crystal growth and aggregation in urine. Bilateral renal calculi and aminoaciduria have been reported with excessive intake of Worcestershire sauce, representing a suspected environmental lithogen. No specific component of the sauce was identified as the possible cause.

Bladder disorders

Neurogenic bladder. A number of pharmacologic agents are capable of causing bladder dysfunction. In the late 1970s, neurogenic bladder associated with the polyurethane foam catalytic agent dimethylaminopropionitrile (DMAPN) occurred in epidemic proportions at two separate polyurethane manufacturing plants following introduction of the agent, and additional symptomatic cases were later identified at five other plants.⁵⁵ Although DMAPN had already been used as a catalyst in an acrylicamide waterproofing process for more than 10 years without any recognized problem, more than one-half of the exposed workers at the polyurethane plant had symptomatic bladder dysfunction, most often manifested as urinary retention. Of individuals referred for neurologic evaluation, seven of eight reported cases lacked either a detrusor reflex or normal sensation of bladder filling, and three had prolonged sacral latencies, with two of those three having evidence of partial denervation on external anal sphincter examination.

Electrophysiologic findings of distal extremity peripheral neuropathy were also present in most members of this selected subgroup. Broad surveys at the affected plants also revealed symptomatic evidence of sexual dysfunction (partial impotence and increased libido) and non-specific symptoms of irritability, insomnia, and headaches. The symptoms of urinary retention occurred as early as 1 week after the first exposure, and persisted without improvement in most cases until the DMAPN exposure ceased. About

one-half of cases improved within 1–2 weeks after the agent was withdrawn, and of the 14% who were still symptomatic after 3 months, nearly all were still symptomatic 2 years later. Several individuals still had objective findings on cystometric and electrophysiologic examinations.

Experimental animal studies and isolated reports of human pathologic studies of biopsied sural nerves indicate that the primary site of DMAPN action is probably the neuronal axon. The predominance of genitourinary over extremity dysfunction is unusual for toxic neuropathies and is still not fully explained. Urinary difficulties have also been described in a few cases of neuropathy from acrylamide, another nitrile compound, but these manifestations of autonomic involvement have only appeared late in the course of peripheral neuropathy. Rodents can develop urine retention in less than 12 hours after oral doses of DMAPN, and then bladder function returns to normal within 2 to 3 days. A study of rats exposed separately to equimolar doses of DMAPN, cyanoacetic acid, and dimethylamine found urinary retention in 100%, 50%, and 25%, of animals respectively. The relevance of these additional findings is not established for human exposures.

Cystitis. Acute hemorrhagic cystitis and urinary irritative symptoms (e.g., dysuria and frequent urination) have occurred in humans with exposures to formamidine pesticides, toluidines (methyl aniline homologues), and chlorotoluidines. The conditions have generally cleared promptly after exposure cessation. As an illustration, two individuals had abdominal pain, dysuria, and gross hematuria during the evening after having cleaned a water tank earlier that day. Cystoscopic bladder biopsies demonstrated hemorrhagic cystitis. Hematuria resolved within 2 days and dysuria within about 1 week. Based on the presence of a metabolite of the chlorotoluidine pesticide chlordimeform (chlorphenamidine) in the serum and urine specimens, it was determined that the tank had been used previously to haul chlordimeform, resulting in this acute exposure. Lower urinary tract symptoms have also been reported among jewelers exposed to cadmium in brazing materials. Consideration should always be given to the possibility that hematuria of bladder origin, particularly in instances of suspected chronic chemical exposures, could represent an initial manifestation of malignant or premalignant disease.

Chapter 26

Gastrointestinal Disorders

26.1 Liver Diseases

Carl A Brodtkin, Stan Lee, Carrie A Redlich

Occupational and environmental liver diseases include acute and chronic liver injury caused by workplace or environmental exposure(s). In the first half of the 20th century, a number of case reports and series documented liver injury following exposure to now well-recognized hepatotoxins such as carbon tetrachloride, trinitrotoluene, tetrachloroethane, and yellow phosphorus. The use of such agents has been reduced or eliminated in most workplace settings. However, liver injury associated with exposure to chemicals used in the workplace still occurs and may be underdiagnosed. Hepatotoxic exposures also can be encountered in the environment by contact with contaminated water, air, soil, or food, or with naturally occurring hepatotoxins such as aflatoxins.

Occupational and environmental liver injury can be challenging to recognize, diagnose, and manage for several reasons. The incidence, etiologic agents, natural history, diagnostic criteria and management strategies for occupational liver disease have not been fully characterized. Acute toxic liver injury frequently has a non-specific clinical presentation, whereas chronic liver injury usually remains asymptomatic until it reaches an advanced stage. It is unknown how often occupational liver disease goes unrecognized, is attributed to other etiologies, or is misclassified as idiopathic.

Once liver disease is recognized, it must be distinguished from non-occupational or non-environmental etiologies on the basis of clinical presentation, exposure history, laboratory findings, and pathologic findings when available. The existence of two common causes of liver disease, namely alcohol and hepatitis viruses, must be considered. Although exposure to alcohol and hepatitis viruses may be more frequent in certain occupations, the majority of liver disease caused by these two entities occurs outside the workplace. However, even the separation between occupational and non-occupational liver disease is not absolute. For example, a study of cirrhosis mortality and occupation in California from 1979 to 1981 found the highest cirrhosis mortality rates among "blue-collar" occupations (construction workers, carpenters, painters, machinists). Notably, these occupations often carry greater exposure to hepatotoxic chemicals that may directly contribute to cirrhosis or potentially interact with alcohol consumption, to increase risk.¹

The diagnosis of occupational liver injury is facilitated by human and toxicologic data. The information available is based on the following sources: (1) isolated case reports of liver injury, usually following obvious overexposure; (2) epidemiologic studies demonstrating liver function test

abnormalities or increased incidence of chronic liver disease in certain groups (frequently with multiple, poorly characterized exposures); and (3) animal toxicology studies documenting hepatotoxic responses to specific agents. Because of limited human data, the hepatotoxic potential of a given substance frequently is determined based on animal studies. Such studies often focus on effects of a single acute high exposure rather than on chronic low-level or simultaneous multiple exposures that reflect most occupational exposure conditions. Significant interspecies differences in susceptibility, possibly related to variable hepatic metabolism, also limit the applicability of animal findings to the prediction of human hepatotoxicity.

The diagnosis of occupational liver disease is complicated by several host and acquired factors, discussed later, that can potentiate hepatotoxic effects and may result in enhanced or unexpected toxicity. Thus, a high level of suspicion is required to recognize and diagnose liver disease of occupational or environmental origin; the diagnosis need not be dismissed because liver injury associated with a given substance has not been reported previously.

This chapter reviews acute and chronic non-malignant occupational and environmental liver injury, including clinical features, known and suspected causative agents, strategies for diagnosis, screening for preclinical disease, and management.

ROLE OF THE LIVER IN METABOLISM

The liver is the major site for the biotransformation of exogenous substances such as chemicals, drugs, and dietary factors, and it is a frequent site of toxicity. These exogenous substances, or xenobiotics, are generally lipophilic and not easily cleared from the body. They are metabolized primarily by the cytochrome *P*-450 mono-oxygenase enzyme system, a large family of related enzymes located in the smooth endoplasmic reticulum of the hepatocyte. There are additional hepatic enzyme systems that metabolize certain alcohols, nitrogen and sulfur compounds, oxides, and other xenobiotics (see Chapter 5). Hepatotoxicity may result from the xenobiotic directly, or from its metabolism to toxic intermediates – often electrophilic compounds or free radicals. Normally these intermediates are detoxified by conjugation or transferase reactions to less toxic, water-soluble compounds and excreted in the urine or bile.²

The toxicity of a given substance may be assessed by the activity of the specific hepatic enzyme system responsible

for its bioactivation and detoxification, as well as by factors affecting the substance's absorption, storage, and excretion. Significant interindividual variation in these enzyme systems can occur. Such differences are determined by (1) host factors, including genetically inherited polymorphisms, age, and sex, and (2) acquired or exogenous factors, such as medication, ethanol or cigarette use, diet, and pre-existing liver disease. All of these factors may contribute to individual differences in susceptibility to exogenous chemicals and drugs.

Numerous drugs (including barbiturates, phenytoin, and steroids), foreign chemicals (including organic solvents, polycyclic aromatic hydrocarbons in cigarette smoke, halogenated pesticides, dioxins, and polychlorinated biphenyls [PCBs]), and dietary factors (such as ethanol or vegetable indoles) are potent inducers of the cytochrome *P*-450 enzymes. Metals, antibiotics, cimetidine, carbon monoxide, ethanol, and altered nutritional status can inhibit the cytochrome *P*-450 system. The ability of many of these exogenous agents to potentiate hepatotoxicity has been well documented in animal studies and human case reports. In animals, the administration of alcohols (e.g., ethanol, isopropanol), ketones (e.g., acetone), trichloroethylene (TCE), medications (e.g., phenobarbital), and PCBs have been shown to potentiate the hepatotoxicity of carbon tetrachloride and other chlorinated hydrocarbons. In humans, ethanol administration has been shown to increase the toxicity of TCE, carbon tetrachloride, and drugs such as acetaminophen. Recent human exposure studies have shown that ethanol can alter the metabolism of a number of chemicals including styrene, methyl ethyl ketone, and toluene. Similar interactions probably occur with many occupational, environmental, and dietary substances, and these interactions may be important determinants of hepatic toxicity.

These findings have an impact on the evaluation of occupational liver disease, because workers are frequently exposed to multiple chemicals, alcohol, medications, cigarettes, and varied diets. Interactions between these factors may potentiate hepatotoxic effects and must be considered in evaluating patients with possible occupational or environmental liver injury.

CLASSIFICATION OF OCCUPATIONAL HEPATOTOXINS AND MECHANISMS

Hepatotoxins can be classified as either intrinsic or idiosyncratic toxins. Most hepatotoxins are intrinsic toxins, that is, their hepatotoxicity is a predictable property of the substance itself, and most individuals will be affected if the dose is sufficient. Most intrinsic toxins (e.g., carbon tetrachloride) also are classified as direct toxins, namely, the substance or its metabolite directly injures the liver. Acute and subacute injury by such toxins usually produces varying degrees of dose-dependent hepatocellular injury with necrosis and steatosis.

The mechanism of hepatic injury related to alcohol and other organic solvents, representing a large class of intrinsic

hepatotoxic agents, is illustrative. An etiologic model of alcohol-induced hepatocellular damage involving oxidative stress has been demonstrated in animal studies. In addition to ethanol,³ the microsomal ethanol oxidizing system (MEOS) has a high capacity to oxidize numerous solvent substrates including halogenated compounds such as carbon tetrachloride⁴ and non-chlorinated solvents including acetone,⁵ butanol, pentanol, and benzene.⁶ Potentiation of hepatotoxicity from solvent mixtures has been demonstrated with the induction of microsomal cytochrome P450IIE1 by alcohol consumption in the presence of bromobenzene.⁷ This solvent inducible enzyme system can produce highly reactive intermediates, leading to peroxidation of lipid membranes⁸ such as endoplasmic reticulum, and covalent binding to cellular macromolecules (DNA, RNA, and proteins). Support for a mechanism of direct biologic injury includes (1) the anatomic association between selective centrilobular injury and enhanced microsomal P450IIE1 activity in this region,⁹ and (2) animal models demonstrating marked enhancement of ethanol-induced hepatic injury with carbon tetrachloride, with striking activation of P450IIE1.¹⁰

In contrast to intrinsic hepatotoxins, a few hepatotoxins (e.g., beryllium) are idiosyncratic in that they cause liver injury that is sporadic and generally not dose related, possibly by a hypersensitivity or other immunologic reaction. Typically, granulomas or eosinophilic infiltrates are found on liver biopsy.

Hepatotoxins can also be classified by the pathologic or clinical syndrome they cause, although exposure to a specific hepatotoxin can result in more than one type of liver injury. For example, acute exposure to the solvent carbon tetrachloride can result in acute necrosis, whereas chronic exposure results in steatosis, fibrosis, and cirrhosis in animals. In Table 26.1.1, occupational and environmental liver disorders are classified based on both their clinical

Type of injury	Selected agents
Acute/subacute Acute or subacute hepatic necrosis (\pm steatosis)	Halogenated aliphatics (CCl ₄ , tetrachloroethane, trichloroethylene, ethylchloroform) Nitro compounds (dimethylformamide, trinitrotoluene, 2-nitropropane) Aromatic hydrocarbons (toluene) Metals (arsenic, lead, phosphorus) Viral agents (hepatitis A, B, C) (see Chapter 22)
Acute viral hepatitis	Methylene dianiline
Acute cholestatic hepatitis	See acute necrosis
Chronic Steatosis Chronic hepatocellular disease (fibrosis/cirrhosis)	CCl ₄ and other chlorinated organic solvents, arsenic, mixed solvents
Chronic hepatitis Granulomatous hepatitis Hepatoportal sclerosis	Viral agents (hepatitis B, C) Beryllium, copper Vinyl chloride monomer, arsenic, thorium

Table 26.1.1 Classification of non-malignant occupational liver disease

presentation and pathologic processes, with examples of proven or suspected etiologic agents.

Table 26.1.2 lists the major known or suspected occupational and environmental hepatotoxins associated with non-malignant liver injury. The toxicity of certain agents is predicted on the basis of their chemical structure. An agent that has documented hepatotoxicity in animal studies should be considered a possible human hepatotoxin.

Hepatotoxic substances may be encountered in a variety of occupations, including construction activities, electronic manufacturing, farming, painting, and textile and dye manufacturing. Epidemiologic studies of workers in such occupations have shown variable evidence of liver injury. Contributing to this variability is the lack of sensi-

tivity and specificity of current screening tests for subclinical liver disease and imprecise exposure assessment.

Exposure to hepatotoxic substances also can occur in a number of home or environmental settings such as with cleaning agents, paints or paint removers, chemical contaminants, or natural toxins in the environment. Dramatic instances of liver disease associated with massive environmental contamination have been reported, such as cooking oil heavily contaminated with PCBs (Japan, 1968), wheat with hexachlorobenzene (Turkey, 1955 to 1957), and flour with 4,4'-diaminodiphenyl-methane (England, 1965). There is often little information available on the effects of low-level exposure to the numerous natural and man-made substances present in the environment and food chain.

GENERAL EVALUATION

Clinical history

As with most environmental illnesses, a careful medical, occupational, and exposure history is the key to suspecting and diagnosing work-related or environmental hepatotoxicity. The clinical presentation of acute and chronic toxic liver injury can range from no symptoms to acute nausea, abdominal pain, and jaundice. Occasionally, it presents insidiously as end-stage liver disease. Most hepatotoxins also affect other organs, including the central and peripheral nervous systems, kidney, and mucous membranes. Symptoms related to these organs may predominate, and information on these symptoms should be elicited from the patient and coworkers. Central nervous system symptoms (e.g., euphoria, headaches, and dizziness), mucosal irritation, and disulfiram-like reactions following alcohol ingestion suggest excessive solvent exposure. The temporal relationship between the exposure and onset of symptoms is essential to diagnosing acute hepatotoxicity but is less helpful in diagnosing chronic disorders. Symptoms usually develop within days to weeks following acute solvent exposure, depending on the extent of poisoning. Exposure to solvents, pesticides, and heavy metals should be specifically assessed.

Further information about potential hepatotoxic exposures can be obtained from material data safety sheets, the employer, Occupational Safety and Health Administration (OSHA), and industrial hygiene monitoring. A description of the workplace, including the use of protective equipment and ventilation systems, is helpful in assessing the mode (dermal, inhalation, or ingestion) and extent of exposure. The introduction of any new chemicals and the occurrence of unusual or accidental exposures also should be investigated. A prior history of liver and biliary disease, medication and alcohol use, obesity, diabetes, and risk factors for viral hepatitis (blood transfusions, sexual practices, and intravenous drug abuse) should be ascertained to rule out other contributing causes of hepatic injury. Alternative hepatotoxic exposures, such as hobby or other home chemical use, and additional jobs, should also be excluded.

Halogenated hydrocarbons
Carbon tetrachloride
Tetrachloroethane
Tetrachloroethylene
Trichloroethylene
1,1,1,-Trichloroethane
Chloroform
Vinyl chloride
Anesthetic gases
Hydrochlorofluorocarbons (HCFCs)
Halothane
Methoxyflurane
Alcohols
Ethyl alcohol
Aromatic hydrocarbons

N,N-Dimethylformamide
Pesticides
Organochlorine insecticides
Chlordecone
Fungicides
Hexachlorobenzene
Herbicides
Paraquat
Chlorphenoxy acids (2, 4, 5-T, Agent Orange)
Chlorinated aromatic compounds
Polychlorinated biphenyls
Chloronaphthalenes
2, 3, 7, 8-Tetrachlorodibenzo-p-dioxin (TCDD)
Dibenzofurans
Metallic compounds
Arsenic
Beryllium
Cadmium
Copper
Iron
Thallium
Lead
Phosphorus
Environmental agents
Aflatoxin
<i>Amanita phalloides</i> toxin

Table 26.1.2 Partial list of known or suspected human hepatotoxins associated with non-malignant liver disease

Physical examination

Although typical signs of hepatic injury or dysfunction may be present (right upper quadrant tenderness, hepatosplenomegaly, jaundice), the physical examination is not a sensitive indicator of liver disease. The examination should not be limited to the abdomen; evidence of toxicity to other organ systems, such as mucous membranes and nervous system, and extra-abdominal manifestations of liver disease should be evaluated.

Laboratory and radiographic assessment of hepatotoxicity

Tests for evaluating hepatotoxicity fall into four general categories: (1) serum markers of hepatobiliary disease, (2) biochemical tests of liver function, (3) imaging tests, and (4) liver biopsy.

Serum markers of hepatobiliary disease

Most useful in the evaluation of hepatotoxicity are markers of hepatocellular necrosis, which reflect the release of intracellular enzymes into serum following cytotoxic injury.¹¹ Enzyme release results from increased hepatocyte membrane permeability. The most important of these tests are aspartate aminotransferase (AST or SGOT), a mitochondrial and cytosolic enzyme, and alanine aminotransferase (ALT or SGPT), a cytosolic enzyme. AST also is present in muscle, heart, and kidney, whereas ALT is more specific for liver. Both markers have been validated in a wide variety of clinical and experimental settings. Severe elevation (> 8 – 10 times normal) may occur in acute toxic and viral injury. Mild elevation (< 2 – 3 times normal) is generally seen in chronic or resolving hepatocellular injury or less severe acute injury. ALT activity is reduced in alcohol-related liver disease;¹² levels of greater than 300 are uncommon in alcoholic liver injury. The pattern of transaminase elevation also can be helpful in distinguishing alcohol from other hepatotoxic injury. Since alcohol selectively inhibits ALT activity, a high AST/ALT ratio (greater than one) is often seen in this setting.¹³ In contrast, other toxin- and viral-induced hepatic injury usually results in an AST/ALT ratio of less than one.¹⁴ It is important to recognise that subclinical disease can occur despite normal aminotransferases, especially with chronic liver injury.

A second group of serum markers include enzymes whose synthesis is induced by cholestasis. The most important of these are alkaline phosphatase (AP) and γ -glutamyl transpeptidase (GGT). The specificity of AP for liver disease is reduced by the presence of other AP isoenzymes in bone, intestine, and placenta. AP is useful in assessing hepatotoxic exposures associated with cholestasis, such as methylenediamine. Although GGT is sensitive for hepatocellular injury, it lacks sufficient specificity to be useful diagnostically. This lack of specificity is due to its presence in several organs (kidney, seminal vesicles, pancreas, spleen, heart, brain, and common bile duct), its inducibility by alcohol and other medications, and its long half-life in serum (26 days).

Biochemical tests of liver function

Measurements to assess various functions of the liver include tests of hepatic clearance, tests of hepatic metabolism, and tests of synthetic function.

Tests of hepatic clearance Clearance tests dynamically assess three levels of hepatocyte function simultaneously: uptake, metabolism, and excretion. These tests assess the liver's ability to clear exogenously introduced or endogenously produced organic anions. Hepatic clearance was traditionally assessed by the sulfobromophthalein sodium test (BSP). BSP is eliminated by biliary excretion following conjugation with glutathione in the liver. The irritative effects of BSP during infusion have limited its clinical utility.

Indocyanine green (ICG) dye is excreted without conjugation by the liver, reducing biologic variability due to enzyme induction (e.g., from diet and medications). Increased retention of ICG thus reflects diminished hepatic clearance. The utility of ICG clearance in detecting occupational liver injury has been evaluated primarily in workers exposed to vinyl chloride monomer. ICG clearance is believed to be the most specific test in detecting early liver injury in this population. The utility of the ICG test in other exposure settings is unclear. The test also is limited by cost, availability, and cumbersome administration.

Cholic and chenodeoxycholic bile acids, which are included in the bile, are endogenously produced organic anions. Bile acids are cleared exclusively by the liver; thus, their serum concentrations reflect hepatic function, analogous to serum creatinine in the assessment of renal function. Measurement of fasting serum bile acids (SBA) avoids the administration of exogenous agents, and has been advocated as a sensitive screening test for hepatobiliary disease. Conjugated cholic acid (CCA) appears to provide high positive predictive value for hepatobiliary disease.¹⁵ Serum bile acids more specifically reflect excretory function than serum bilirubin, and in occupational settings, several studies have revealed increased serum bile acid levels in workers exposed to mixed solvents as well as styrene.^{16–19} Bilirubin levels may be elevated in cholestasis, severe acute hepatitis, and chronic liver injury; conjugated (direct) bilirubin and direct/total bilirubin may be useful in assessing early hepatic dysfunction on a population basis in solvent-exposed workers.^{20,21}

Tests of hepatic metabolism The hepatic biotransformation system, composed predominantly of cytochrome *P*-450 (microsomal) enzymes, is the major site of metabolism for exogenous compounds such as drugs or chemicals. Measurement of an exogenous substance's clearance can be used to assess hepatic metabolic enzyme activity. Changes in metabolism may reflect (1) advanced hepatocellular injury, resulting in reduced enzyme activity, or (2) the induction or inhibition of certain hepatic metabolic enzymes by xenobiotic agents. The metabolism of radiolabeled antipyrine and aminopyrine, both of which can be measured non-invasively, most frequently has been used in research settings. Several studies have reported altered antipyrine metabolism

in workers exposed to solvents and pesticides. However, the significance of such findings is unclear.

The liver and erythropoietic systems are organs of heme synthesis, via porphyrin intermediates. Accumulation of several porphyrin metabolites, which are measurable in urine, can occur with hepatic dysfunction. Coproporphyrinuria has been demonstrated in the setting of alcohol, lead, and hexachlorobenzene exposure. Although urinary porphyrin levels have not been validated clinically, they may provide a useful biologic marker of exposure in the future.

Tests of hepatic synthetic function

Hepatic function can be assessed grossly by serum measurement of proteins synthesized and secreted by the liver, such as serum albumin, ferritin, urea, and coagulation factors, measured indirectly by prothrombin time (PT). These tests are limited clinically by poor sensitivity. This poor sensitivity is due to the large functional reserve of the liver; generally more than 90% of hepatic parenchyma must be destroyed before measurable changes in protein synthesis occur.

Imaging tests

Imaging studies provide a clinically useful, non-invasive means of hepatic tissue characterization. Ultrasonography compares sonic penetration of hepatic and renal parenchyma: steatosis and fibrosis increase liver echogenicity relative to the kidney. In a prospective, controlled study of 85 patients with biopsy-proven hepatic disease, Saverymuttu observed a sensitivity of 94%, and specificity of 84% in detecting hepatic parenchymal changes.²² A significant exposure-response relationship between sonographic parenchymal changes and hepatotoxic exposure to vinyl chloride monomer and perchloroethylene has also been observed in occupational settings.²³⁻²⁵ Neither ultrasound nor CT distinguishes steatosis from fibrosis with precision. Ultrasound is preferred in the initial evaluation of biochemical abnormalities, to assess biliary as well as parenchymal disease. In patients with chronic hepatic injury, magnetic resonance imaging (MRI) may be useful in distinguishing inflammatory and necrotic changes (patchy enhancement) from fibrosis (linear enhancement) using a gadolinium-enhanced technique.²⁶

Liver biopsy

Histopathologic examination offers the most precise assessment of hepatotoxic parenchymal changes, such as hepatocellular injury, inflammation, steatosis, and fibrosis. Thus, it is considered the definitive "gold standard" test for liver disease and can be helpful both diagnostically and prognostically in characterizing the type, extent, and activity of liver injury. In experienced hands, percutaneous liver biopsy is a safe procedure that can be performed on an outpatient basis. However, as with any invasive procedure, it does carry some risks (e.g., hemorrhage, infection). Indications for liver biopsy include persistently elevated aminotransferases of unclear etiology, unexplained hepatomegaly, and anatomic abnormalities. Histologic evidence of hepatocellular injury such as necrosis or regen-

eration and steatosis (microvesicular, macrovesicular, or both), although not unique for toxic liver injury, are suggestive of the condition. Centrizonal (perivenular or Zone 3) distribution of injury within the hepatic lobule is characteristic of solvent-induced injury, though this may be diffuse in more severe cases. Such findings may be subtle, especially if the biopsy is performed weeks to months after the exposure of concern, as frequently occurs, and they are not specific for a given substance. Ultrastructural examination may provide further, or confirmatory, findings suggestive of a toxic injury, such as small droplet fat formation and prominent vesicular endoplasmic reticulum. If environmental liver injury is suspected prior to biopsy, part of the tissue should be fixed in glutaraldehyde, because it enables the evaluation of both fat content and ultrastructure. The lack of certain findings on biopsy, such as Mallory's hyaline and ground glass hepatocytes, also can be helpful in ruling out alternative diagnoses such as alcohol- or viral-induced injury.

Overview of laboratory tests

In summary, of the numerous laboratory and imaging tests available, serum aminotransferases (ALT and AST) are most helpful in the evaluation of patients with hepatocellular injury and in screening exposed populations. However, such tests may not be sensitive enough to detect mild acute injury, and are much less useful in the detection of chronic liver injury. They also are not specific for chemical or occupational-induced injury. Although liver biopsy is useful in evaluating individual cases of suspected hepatotoxicity, it is an invasive procedure that carries cost and some risk for morbidity (and in rare instances, mortality), making it impractical as a screening test. See Table 26.1.3 for further comments regarding these diagnostic tests.

ACUTE OCCUPATIONAL AND ENVIRONMENTAL LIVER DISORDERS

Acute and subacute hepatocellular diseases

Acute and subacute hepatocellular injuries are the most commonly recognized occupational liver disorders. They include a spectrum of liver injury ranging from acute injury following a single massive hepatotoxic exposure, as occurs in accidental poisoning, to repeated hepatotoxic exposures over days to weeks. Although numerous suspected and known animal hepatotoxins, primarily organic solvents, are widely used throughout industry today, there is a limited amount of human data on the effects of such exposures. The incidence of acute and subacute occupational and environmental hepatotoxicity is unknown.

Pathogenesis

The typical pathologic findings are varying degrees of hepatocellular necrosis and steatosis. Neither of these

Test	Type of injury	Comments
Serum markers		
Aminotransferases (AST, ALT)	Acute/subacute hepatocellular injury.	Best available test for acute/subacute hepatocellular injury Not sensitive for fatty liver
Alkaline phosphatase	Cholestatic injury (i.e., methylenediamine)	High sensitivity for cholestatic injury; not very specific
γ -glutamyl transpeptidase (GGT)	Cholestatic and hepatocellular injury	Elevated with ethanol consumption, hepatobiliary disease, low specificity
Tests for function		
<i>Tests of hepatic clearance</i> Indocyanine green (ICG)	Early hepatobiliary injury	Useful for vinyl chloride toxicity Requires IV infusion and multiple blood samples
Bile acids (SBA) (cholic, chenodeoxycholic acid)	Early hepatobiliary and hepatocellular injury	Not readily available. Improved sensitivity compared to AST, ALT for hepatobiliary and hepatocellular disease in some settings (e.g., vinyl chloride)
Bilirubin	Cholestatic with hepatocellular injury	Elevated conjugated (direct) bilirubin, conjugated (total bilirubin ratio observed with styrene and other solvent exposure) Less specific than SBA or AST, ALT
<i>Tests of hepatic metabolism</i> Antipyrine clearance	Early hepatocellular injury	Not readily available, high test individual variability. May be marker of exposure rather than toxicity
<i>Tests of synthetic function</i> Albumin, PT	Late hepatocellular injury	Low sensitivity for early disease
Imaging tests		
Ultrasound	Biliary disease, fatty change, hepatocellular injury	High sensitivity and specificity for biliary disease. Efficacy not established for parenchymal disease
CT scan	Fatty change, hepatocellular injury	Efficacy not established for parenchymal disease
MRI scan	Chronic hepatocellular injury and fibrosis	Fibrosis observed by linear enhancement using gadolinium
Liver biopsy	Subacute/chronic hepatocellular injury	Gold standard for the diagnosis of parenchymal disease. Centrizonal (Zone 3) changes in solvent-induced injury

Table 26.1.3 Diagnostic tests for occupational liver disease

conditions is specific for occupational or environmental toxins. Necrosis can occur with either a zonal pattern (usually centrizonal) or more diffusely, depending on the toxic agent and degree of exposure. Some degree of inflammatory response, with a lymphocytic infiltrate, also may be seen. Agents causing acute hepatocellular injury also may result in more chronic hepatocellular disease following repeated exposure, and are discussed in the following section. Some established and suspected human hepatotoxic agents, grouped by classes of substance, are listed in Table 26.1.2.

Clinical features

The clinical effects of acute and subacute hepatic necrosis may vary greatly in severity from asymptomatic histologic or functional abnormalities to manifestations of severe hepatic necrosis, depending on the intrinsic toxicity of the hepatotoxic agent, the degree of exposure, and host susceptibility factors (either genetic or acquired). Fulminant hepatic injury, with abdominal pain, nausea, and jaundice, may occur following heavy acute. Historically, exposures have frequently involved chlorinated organic compounds (e.g., carbon tetrachloride).²⁷ Most recently reported cases have occurred following accidental overexposure, ingestion,

abuse (e.g., sniffing), extensive dermal contact, or respiratory exposure in a closed or poorly ventilated area. Agents have included dimethylformamide, 2-nitropropane, 1,1,1-trichloroethane, or trichloroethylene (TCE). Such acute hepatic injury usually is part of a multisystem disease, with prominent central nervous system and renal involvement. With less extensive exposure, asymptomatic elevations in liver aminotransferases may be noted. A clinical presentation between these extremes, with non-specific gastrointestinal symptoms, also occurs. Individual host factors, or additional exposures such as alcohol, medications, or other chemicals in the workplace may alter the severity of the toxic hepatic injury.

Physical findings depend on the severity and duration of the hepatocellular injury. They range from a normal examination, to right upper quadrant tenderness, hepatomegaly, jaundice, and signs of hepatic failure in extreme cases.

Diagnosis

In acute fulminant cases, the diagnosis of hepatitis and the specific etiology usually are not difficult to determine. Often, there is a history of an unusual overexposure occurring immediately prior to the onset of symptoms (1–3 days). Markedly elevated liver aminotransferase and bilirubin

levels are noted, along with other findings of hepatic failure, such as coagulopathy, renal, and neurologic dysfunction. The specific hepatotoxin(s) usually can be determined from occupational and environmental history. Occasionally, blood or urine testing can be performed to identify a particular chemical or its metabolite. Less severe clinical presentations, such as that following subacute poisoning, can be more difficult to recognize and diagnose. Symptoms and physical findings may be unremarkable so liver function tests are not obtained. The clinician must therefore have a high level of suspicion for occupational liver disease. Elevated aminotransferase levels (ALT and/or AST) are the best available indicator of acute hepatic injury, but other causes for hepatic injury should be excluded before attributing the injury to a workplace exposure.

A thorough exposure history is essential to recognizing an occupational etiology. A medical history, physical examination, and blood tests help exclude other causes of elevated levels of liver enzymes, including medications; hypervitaminosis (due to megavitamins); obesity; metabolic disorders, including diabetes hypertriglyceridemia, and hemochromatosis; pregnancy; viral hepatitis; and alcohol. Serologic tests for hepatitis A and B are useful in detecting acute viral hepatitis; in hepatitis C, the serologic test may take up to 6 months after infection to become positive. Polymerase chain reaction (PCR) tests for both hepatitis B DNA and hepatitis C RNA are extremely sensitive for viral hepatitis in both the acute and chronic setting (see Chapter 22). The possibility of unrecognized alcohol use or idiopathic liver injury are usually the most difficult differential diagnoses to definitively rule out. With alcohol-induced liver injury, AST levels greater than 300 are uncommon and the AST/ALT ratio usually is greater than one. An occupational or environmental etiology is strongly suggested if aminotransferase levels improve within 2–6 weeks following removal from the exposure(s), but it is not ruled out if the aminotransferase levels remain elevated (see later).

If liver aminotransferases remain elevated, a liver biopsy should be considered. Findings of hepatocellular injury and steatosis are consistent with a hepatotoxic etiology, whereas marked inflammation is more suggestive of a viral one.

Natural history and management

Acute occupational hepatitis is a severe, potentially fatal disease that usually occurs 1–3 days following a massive accidental hepatotoxic exposure. Multiorgan system failure, including central nervous system depression (i.e., coma) and renal failure, is frequently present, particularly in fulminant cases. Acute occupational hepatitis should be treated in a similar manner to any other type of severe hepatitis, with appropriate supportive measures. Referral to a liver transplant center may be required in fulminant cases. If the patient recovers from the acute episode, the prognosis is usually good. Aminotransferase elevations and symptoms generally improve within days, with resolution over weeks, but the time course is variable.

Subacute hepatocellular injury may develop weeks to months following the hepatotoxic exposure, depending on the nature and extent of the exposure. If the patient is

diagnosed or strongly suspected of having undergone toxic exposure, he or she should be removed from the suspected exposure and observed. Exposure to other risk factors such as alcohol consumption should be minimized. The workplace and environment should be evaluated for hepatotoxins, and appropriate measures taken to reduce exposures. Elevated aminotransferase levels and symptoms generally improve 1–4 weeks following removal from exposure, but the time course is variable, depending on the specific hepatotoxin; persistent elevations that last for months have been documented in outbreaks. Whether chronic liver disease may result following subacute hepatotoxic injuries is unclear.

Acute cholestatic injury

Acute cholestatic liver injury is rare following occupational or environmental exposures but has been reported following exposure to methylene dianiline, an aromatic amine used as an epoxy resin hardener.²⁸ An epidemic of cholestatic jaundice occurred in Epping, England (so-called Epping jaundice) in 1965 after bread made from flour contaminated with methylene dianiline was ingested. Similar cases have been reported following occupational exposure during the manufacture or handling of methylene dianiline.

The clinical, laboratory, and pathologic findings are consistent with a mixed cholestatic-hepatocellular injury,²⁹ that is dose dependent rather than idiosyncratic. Symptoms may include abdominal pain, pruritus, fever, and jaundice. Laboratory studies show elevated bilirubin, alkaline phosphatase, and aminotransferase levels. A consistent pattern of injury with bile stasis, portal inflammation, and variable hepatic necrosis is found on liver biopsy. The diagnosis depends on an appropriate exposure history, clinical and laboratory presentation, and elimination of other causes of acute cholestatic injury, such as drugs or biliary obstruction. Resolution of liver injury following removal typically occurs from exposure has not been reported.

CHRONIC (NON-MALIGNANT) OCCUPATIONAL AND ENVIRONMENTAL LIVER DISORDERS

Fatty liver (steatosis) and steatohepatitis

Fatty change in the liver, termed steatosis, was first characterized in alcohol-related liver disease. Steatosis is defined morphologically as greater than 5% hepatocytes containing fat, or quantitatively as greater than 5 g lipid per 100 g hepatic tissue. Steatosis occurs in other disorders, including diabetes mellitus, hypertriglyceridemia, obesity³⁰ (with 90% prevalence in the morbidly obese); with various medications; and as a normal variant, with up to 20% prevalence in some series.³¹ Some degree of steatosis usually is found accompanying acute hepatocellular necrosis. Marked steatosis is more commonly seen in chronic toxin-induced

liver injury, frequently as the predominant finding. Steatosis may be accompanied by varying degrees of inflammation, termed steatohepatitis. There is good evidence that this can be multifactorial, thus industrial hepatotoxins may interact with underlying metabolic disorders and other causes of non-alcoholic steatohepatitis (NASH).³²

Pathogenesis

Steatosis results from the pathologic alteration of hepatic fat metabolism. Dietary fat normally is transported to the liver via the portal vein as chylomicrons containing fatty acids. Hepatocytes convert free fatty acids to a transportable form, very low-density lipoprotein (VLDL), which is secreted into the circulation. Hepatotoxins can block fat metabolism at several steps, resulting in intrahepatic accumulation of free fatty acids and triglycerides, producing lipid droplet formation at the cellular level and diffuse or focal steatosis at the tissue level.

Clinical presentation

Fatty liver associated with occupational exposure was first described with yellow phosphorus poisoning in the 19th century, with pronounced steatosis and necrosis found at autopsy. Similar cases of acute massive necrosis and steatosis have been described with trinitrotoluene in munitions industries, arsenical pesticide use in vintners, and the use of certain chlorinated aliphatic solvents (such as carbon tetrachloride, methyl chloroform, and tetrachloroethane), usually following accidental massive exposures. More subtle microsteatosis was recently described following routine short-term exposure to dimethylformamide in a fabric-coating factory.

The prevalence of fatty changes related to chronic, low-level, chemical exposure is not known. Patients are usually asymptomatic. Screening tests (AST, ALT) may not detect steatosis in the absence of inflammation and necrosis. Investigation of steatosis is usually limited by strong reliance on histologic diagnosis, which is invasive and may not be available. Diagnosis is further complicated by the confounding etiologies of fatty liver, including alcohol consumption, obesity, diabetes, medications, and their interactions with suspected toxins.

Chronic exposure to chlorinated solvents such as carbon tetrachloride can cause varying degrees of steatosis and hepatocellular injury. Although the evidence is less consistent with non-chlorinated solvents, several studies have found steatosis in workers exposed to non-chlorinated solvents, including dimethylformamide, toluene, and mixed aliphatic and aromatic solvents. The relative degree and severity of steatosis and necrosis found on histopathologic examination is likely related to the chronicity and extent of the exposure, as well as the hepatotoxic characteristics of the particular exposure. Acute high-level exposures tend to be associated with greater amounts of necrosis, whereas steatosis tends to predominate with more chronic exposures.

Natural history

The natural history of chemically induced hepatic steatosis has not been well characterized. Histopathologic data from

animal models indicate that fatty change occurs as part of a continuum of reversible, morphologic changes: cloudy swelling is followed by hydropic changes and, finally, steatosis. In humans, the reversibility of alcohol-related fatty change with abstinence has been well documented. Acute solvent-related steatosis is generally associated with necrosis and elevated aminotransferase levels. The elevated aminotransferase levels generally resolve within weeks to months of removal from exposure. Because of the need for histologic evidence, the natural history of the accompanying acute steatosis is less clear, but the condition most likely also resolves over time. Steatosis following acute exposures is thus likely to represent subclinical injury at a reversible stage.

At present, there are no human longitudinal studies addressing the sequelae of isolated steatosis with prolonged or ongoing occupational exposure. Necrosis, steatosis, and fibrosis can be induced in animals by the chronic administration of carbon tetrachloride. Evidence exists in both animal and human studies that steatosis can occur in the absence of elevated serum hepatic transaminase levels. Balazs demonstrated that rats exposed to low doses of carbon tetrachloride had no ALT elevation, despite marked fatty and hydropic changes histologically.³³ Similarly, longitudinal follow-up of individuals with alcohol-induced or metabolically induced (diabetes and obesity) hepatic injury have demonstrated significant progression of steatosis to fibrosis histologically, termed 'steatocirrhosis',³⁴ often in the absence of an inflammatory response and associated transaminase elevation.^{35,36} In one study, seven workers exposed to dimethylformamide over a 3-month to 10-year period, with persistently elevated aminotransferase levels, underwent liver biopsy. Variable degrees of steatosis, which was greatest in those with longer periods of exposure, were found; there was no evidence of progression to fibrosis or cirrhosis at the time of biopsy.

Diagnosis

Laboratory tests may not be helpful in diagnosing fatty liver, because they frequently do not detect steatosis in the absence of inflammation. Non-invasive anatomic evaluation of the liver by ultrasonography and CT scan can suggest hepatic steatosis. The definitive diagnosis of steatosis depends on histopathologic examination of a liver biopsy specimen.

When significant steatosis is found, either incidentally or in the work-up of elevated serum aminotransferases, evaluation should attempt to differentiate occupational from other known causes of steatosis, as discussed earlier. The history should include a review of the following: medications associated with steatosis (such as phenytoin [Dilantin], tetracycline, isoniazid, nitrofurantoin, and phenylbutazone) and the presence of hyperlipidemia, diabetes mellitus, obesity or pregnancy, and substance abuse, such as glue sniffing. Laboratory evaluation should include measurements of fasting blood sugar and triglyceride levels.

Management

The presence of steatosis without other obvious etiologies, associated with exposure to hepatotoxic agents, is suggestive

of occupational or environmental liver disease. Although the natural history of steatosis in such settings is unclear, further toxic exposure should be minimized, and removal of the person from the workplace should be considered. Resolution of any concomitant elevation of aminotransferase levels after removal from exposure supports an occupational etiology.

Chronic hepatocellular injury

Chronic hepatocellular injury can occur after prolonged exposure to agents that cause acute and subacute hepatic injury or steatosis. Human data are limited to a few case reports of liver injury following chronic exposure to various hepatotoxic agents (including dimethylformamide, carbon tetrachloride, and mixed solvents) and cross-sectional surveys reporting elevated liver enzyme levels in exposed cohorts such as painters, print or shoe repair workers²⁰ compared with controls. The clinical presentation may range from minimal to pronounced symptoms and aminotransferase elevations. Liver biopsy may show varying degrees of necrosis, regeneration, inflammation, and steatosis.

The diagnosis of chronic hepatocellular injury is made based on the guidelines given earlier for acute and subacute liver injury. However, the diagnosis frequently is more difficult to determine than that of acute or subacute injury. Exposure assessment frequently is complicated by multiple, poorly defined exposures over many years, and it must be differentiated from other etiologies. Resolution of enzyme elevations after removal of the person from exposure is helpful. However, the natural history is not well defined, and aminotransferase abnormalities appear to resolve more slowly than with acute hepatocellular injury. It is unclear whether progression to cirrhosis or increased risk for hepatoma occurs.

Granulomatous hepatitis

Exposure to pathogenic dusts that cause pulmonary granulomatous lesions also may result in hepatic granulomas. Hepatic granulomas also may result from drug-induced hepatic injury or may be a non-specific finding in almost any setting. Hepatic granulomas have been described in chronic beryllium disease, silicosis, vineyard sprayer's lung (presumed secondary to copper exposure), and following mica and cement exposure. The hepatic lesions usually are asymptomatic and functionally not important, but rarely can be accompanied by hepatomegaly, necrosis, or fibrosis. Diagnosis depends on the appropriate exposure history and finding granulomatous changes on liver biopsy. The inhaled foreign particles may be detected in the biopsy specimen. The natural history of such lesions is not well defined but is most likely benign. As with the underlying granulomatous disorder, the lesions may progress after exposure has ceased. It is unclear whether or not the administration of steroids is beneficial. Exposure to additional hepatotoxic agents should be minimized.

Hepatoportal sclerosis

Hepatoportal sclerosis is a rare form of non-cirrhotic periportal fibrosis, which can lead to portal hypertension. It has been described most commonly as a consequence of exposure to vinyl chloride monomer,^{37,38} inorganic arsenicals, and thorium compounds. Inorganic arsenicals and thorium compounds are no longer in common use.

Vinyl chloride monomer, a chlorinated hydrocarbon, is used in the production of polyvinyl chloride (PVC), a widely manufactured plastic. Hepatoportal sclerosis has been documented in several studies of workers exposed to vinyl chloride, primarily in PVC polymerization manufacturing plants.³⁹ Liver histology has shown hyperplasia of hepatocytes and sinusoidal cells, with dilatation of sinusoids and progressive subcapsular, portal, perisinusoidal, and, occasionally, intralobular fibrosis, which is accompanied by portal hypertension and splenomegaly. Workers with hepatoportal sclerosis have a markedly increased risk of developing angiosarcoma of the liver, a rare liver cancer seen almost exclusively in the setting of vinyl chloride or arsenic exposure;⁴⁰ greater than threefold increases in liver cancer (SMR 333; 90% CI 202–521) have been observed in vinyl chloride polymerization plant workers.⁴¹ Hepatoportal sclerosis usually is found in tumor-free areas of the liver in patients with angiosarcoma and may be a premalignant promoting factor (see Chapter 30.6).

Vinyl chloride-induced liver injury presents insidiously, with the diagnosis made frequently 15–20 years after the first exposure.⁴² Portal hypertension with periportal fibrosis may develop eventually. The diagnosis is made on the basis of a consistent exposure history and characteristic findings on liver biopsy. Standard liver function tests usually are of limited value in detecting vinyl chloride-induced liver injury. Several studies have indicated that ICG clearance and serum bile acids provide improved sensitivity and specificity in screening exposed workers.⁴³

There have been a few case reports suggesting that exposure to polymeric vinyl chloride also may be associated with hepatic angiosarcoma. Whether exposure to PVC also can cause non-malignant liver injury is unclear. There generally is little release of vinyl chloride monomer from solid PVC materials, although significant amounts may be released with combustion of PVC products and possibly in the processing or some applications of PVC materials.

Cirrhosis

Cirrhosis, or end-stage liver disease, is defined as a chronic, irreversible condition in which the normal lobular architecture is replaced by fibrous tissue and regenerating nodules derived from the remaining hepatocytes. Cirrhosis is most commonly due to alcohol or viral infection but also may be caused by chronic biliary disease, metabolic diseases such as hemochromatosis, and congestive heart failure. Cases of cirrhosis sometimes are idiopathic. Animal studies have shown that hepatotoxic exposures such as carbon tetrachloride, arsenic, and aflatoxins can result in cirrhosis. The role of occupational or environmental

substances in the development of cirrhosis, either alone or interacting synergistically with other etiologic agents has not been well characterized in humans. Whatever the initial cause, the pathogenesis involves hepatocellular necrosis, with subsequent deposition of large amounts of connective tissue and nodular regeneration of hepatocytes.

There have been isolated, often not well-documented, case reports of cirrhosis associated with repeated exposure to several occupational agents, most of them no longer in use, including carbon tetrachloride, arsenicals, tetrachloroethane, trinitrotoluene, and trichloroethylene (TCE).⁴⁴ Increased mortality due to cirrhosis has been noted in several cohorts of workers with known or suspected hepatotoxic exposures (primarily solvents), including pressmen, shipyard workers, marine inspectors, metal fabrication employees, anesthesiologists, vineyard workers exposed to arsenical pesticides, and PCB workers. Mortality studies have also suggested increased risk for chronic hepatic injury in occupational groups with long-term daily exposure to organic solvents. These studies have observed relative risks for cirrhosis ranging from 1.6 to 2.1 in automobile spray painters and newspaper printers.^{45–48} However, in many of these studies, confounding factors, such as ethanol or viral hepatitis, were not accounted for.

In patients with idiopathic cirrhosis, the diagnosis of an occupational or environmental etiology should be considered if there has been a history of repeated exposure to known or suspected hepatotoxins. Further hepatotoxic exposures should be minimized.

MAJOR HUMAN HEPATOTOXINS

Several specific environmental agents that have been reported to cause liver injury in humans are discussed in this section.

Solvents

Carbon tetrachloride and other chlorinated solvents

Carbon tetrachloride is the classic example of an intrinsic occupational hepatotoxin. The hepatotoxicity of carbon tetrachloride was first recognized in the 1920s, when it was frequently used as a solvent, dry-cleaning agent, fire extinguisher, and anthelmintic. As with most hepatotoxic solvents, acute intoxication results in multisystem disease, with central nervous system depression and acute necrosis of the renal tubules and the liver. Symptoms and liver aminotransferase abnormalities usually occur 1–2 days following the acute exposure and resolve in 1–2 weeks, but the time course may vary depending on the dose and length of exposure. Histology reveals centrilobular necrosis and steatosis; cirrhosis following carbon tetrachloride exposure is well established in animal models, and there are a few case reports in humans. Carbon tetrachloride-related hepatotoxicity is potentiated by ethanol consumption.⁴⁹ Because of renal and hepatic toxicity, use of carbon tetrachloride has decreased greatly, but cases of hepatotoxicity still are reported.

Tetrachloroethane and chloroform also are no longer in general use because of their recognized hepatotoxicity.

1,1,1-Trichloroethane and TCE are widely used chlorinated solvents with documented animal hepatotoxicity. Although they are less hepatotoxic than carbon tetrachloride, exposure to both agents has been associated with case reports of hepatic necrosis and steatosis.^{50–53} Perchloroethylene, a popular dry-cleaning solvent, is also hepatotoxic in animal studies and historical case reports.⁵⁴ Elevations in GGT, in the absence of other liver function test abnormalities have been observed in surveillance of exposed workers.⁵⁵ A cross-sectional field investigation of 29 dry-cleaning operators observed mild to moderate hepatic parenchymal changes in echogenicity, as determined by hepatic ultrasonography, in two-thirds of dry cleaners compared with only one-third of referents (OR 3.2, 95% CI 1.04–9.8),²⁵ with minimal associated changes in transaminase levels.

Dimethylformamide

Dimethylformamide is a widely used hepatotoxic solvent. Several recent reports have documented acute and chronic liver injury in workers exposed to dimethylformamide.⁵⁶ In addition to typical gastrointestinal symptoms, a disulfiram-type reaction (acquired alcohol intolerance) is frequently reported following acute exposure. Elevated serum aminotransferase levels, with an increased ALT/AST ratio, have been found. Liver biopsy following acute exposure (less than 2 months) has shown variable degrees of hepatic necrosis, regeneration, and microvesicular and macrovesicular steatosis, whereas marked steatosis without fibrosis has been found on biopsy following longer exposures⁵⁷ (Fig. 26.1.1). Elevated liver enzyme levels may persist weeks to months after removal of the person from further exposure. The long-term effects of dimethylformamide exposure are not known.

Figure 26.1.1: Liver histology from a patient who had been exposed to the solvent dimethylformamide for several years. Liver architecture is normal, but there is moderate to severe steatosis, mainly in zones 2 and 3. 1, central vein; 2, a portal tract. (Carnoy's fixation, H & E, original magnification $\times 130$.) (From Redlich CA, West AB, Fleming LE, et al. Clinical and pathological characteristics associated with occupational exposure to dimethylformamide. *Gastroenterology* 1990; 99:748–57, with permission from American Gastroenterological Association.)

Aromatic and other solvents

Toluene is one of the most frequently used solvents in industry, and it is a known animal hepatotoxin. Elevated serum transaminase and GGT levels have been found in print workers exposed to toluene^{58,59} and after exposure to glues.⁶⁰ Liver biopsies reveal fatty liver with mild non-specific inflammation. The long-term hepatic effects of toluene exposure are not known.

Several investigations of workers exposed to relatively high levels of styrene (e.g., 50–300 ppm) observed elevations in serum hepatic transaminase⁶¹ and GGT levels,^{62–64} suggesting hepatic necrosis and cholestasis, respectively. Two independent cross-sectional studies of workers exposed to lower levels of styrene, including fiberglass reinforced plastics workers and boat and tank fabricators, observed increased direct bilirubin and AP levels compared to non-exposed referent groups, consistent with diminished hepatic clearance of conjugated bilirubin with associated cholestasis.²¹ The absence of similar elevations in hepatic transaminase levels in these studies suggests that low-level styrene exposure results in mild metabolic dysfunction without significant hepatic parenchymal necrosis.

There are isolated case reports of acute hepatotoxic injury following acute exposure to several other solvents, including 2-nitropane,^{65,66} methyl chloride, tetrahydrofuran, carbon tetrabromide, and xylene.⁶⁷

Mixed solvents

Exposure to solvent mixtures is more common than isolated single exposures. Several epidemiologic studies have reported elevated liver enzyme levels in workers such as painters, print workers, and chemical workers exposed to various solvents including toluene, acetone, benzene, methyl ethyl ketone, and styrene. Typically, aminotransferase levels have been elevated compared with control groups, with AST/ALT ratio less than one. Dossing observed that 13 of 156 (8.3%) career painters with chronic encephalopathy due to 'white spirit' (mixed aliphatic and aromatic hydrocarbons) exposure had elevated serum transaminases.⁶⁸ Liver biopsy revealed that 11 of these 13 painters (85%) had moderate steatosis and focal hepatic necrosis. Evidence of hepatotoxicity has also been demonstrated in painters exposed chronically to solvents, with elevated alkaline phosphatase levels observed in a cross-sectional study of Swedish house painters.⁶⁹ Elevated GGT levels also have been reported in solvent-exposed groups such as paint manufacturers and sprayers,⁷⁰ as well as necrosis and steatosis on liver biopsies of selected subjects.⁷¹ Severe liver injury with centrilobular and hemorrhagic necrosis has been observed in chemical plant workers exposed to mixtures of carbon disulfide, isopropanol, toluene, and acrylonitrile.⁷² In some of these studies, other competing etiologies, such as alcohol, viral hepatitis, or obesity, were not well controlled.

Solvent mixtures may interact to enhance hepatotoxicity, as demonstrated by Charbonneau and colleagues in rodents exposed to CCl₄, acetone, and corn oil.^{73,74} In human volunteers, altered oxidative hepatic metabolism

during mixed solvent exposure has also been demonstrated with toluene,^{75,76} as well as methyl ethyl ketone (MEK) and various alcohols,⁷⁷ and may explain the variable hepatotoxicity observed with mixed solvent exposures.¹¹

Halothane and other anesthetic solvents

Halothane is a general anesthetic agent that can cause hepatitis in patients undergoing general anesthesia, and in occupationally exposed workers, such as anesthetists and operating room personnel.^{78,79} Halothane-induced hepatitis is not dose dependent, and significant liver injury is rare, usually occurring following repeated exposures. Serum aminotransferase levels are elevated, and liver biopsy shows spotty to massive necrosis, frequently with steatosis and eosinophilic infiltration. Fever and eosinophilia usually are present. There are rare case reports of cirrhosis and chronic active hepatitis following halothane exposure. A few epidemiologic studies have reported an increased frequency of liver disease among operating room personnel.⁸⁰ Methoxyflurane, another widely used anesthetic, also has been reported to cause liver injury similar to halothane-induced hepatitis.

Organochlorine pesticides and related polychlorinated compounds

Several non-specific liver abnormalities have been associated with exposure to pesticides. A massive outbreak of acquired porphyria cutanea tarda and hepatomegaly occurred in Turkey following the ingestion of grain contaminated with the fungicide hexachlorobenzene. Chronic hepatic sequelae were not well documented. The organochlorine pesticide chlordane has been reported to cause hepatomegaly, non-specific changes on liver biopsy, and marked proliferation of smooth endoplasmic reticulum on electron microscopy, consistent with induction of P-450 enzymes.⁸¹ These changes resolved following removal of the affected individuals from exposure. The use of organochlorine pesticides has been limited because of potential carcinogenicity, including liver and biliary tract cancer among DDT-exposed workers.⁸²

2,3,7,8-Tetrachlorodibenzo-*p*-dioxin (TCDD), or dioxin, is a contaminant of chlorophenoxy herbicides that can cause chloracne and liver injury.⁸³ Mildly elevated liver aminotransferase and GGT levels have been reported following TCDD exposure, with necrosis and steatosis on liver biopsy. Persistent liver injury has been reported by a European group who found elevated transaminases, GGT, and urinary porphyrins in Austrian chemical workers 25 years after their main exposure to dioxin.⁸⁴ Because of its storage in body fat, dioxin has an extremely long half-life of many years. Persistently elevated transaminase levels have also been documented among Vietnam veterans exposed to Agent Orange.^{83,85}

PCBs and chlorinated naphthalenes have been used widely as insulating liquids in electrical systems. While no longer manufactured because of concerns about their bio-persistence and carcinogenicity,⁸⁶ exposure continues to be

documented in inhabitants living near electrochemical factories.⁸⁷ Heavy occupational exposure or accidental oral ingestion of these agents has been reported to cause hepatic necrosis and, in some cases, subsequent subacute hepatic necrosis and cirrhosis. Among workers manufacturing capacitors and transformers, elevations in LDH and GGT correlated with PCB levels.⁸⁸

Halogenated pesticides such as DDT and hexachlorobenzene, chlorinated dioxins such as TCDD, and polychlorinated biphenyls (PCBs) are all potent inducers of various cytochrome *P*-450 mono-oxygenases, and they may potentiate the hepatotoxicity of other exposures by enhancing metabolism of toxic intermediates.

Metals

Arsenic

Accidental arsenic ingestion can result in acute hepatic injury with necrosis and steatosis. Chronic exposure to arsenic has been seen in vintners,⁸⁹ farmers, and miners, with variable hepatotoxicity. Arsenic in insecticide sprays has been associated with an increased incidence of cirrhosis and hepatoportal sclerosis. Such arsenical compounds are no longer in use. Besides its hepatic effects, arsenic also affects the gastrointestinal tract, central nervous system, and cardiovascular system. Hemorrhagic necrosis of the GI tract, nausea, vomiting, CNS depression, and vascular collapse are frequently seen.⁹⁰ Environmental arsenic poisoning from ground-water sources has been an important public health problem in endemic areas such as Bangladesh and West Bengal, where hepatic abnormalities are frequently seen as part of a multisystemic illness.⁹¹

Lead

Elevated aminotransferase levels have been reported with acute inorganic lead intoxication, usually with lead levels in the range of 80 µg/dl or greater. Levels promptly improve following chelation treatment and removal from further exposure. The presence of liver injury may explain some of the gastrointestinal toxicity found in acute poisoning cases.

Other environmental agents

Although they are primarily industrial hepatotoxins, many of the agents discussed earlier and listed in Table 26.1.1 also are potential environmental toxins. Hepatotoxic exposures could potentially occur through contact with contaminated water, air, soil, or food. Such environmental contamination is of particular concern with chemicals such as DDT or PCBs, which are very stable, resist biodegradation, and accumulate in the environment and food chain. Notably, the substitution of hydrochlorofluorocarbons (HCFC) for ozone-depleting chlorofluorocarbons has resulted in prominent hepatic injury among groups of exposed workers.⁹² In addition, several naturally occurring toxins produce marked hepatotoxicity on ingestion.

Aflatoxins

The fungus *Aspergillus flavus* produces toxins, termed aflatoxins, that can contaminate food products, including nuts, corn, and wheat. The fungus is abundant in tropical and subtropical regions, and thrives under moist, warm conditions. Aflatoxin B1 is a potent inhibitor of RNA synthesis and the most hepatotoxic of these compounds.⁹⁰ Acute exposure has been reported to cause necrosis, steatosis, and inflammation. Chronic exposure is associated with an increased risk of hepatic carcinoma; the risk of malignancy is directly proportional to the amount of toxin ingested.⁹⁰

Mushroom poisoning

Ingestion of *Amanita phalloides* (death cap) mushrooms can result in fatal poisoning, with massive hepatic necrosis. Fulminant hepatic failure is seen, with coma and renal failure common. These mushrooms contain several toxins, with α -amanitin being the most toxic. Amatoxin is thermostable, and can remain active for years. A fatal dose has been estimated to be in the range of 7 mg, or three mushrooms.⁹⁰

Viral agents

Hepatitis A, B, or C can occur as an occupational disease in healthcare workers and others in contact with the excreta or blood from patients or carriers infected with these viruses. Hepatitis A causes an acute hepatitis, typically with no long-term sequelae. Hepatitis B and hepatitis C may cause both acute and chronic hepatitis. A full discussion of viral hepatitis is provided in Chapter 22.

MEDICAL SURVEILLANCE FOR OCCUPATIONAL LIVER DISEASE

Surveillance strategies

Strategies for controlling occupational liver disease follow the general principles of primary and secondary prevention. Primary preventive strategies attempt to identify and remove (or reduce) hepatotoxic exposures. Hepatotoxic substances are identified by review of the chemicals used and assessment of industrial hygiene to limit exposure. Hepatotoxic exposures can be minimized by substituting less toxic agents and by using engineering controls (e.g., improved ventilation) and personal protective equipment.

Secondary preventive strategies involve the screening of workers actively exposed to known or suspected hepatotoxins. This approach is appropriate when exposure is unpredictable or unavoidable (i.e., not amenable to primary prevention). Such strategies attempt to identify hepatic disease at an early, reversible stage.

Screening tests for occupational hepatotoxicity

Screening tests for occupational liver disease include the biochemical, clearance, and metabolic tests described earlier.⁹³ Despite high sensitivity and specificity in particu-

lar settings, all tests are potentially limited by low predictive value.^{11,94} Because of a low prevalence of hepatic disease in the general population, only a small percentage of individuals who have positive test results actually have liver disease. For example, serum aminotransferase levels, which are more than 90% accurate in the diagnosis of acute viral hepatitis, have a predictive value of less than 10% in screening for chronic liver disease in the general population.

Determining the predictive value of screening tests is complicated by the lack of prevalence data for occupational liver disease. A notable exception is vinyl chloride monomer, with a 2–3% prevalence of chronic liver disease in exposed workers. The most accurate test for such disease is ICG clearance, with a predictive value of 20%. In most industries, however, the prevalence of hepatic disease is unknown and probably variable; the efficacy of a screening test in one setting cannot be assumed to be the same in another.

Screening of healthy workers is recommended only when there is exposure to known or strongly suspected hepatotoxic agents. Because no ideal screening test for occupational liver injury exists, serum aminotransferase tests (AST and ALT) remain the best practical choice at present. They are inexpensive, available, and clinically validated. Combination testing, namely requiring positive results on two different tests, may enhance predictive value, but this approach has not been validated and may result in high rates of false-negative results. Metabolic tests such as antipyrine clearance should be considered markers for specific exposures rather than for actual hepatic injury.

Clinical management of abnormal liver function tests

Management of abnormal liver function tests depends on the clinical presentation (the extent and type of liver injury) and exposure setting (the likelihood and extent of hepatotoxic exposure).⁹⁵ In acute and subacute settings, with well-documented exposure to a known or suspected hepatotoxin, an association between the liver injury and hepatotoxic exposure frequently can be determined, once other possible etiologies have been excluded. Prompt removal of the affected individual from exposure to any workplace or environmental hepatotoxin is indicated. Transaminase levels are generally elevated several fold and should be monitored closely, with the use of early hepatic ultrasound to rule out biliary obstruction. Supportive care, including hospitalization, may be required in severe cases.

On the other hand, in the setting of chronic low-level exposures, as often occurs in mass screening of healthy workers, the relationship between elevated hepatic transaminase levels and specific exposures may be much more difficult to determine. Because low predictive values, in the range of 5–20% for available tests, generate high rates of false-positive findings, emphasis should be placed on distinguishing true from false-positive results. Removal of the affected individual from work should be considered only after alternative etiologies, such as medications, non-occupational liver disorders, and excessive alcohol use

have been excluded.⁹⁶ For example, mild hyperbilirubinemia in an otherwise healthy worker likely represents Gilbert's syndrome and usually does not warrant further evaluation. There are no strict guidelines for the management of abnormal serum aminotransferase levels, which are often minimally elevated. In situations in which significant exposure is unlikely and transaminase levels are between one and two times normal, repeat testing in 4 weeks has been advocated, with further investigation reserved only for persistent elevations.

A general approach for evaluating possible occupational or environmental liver disease is summarized in the following list, although modifications are needed, depending on the particular clinical and exposure setting.

1. Assess both occupational and non-occupational causes of liver disease, including significant alcohol use, viral hepatitis (A, B, and C), biliary disease, medications, blood transfusions, and hepatotoxic exposures from work, hobbies, the home, and second jobs (see item 3). Potential hepatotoxic medications are numerous⁹⁷ (e.g., acetaminophen, isoniazid, erythromycin, estrogens, phenytoin, and megavitamins such as vitamin A) and should be discontinued, when possible. The abnormal liver tests should be repeated in 2–4 weeks. Metabolic etiologies including diabetes mellitus, hemochromatosis, hypertriglyceridemia and obesity should be considered.

2. Consider the AST/ALT ratio. Ratios less than one are suggestive of viral or toxic exposures rather than alcohol use.

3. Attempt to determine the presence of any known or suspected hepatotoxins in the workplace or environment. Sources of such information may be obtained from material data safety sheets, the worker, the employer, the manufacturer, and industrial hygiene sampling, if available.

4. If a significant hepatotoxic exposure is identified, the individual should be removed from further exposure and his or her AST and ALT should be rechecked in 2–4 weeks. Recovery suggests an occupational or environmental etiology, but persistent elevations do not rule it out. Such persons may return to work or the same environmental setting on a trial basis if appropriate controls or exposure modifications have been implemented. Close follow-up, with continued monitoring of AST and ALT levels, is necessary in these situations.

5. Persistent elevation of AST and ALT levels greater than twice normal for over 2 months warrants further investigation; referral to a hepatologist should be considered. Such individuals have an increased likelihood of chronic active hepatitis, steatohepatitis, and fibrotic changes.⁹⁸ Hepatic ultrasonography, liver biopsy, or both, may be indicated. Findings of steatosis and necrosis are particularly suggestive of an occupational etiology. A trial entailing removal of the affected individual from hepatotoxic exposures, even if they are only suspected, should be considered. Because various hepatotoxins may interact, alcohol use and potentially hepatotoxic medications should be minimized.

In the end, the diagnosis of occupational or environmental liver injury must integrate the clinical data discussed

above with knowledge regarding the intrinsic hepatotoxicity and nature of the exposure(s). Limited knowledge regarding hepatotoxicity, particularly for new or poorly characterized chemicals, as well as a determination of the nature and extent of exposure, especially with more chronic presentations, frequently represent challenges to the clinician.

26.2 Disorders of the Gut and Pancreas

Stan Lee, Lora E Fleming, Carl A Brodtkin

INTRODUCTION AND APPROACH TO THE PATIENT

Occupational and environmental diseases of the gastrointestinal (GI) tract often are unrecognized. A variety of toxic exposures in the workplace may cause GI symptoms (see Table 26.2.1). Organic solvents may cause nausea and vomiting by acute solvent intoxication, presumably mediated through their effects on the central nervous system. In addition, exposure to a variety of toxins may cause non-specific GI symptoms, such as nausea among workers exposed to lead.

The prevalence of non-malignant GI diseases of occupational and environmental etiology is unknown. This is due in part to lack of clinical recognition: because GI symptoms are so common, clinicians often fail to consider workplace exposures in the differential diagnosis.

The clinical evaluation of GI disease of suspected environmental origin follows the same general principles as that in general medical practice. The history and physical examination should not be limited to the GI system. Toxins that cause GI symptoms, such as metals, solvents, and pesticides, often cause more direct effects on other systems such as the central nervous system or skin. Laboratory tests of GI system anatomy and function are rarely diagnostic of etiology. In contrast to infectious diarrhea in an agricultural worker, with a finding of ova and parasites in the stool, organophosphate poisoning in the same worker would have no specific GI finding. As with the physical examination, the laboratory investigation should never be limited to tests of the GI system and should be directed by the history. Nevertheless, acute GI symptoms, such as vomiting, abdominal pain, and severe diarrhea, have to be ameliorated because these symptoms often are what brought the patient to medical attention, not the fact of a toxic exposure. The suspected or established causes of common GI disturbances are summarized in Table 26.2.2 and discussed in detail in the following section.

UPPER GASTROINTESTINAL DISORDERS

Esophagitis and gastritis

Occupational and environmental causes

Most cases of occupationally related esophagitis and gastritis are associated with corrosives and solvents. Accidental exposures to corrosives, which include strong acids (such as sulfuric and chromic acids), fixers (such as formaldehyde), and strong bases (such as lye) cause direct tissue injury. Ingestion injury is the classic route of exposure for the aforementioned toxins. However, alternative routes of exposure, including dermal absorption and inhalation of high concentrations of irritant vapors, may be important with other agents. Grade 2 esophagitis has been reported

in a plastics industry worker accidentally exposed to dimethylacetamide and 1,2-ethanediamine.¹

Occupationally related gastritis has also been reported without an ingestion exposure. Solvents often have excellent penetration through both dermal and inhalational routes; for example, up to 10% of topical and 2% of inhaled dimethylacetamide is absorbed into the blood stream.² Excessive exposure to solvents frequently causes nausea and anorexia, through the central nervous system (see Chapter 40). Solvents additionally exert direct irritational effects on gastric (as well as bowel) mucosae, contributing to symptoms. More severe or localized effects are most likely to occur following ingestion. Gastritis has been observed in worker populations exposed to the solvent dimethylformamide, another solvent with high skin penetration. Chronic gastritis has been reported in a laboratory technician using a solution containing 80% methylmethacrylate for tissue preparation; concomitant skin changes were also present, with contact dermatitis. Interestingly, GI symptoms were reproduced with positive skin patch testing with methylmethacrylate.³ Chronic gastritis has also been observed in several workers following an industrial exposure to methylmethacrylate; the symptoms continued for several years despite withdrawal from exposure.

Clinical course, diagnosis and management

Except for a history of ingestion and/or inhalation, occupationally related esophagitis and gastritis present similarly to non-environmentally related cases. Symptoms of esophagitis may include throat pain and dysphagia. Symptoms of gastritis may include upper- to mid-epigastric abdominal pain, with or without food intolerance.

The diagnosis and treatment is also similar to non-occupational cases, but must emphasize elimination or protection from exposure. This can serve as a diagnostic trial as well as a therapeutic intervention.

Peptic ulcer disease (gastric and duodenal)

Occupational and environmental causes

Peptic ulcer disease, encompassing both gastric and duodenal ulcers, has been reported in higher prevalence among certain occupations, with increased risk observed in a number of epidemic studies. There is a controversial association between occupational stress (either physical or emotional) and an increased prevalence of peptic ulcers; it is a controversy partially due to inconsistent and non-specific definitions of stress.

Traditionally, a number of sedentary, professional jobs with high stress, such as air traffic controllers and executives, have been found to have a higher prevalence of ulcers among workers.⁴ However, more recent work has shown an increased prevalence of peptic ulcers in unskilled workers as well. In particular, immigrants and manual labor workers

Symptom	Type of exposure (examples)
Nausea and vomiting	Central nervous system depressant (organic solvents with acute solvent intoxication) Cholinesterase inhibitors (organophosphates, carbamates) Metabolic Methemoglobin formers (organic nitrogen compounds) Caustic Irritants (epoxy resins, copper and tin fumes)
Constipation	Heavy metals (lead, barium, thallium)
Diarrhea	Infections (parasites, bacteria) Cholinesterase inhibitors (organophosphates) Metals (arsenic, phosphorus)
Jaundice	Hepatotoxins (organic solvents) Hemolytic agents (arsine, naphthalene, phenylhydrazine, stilbene)

Table 26.2.1 Major acute gastrointestinal symptoms and their common occupational and environmental causes

Disorder	Exposure or occupation (examples)
Upper GI tract disorders	
Esophagitis/gastritis	Dimethylformamide Methylmethacrylate Dimethylacetamide
Peptic ulcer disease	Shift work
Pancreatitis	Chlorinated naphthalenes Organophosphate pesticides Organic solvents Scorpion toxin
Lower GI tract disorders	
Infectious gastroenteritis	Hospital workers Laboratory workers Food producers Abattoir workers Farm workers Sewage workers
Celiac disease	Allergens associated with hypersensitivity pneumonitis (see Chapter 19.6)
Pneumatosis cystoides intestinalis	Trichloroethylene
Non-specific toxic GI syndromes	Lead Other heavy metals Organophosphate pesticides

Table 26.2.2 Environmental agents/occupations associated with gastrointestinal disorders

have a higher prevalence and mortality from peptic ulcer disease (gastric rather than duodenal) than sedentary workers. Among some groups of miners, such as the copper miners in Chile, the incidence of peptic ulcer disease is much higher than in mine administrators or mechanics. Of note, the increases among manual and migrant workers parallel the increased mortality rate among lower socioeconomic classes, and may be a confounding factor in these studies.^{5,6}

The role of physical work, energy expenditure, and other physical factors appears to be important in ulcer prevalence and mortality rates.⁷ In a study in the metalworking indus-

try in Italy, an increased prevalence of peptic ulcer disease and chronic gastritis was noted, which correlated in a dose-related fashion with number of years worked, noise, temperature, vibration, workshift, and workload.⁸

Ulcer prevalence is higher in shift workers than in daytime workers;⁹ this increased prevalence is believed to be due to sleep disturbance and altered eating patterns in the shift worker. A study from Denmark found that low socioeconomic status and non-daytime work were associated with an increased risk of gastric ulcer.¹⁰ The authors hypothesized that shift workers experienced physiologic and psychologic stress from disruption in circadian rhythms, limitations in family and social life, and sleep difficulties. During deep (e.g., rapid eye movement [REM]) sleep, there is a decrease in gastric acid secretion and an increase in gastric motility. Disruption of sleep processes may, therefore, theoretically increase the risk of ulcer disease.¹⁰

In addition to stress, food and smoking may also play a role in peptic ulcer disease. A study in a Japanese plastic processing plant demonstrated an association between peptic ulcers and smoking, as well as family history.⁵ In another study, fishermen and transportation workers in Norway had an increased prevalence of both gastric and duodenal ulcers compared with 11 other occupational groups. This prevalence was believed to be due to irregular meals, high coffee intake, and heavy smoking.⁶ Similar findings in a Russian study of railroad workers found an increased prevalence of peptic ulcer disease that correlated with irregular hurried meals of both cold and fried foods.¹¹

Clinical course, diagnosis, and management

The diagnosis and treatment do not differ from that in the general medical setting. Management of shift work may be challenging, but regular meals and sleep habits should be emphasized. Acid suppression should be prescribed to effect ulcer healing or symptom resolution. *Helicobacter pylori* should be treated if present. Use of non-steroidal anti-inflammatory drugs and aspirin should be eliminated if possible. Behavioral changes such as smoking cessation and decreased coffee and alcohol consumption should be encouraged.

Pancreatitis

Occupational and environmental causes

Toxin-induced pancreatitis may be more common than is now recognized, especially given the high proportion of cases now considered to be idiopathic or drug related. Extremely high exposures to a variety of occupational toxins (such as the chlorinated naphthalenes), that are also associated with severe liver damage and systemic toxicity, have been associated with diffuse pancreatic damage.¹² Isolated islet cell injury has been reported with accidental ingestion of the rodenticide pyriminil (Vacor).

The organophosphate pesticides have been associated with pancreatitis and other pancreatic disorders. Accidental ingestion of the organophosphate pesticide O-ethyl-S-

phenylethylphosphophenodithioate leads to pancreatitis, frequently with pancreatic pseudocyst formations, during the acute stages of organophosphate poisoning. A male farm worker exposed to the organophosphate Q Dimethoate developed pancreatitis with acute organophosphate poisoning.¹³ Two out of nine patients who ingested parathion developed painless acute hemorrhagic pancreatitis.¹⁴

Acute and chronic pancreatitis have also been associated with occupational exposures to organic solvents.^{15,16} Numerous cases have now been described in association with occupational exposure to perchloroethylene, trichloroethylene (TCE), mineral spirits, solvent-based paints, and diesel fuel. There have been at least two case reports of pancreatitis associated with occupational exposure to the solvent dimethylformamide (a known hepatotoxin) with no history of concurrent alcohol use; full recovery was apparent following removal from exposure.¹⁷ Experimental animal evidence also indicates that this solvent causes pancreatic damage.

Acute pancreatitis has also been reported with scorpion bites (*Tityus trinitatis*), both occupationally and environmentally, in Trinidad.

Pathogenesis

Experimental models of poisoning in pigs and dogs with organophosphates reveal increases in amylase levels and increased intraductal pressures within the pancreas. The postulated mechanism is the stimulation of parasympathetic pathways to the pancreas through cholinesterase inhibition, which, in turn, augments the secretory flow, increasing intraductal pressure. This response can be attenuated experimentally through pretreatment with atropine. Pancreatitis associated with scorpion toxin appears to be related to increased cholinergic stimulation, as well as a direct toxic effect.^{18,19}

Clinical course, diagnosis, and management

Clinical features of pancreatitis of environmental or occupational etiology do not appear to differ from those of other established causes. The key difference in treatment is prevention of re-exposure to the suspected toxin. As with

other occupational GI diseases, removal of the affected individual can be a useful diagnostic as well as therapeutic intervention.

LOWER GASTROINTESTINAL DISORDERS

Infectious gastroenteritis

Occupational and environmental causes

Occupationally related gastroenteritis has been reported in workers and their families from a number of occupations (Table 26.2.3). In particular, parasitic and bacterial forms of gastroenteritis have been noted in specific occupations (such as healthcare workers, laboratory technicians, and sewage workers) that involve contact with infected materials.^{20–24} Zoonotic illness resulting in gastroenteritis has been reported among animal handlers and laboratory technicians; agricultural workers and other rural manual laborers (and their families) have been noted to have increased parasitic and bacterial infestations, probably due to infected water supplies, poor hygienic conditions, and the use of night soil (human waste) as a fertilizer.

Clinical course, diagnosis, and management

While the signs and symptoms, as well as the diagnosis and treatment, of occupationally related gastroenteritis are the same as for any gastroenteritis, management should emphasize examination of family members who may be infected from common sources.

Celiac disease

Occupational and environmental causes

Hypersensitivity pneumonitides such as farmer's lung and bird fancier's lung have been associated with celiac disease in some cases. Celiac disease involves a malabsorption syndrome, with duodenal or jejunal villous changes

Table 26.2.3 Occupational gastroenteritis: occupations and pathogens

observed on biopsy; it can present clinically, prior to or concomitant with the pulmonary disease.²⁵

There is still considerable controversy regarding the actual existence of this disease entity.²⁶ Berrill's investigation of 42 patients with bird fancier's lung (including exposure history, diffuse lung disease, and precipitins to bird serum) showed that eight persons had villous atrophy on jejunal biopsy.²⁵ In another large series, four of 57 patients with farmer's lung had celiac disease on biopsy; low red cell folate levels and multiple food antibodies were also observed.²⁷ Other investigations have failed to show celiac disease on biopsy of patients who had proven bird fancier's lung, and this may represent as infrequent complication.

Pathogenesis

This environmentally related enteropathy appears to be distinct from traditional celiac disease. There often are specific antibodies to birds or molds that are distinct from the avian antibodies seen with common celiac disease (these antibodies are believed to be antigens to hen's egg yolk).²⁸ Specific respiratory responses to provocation inhalation tests are observed with these patients that are not seen in patients with common celiac disease. In addition, although these patients have antibodies to gluten, often these are not antibodies to the gliadin fraction of gluten (seen with common celiac disease). Of interest, this enteropathy seems to respond to removal of the affected individual from exposure, in combination with a gluten-free diet. One etiologic theory posits that there may be a genetic predisposition that is triggered by exposure to specific antigens; notably, both celiac disease and some types of fibrosing alveolitis, including farmer's lung disease, are more common in persons of the HLA B8 genotype.

Clinical course, diagnosis, and management

The signs and symptoms of this disease entity are due to the concurrent involvement of the GI and respiratory systems, including mouth ulcers, food intolerance, abdominal pain, diarrhea, constipation, as well as weight loss, dyspnea, general malaise, and bronchospasm. These symptoms may coexist or can precede one another.

A history of occupational or heavy environmental exposure to hay, straw, or birds should raise clinical suspicion in an individual with lower GI symptoms. A duodenal or jejunal biopsy showing villous atrophy as well as antigen testing (e.g., avian precipitins [bird fancier's lung] or *Micropolyspora faeni* [farmer's lung]) are diagnostic. For diagnostic issues regarding the respiratory component, please refer to Chapter 19.6. In addition, there should be no evidence for malignancy or collagen vascular disease. Of note, there are reports of co-existing celiac disease in spouses, supporting a common source exposure.

Removal of the individual from exposure in combination with dietary restrictions (e.g., gluten free, egg free) appear to be key factors in management of the condition. Sometimes, more aggressive treatment, such as corticosteroids, is necessary, particularly for the lung disease. The prognosis is good, especially with removal of the individual from exposure.

Pneumatosis cystoides intestinalis

Occupational and environmental causes

Pneumatosis cystoides intestinalis (PCI) is a relatively rare, usually benign condition, characterized by the formation of multiple intramural gas-filled cysts along some portion of the GI tract involving most commonly, though not invariably, the lower gastrointestinal tract. Over 350 cases have been reported in Japan, many of them associated with occupational exposure to TCE.^{29–31}

There appear to exist two etiologic groups of PCI. One is primary or idiopathic PCI, with no particular responsible or associated abnormalities; it is a relatively benign condition that occurs more frequently in women. The other group, so-called secondary PCI, is seen with a broad variety of associated lesions, including intestinal obstruction (with concurrent pyloric stenosis related to peptic ulcer disease), chronic obstructive pulmonary disease, and connective tissue diseases. Since 1952, when the first cases were reported, the majority of patients have fallen in the second group, with lesions predominantly in the small intestine. More recently, in Japan, there have been a series of reports of primary PCI, predominantly in the large intestine (especially the sigmoid colon); this condition also has been called pneumatosis cystoides coli (PCC). Many of these PCI (or PCC) patients have a history of occupational exposure to TCE, for degreasing metal parts and products.

In cases of TCE-associated PCI, TCE has been found in gas through endoscopic collection in the cystic spaces, and the metabolite trichloroacetic acid (TCA) has been found in the urine and bile of patients. However, the etiologic mechanism of TCE is not well understood.³² Another possible mechanism is the inhibition of bacterial hydrogen consumption by alkyl halides such as TCE. This may lead to increased net hydrogen gas production, resulting in 'counterperfusion supersaturation' and formation of gas cysts.³³

Clinical course, diagnosis, and management

The symptoms of PCI are non-specific and include abdominal fullness, tenderness, and pain; constipation; and a frothy mucous discharge from the rectum (described by patients as foamy tomato juice). Pneumoperitoneum occurs frequently, but because of the sterility of the gas collections, patients rarely have complications of peritonitis.³⁴ A period of up to 10 years may be required before symptoms develop. On barium enema, polypoid changes are noted, with multiple elevated lesions found on sigmoidoscopy. Needle aspiration of these areas reveals gas. No malignancy or other source for the pain and hematochezia is identified in the workup. Associated etiologic conditions should be sought to exclude secondary PCI.

Removal of the individual from exposure to TCE and, in some cases, oxygen therapy are the major forms of treatment for PCI.³⁵ Some studies have examined the use of metronidazole to decrease anaerobic bacteria and reduce production of luminal gas. Primary PCI often disappears spontaneously, with or without other interventions. For secondary PCI, treatment of the underlying disease process

is generally necessary. With pneumatosis secondary to TCE exposure, removal of the individual from further exposure is associated with a good prognosis.

Non-specific toxic gastrointestinal syndromes

Lead poisoning

Lower gastrointestinal symptoms have been considered a hallmark of lead intoxication, both in children and in adults. Symptoms of colic with either constipation or diarrhea, sometimes severe enough to mimic an acute abdomen, are particularly dominant in acute poisoning, in which a rapid rise in tissue lead levels occurs. In more chronic cases, GI symptoms are less apparent. The effect on the GI tract is probably, in part, due to inhibition of autonomic function of intestinal smooth muscle. In its most extreme form, this condition may lead to toxic megacolon, which is well described in children.

Management of lead toxicity involves removal of the individual from exposure in every case, and careful evaluation to exclude other remediable GI lesions such as ulcers or malignancy. In acute lead poisoning, chelation therapy usually results in prompt relief of GI symptoms. Chelation may be accomplished by intravenous calcium disodium EDTA therapy or oral meso-2,3-dimercaptosuccinic acid (DMSA; Succimer) therapy.³⁶

Other metals

Many other metals, including aluminum, arsenic, barium, copper, iron, mercury, and thallium, can cause gastroenteritis with anorexia, and a combination of upper GI (e.g., nausea, vomiting) and lower GI changes in bowel habits. In general, these toxicities are related to acute and subacute exposures, especially through the oral route, and less frequently with long-term exposures. The pathogenesis is not well understood in most cases, but, in general, it appears to involve some disruption of epithelial cell function, leading to cellular necrosis in severe cases.

Cholinesterase inhibitors

Methylcarbamates and organophosphates inhibit cholinesterase, and may cause anorexia, vomiting, cramps, and diarrhea owing to their cholinergic (muscarinic) effects on bowel function. Increased motility and intestinal secretion, and impaired salt and water reabsorption probably account for the major lower GI symptoms that may occur in acute poisoning. The treatment is removal of the individual from exposure; atropine inhibits the muscarinic effects acutely (see Chapter 48).

Chapter 27

Endocrine and Reproductive Disorders

27.1 Endocrine Disorders

Ulrike Luderer, Mark R Cullen

During the past decade, interest in the effects of environmental agents on the endocrine system has burgeoned. This is, in part, due to the concern that environmental contaminants, acting via hormonal mechanisms, may be responsible for a number of adverse health outcomes in humans and wildlife. It has been hypothesized that these environmental endocrine disrupters may be playing roles in the etiology of breast, testicular, and prostate cancer, decreased fertility, endometriosis, and abnormalities of male reproductive system development such as hypospadias and cryptorchidism.¹⁻³ Although much of the impetus has come from concern about the reproductive effects of these agents, new knowledge has also begun to accumulate regarding their impact on thyroid, adrenal, and pituitary function. At the same time, study of the effects of the environment on the endocrine functions of gastrointestinal organs, and bone and calcium metabolism has begun, albeit in a more limited way to date. Collectively, these aspects are the subjects of this chapter. Related discussions of the reproductive effects appear in Chapter 27.2, while the subject of neoplasms of the endocrine and reproductive organs is covered in Chapters 30.7 and 30.8.

Although understanding of this potentially enormous subject remains relatively limited compared with other targets of environmental factors, certain principles regarding non-reproductive endocrine disorders can be stated that simplify the practitioner's task. First, with the possible exception of the potent rodenticide Vacor, it appears that agents that affect endocrine functions other than reproduction tend to be ones with diffuse effects on other organs as well, such as heavy metals, pesticides, and solvents. In general, therefore, the search for environmental factors is most relevant to patients with medical problems in addition to those problems that might be attributable to endocrinopathy, such as central nervous system (CNS), hepatic, respiratory, dermal, and, importantly, reproductive disorders. In other words, it would be uncommon, given our present understanding, to find an endocrine disorder as the sole manifestation of environmental toxicity in adults. This is in marked contrast to agents with primary reproductive effects that may often dominate the clinical picture of toxicity, obscuring other less salient effects. Subclinical effects, however, could precede other measurable effects, because even subtle alterations may be potentially useful as biomarkers in exposed populations. The advantage they provide over merely measuring exposure levels is that changes in these endpoints indicate that sufficient absorption has occurred to cause a physiologic effect. Interventions to reduce expo-

sure can then be instituted before the onset of clinically significant effects.

The corollary of the first principle is that environmental agents typically cause subtle, rather than profound disturbances of endocrine function, except in cases of massive exposures in adults. Classic presentations of organ failure or hyper-reactivity, such as myxedema, thyroid storm, pituitary apoplexy, and addisonian crisis (adrenal insufficiency) are not part of the spectrum of endocrinopathies described in human cases or predicted by dose-response testing in animals or cell cultures. Rather, the effects of environmental agents on endocrine functions other than reproduction tend to be subtle and easily masked, unless they are specifically considered and tested for. However, given our increasing understanding of the importance of endocrine balance for a wide range of crucial functions, such as growth and development, response to stress, and risk for longterm cardiovascular disease, these relatively subtle effects of the environment may be more important than previously appreciated, particularly on a population basis. Indeed, recent work suggests that even small disruptions of thyroid homeostasis in utero and during early postnatal development may have significant adverse effects on the developing brain. For example, it has been long known that infants with congenital hypothyroidism will develop mental retardation and severe motor abnormalities if not treated from birth with thyroxine; however, only recently has it begun to be appreciated that even with thyroxine replacement from birth, these children may manifest subtle, but measurable, deficits of IQ, motor function, and coordination.⁴

MECHANISMS OF ENDOCRINE TOXICITY

There are a variety of mechanisms by which toxicants can affect endocrine function (Table 27.1.1). Induction of cell death within an endocrine gland or tissue is used therapeutically in the treatment of Graves' disease by means of ablative therapy with radioactive iodine. Induction of apoptosis or programmed cell death in ovarian follicle cells also appears to be one mechanism by which the chemotherapeutic drug cyclophosphamide causes ovarian failure. Many diverse compounds have been shown to disrupt endocrine function by binding to hormone receptors, acting as receptor agonists or antagonists (see Chapter 45). The organochlorine insecticide methoxychlor is an estrogen receptor agonist, while

Mechanism	Example	References
Induction of cell death	Cyclophosphamide, radioactive iodine	69
Hormone receptor binding	Methoxychlor, p,p'-DDE*	70,71
Transport protein binding	Polychlorinated biphenyls	16
Altering hormone synthesis or secretion	Perchlorates, thiocyanates, styrene	38,47
Altering hormone metabolism	Heptachlor, chlordane	72
Altering hormone receptor levels	Gonadotropin-releasing hormone agonists	73
Modulating intracellular signaling pathways	Lithium	38

*1,1-dichloro-2,2'-bis(p-chlorophenyl) ethylene

Table 27.1.1 Mechanisms of endocrine toxicity

1,1-dichloro-2,2'-bis(p-chlorophenyl) ethylene (p,p'-DDE), a metabolite of another organochlorine insecticide, 1,1,1-trichloro-2,2'-bis(p-chlorophenyl) ethane (DDT), is a potent androgen receptor antagonist. Yet other compounds compete with endogenous ligands for non-receptor transport proteins. Hydroxylated metabolites of various polychlorinated biphenyls have been demonstrated to potentially bind transthyretin, disrupting thyroid homeostasis. Some endocrine toxicants act by altering hormone synthesis or secretion. For example, the aromatic solvent styrene increases pituitary prolactin secretion, and thiocyanates and perchlorates inhibit thyroid hormone synthesis by blocking iodine uptake into the thyroid.

Endocrine homeostasis can also be disturbed by compounds that alter hormone metabolism. The cyclodiene insecticides heptachlor and chlordane are potent inducers of hydroxylases that metabolize sex steroids, resulting in reduced circulating levels of these hormones. Additional mechanisms by which toxicants might disrupt endocrine function are by up- or down-regulating hormone receptor levels or by interfering with hormonal intracellular signaling pathways. For example, lithium suppresses thyroid hormone release by inhibiting cyclic AMP-mediated effects of thyroid-stimulating hormone (TSH).

A useful mechanistic distinction for understanding the developmental effects of endocrine toxicants is that of organizational versus activational effects of hormones.⁵ Organizational effects occur early during development, usually before birth, and are permanent. In contrast, activational effects usually occur during adult life and are transient. Organizational effects of hormonally active toxicants usually require lower doses and shorter exposures during critical windows of development than do activational effects. Examples of organizational effects of hormones include the stimulation by androgens of male reproductive duct and gland development, and the masculinization of the CNS by exposure to estrogens in utero. Examples of activational effects include the stimulation of thyroid gland hyperplasia by TSH or of uterine endometrial proliferation by estrogens.

CLINICAL EVALUATION

History and physical examination

For the reasons outlined earlier, the typical historic and physical findings associated with primary endocrine

diseases are not likely to be found in patients with endocrine effects resulting from environmental factors. In fact, where classic findings such as frontal bossing, lid lag, galactorrhea, and hyperpigmentation are uncovered, serious consideration must be given to non-environmental causes such as autoimmune disease or tumors. Nonetheless, any suspicion of endocrine dysfunction should prompt a thorough review of systems for each of the classic historic features of primary endocrine disturbance and a careful physical examination that includes a search for the well-known physical findings.

Far more relevant to uncovering endocrine effects of environmental agents are the subtle and less specific consequences of hormonal imbalances. The client's medical history should include information on each of the following topics:

- sleep disturbance or changes in energy level or mood;
- alterations in weight, appetite, and bowel function;
- sexual interest and function, and, in women, menstrual changes;
- changes in temperature perception, sweating, or flushing; and
- alterations of body habitus, hair growth, and skin texture.

In addition to these specific inquiries, the history should also include a careful search for other toxic effects of suspected causal agents, for the reasons mentioned earlier. Often, these effects may overlap with or obscure endocrine-related phenomena, especially those that involve the CNS, gastrointestinal, or reproductive symptoms. The presence of such symptoms, although initially confusing, should heighten rather than diminish suspicion of environmentally induced endocrinopathy. These non-specific symptoms mandate a search, usually requiring laboratory tests, to identify effects on each organ that may be contributing to the symptoms. It should not be presumed that identification of one possible disorder, such as mild encephalopathy, precludes the need to evaluate the integrity of endocrine function when exposure to a suspect agent has occurred.

The same general principle applies to the physical examination. Although careful examination may uncover a very revealing and localizing sign, such as a goiter or change in a secondary sexual characteristic, the greater usefulness of the examination is in identification of more typical, non-endocrine markers of toxicity from the environmental agent in question, such as Mees lines (skin

lesions associated with heavy metal exposure) or neurologic changes due to solvents, organophosphates, organochlorine, or heavy metals. A second important role for the physical examination is to carefully evaluate evidence of non-environmental causes for endocrinopathy such as a tumor (e.g., if milk can be expressed from the breast of a non-lactating woman).

Laboratory evaluation

Given the subtle, non-specific nature of historic clues and physical findings for endocrinopathy of environmental origin, the appropriate use of laboratory tests is essential. There are four specific goals in the use of these tests:

- detection of mild, often subclinical alterations of function;
- localization of the injury within the hierarchy of endocrine regulation (e.g., hypothalamus or pituitary versus end organ);
- exclusion of tumor or other primary endocrine organ failure due to non-environmental causes; and
- establishment of markers of exposure to a causal agent or evidence of other organ system damage from the agent.

Satisfactory accomplishment of the first three goals requires a detailed understanding of the available strategies for testing and localizing endocrine lesions, which is beyond the scope of this text. Certain generalization is worth noting here regarding available tests.

Tests of end-organ function

The circulating levels of virtually every hormone can now be measured directly, including thyroid hormones, adrenal steroids and amines, anterior and posterior pituitary secretions, parathormone, and 1,25-dihydroxycholecalciferol. For some of these hormones, levels are sufficiently stable over time so that a single measurement accurately reflects organ function. Examples of these include thyroid hormones and cholecalciferols. For others, such as cortisol and insulin, blood levels fluctuate so rapidly that baseline function cannot be adequately assessed from a single or even from multiple random measures; instead, some integrated measure is needed, such as collection of steroid metabolites in a timed urine collection, or the hormone must be measured under specified conditions known to maximize or suppress glandular activity, such as fasting or glucose ingestion for insulin secretion. For some hormones, such as insulin, indirect measurements of hormonal function are often more readily available, such as blood glucose levels.

However baseline function of the end organs is assessed, it must be remembered that the endocrine system as a whole is finely balanced to ensure homeostasis even in the face of injury. For example, a partially diseased thyroid gland may still be capable of secreting an adequate (i.e., normal) level of thyroxine (T₄) by stimulating the pituitary compensatory secretion of TSH. Thus, a subtle lesion in the thyroid axis would not necessarily be revealed by simple measurement of the end product, but would

become apparent if TSH were simultaneously measured. For other hormones, even simultaneous measurement of trophic hormone and its end product may mask a lesion. For example, mild adrenal insufficiency may not be apparent from cortisol levels or urinary excretion of adrenal metabolites under normal conditions, but they may be significant or even life threatening under stresses such as infection or bleeding.

An array of stress tests have been devised that can allow detection of more subtle lesions that are insufficient to alter function under normal conditions. The best known example of such is the glucose tolerance test, which indirectly assesses the adequacy of insulin regulation by measurement of timed glucose levels after a challenge. In the reverse direction, administration of insulin to induce mild hypoglycemia is an excellent way to assess whether the adrenal axis is intact, because lowering of blood sugar is a very potent stimulus for cortisol secretion. The same stress should also induce an outpouring of growth hormone, even if baseline levels are low. It is important to recognize, however, that many of these stresses are inherently dangerous, especially in patients with suspected defects of endocrine function. The tests should be performed under tightly controlled circumstances and always by individuals experienced in their administration and interpretation.

DISORDERS OF THYROID FUNCTION

The ability of environmental factors to affect the function of the thyroid gland has been appreciated for centuries because of the occurrence of endemic goiters. Although iodine deficiency was recognized as an important cause of goiter before the days of dietary supplementation, the presence of various goitrogens in medicines, food, and drinking water was also recognized. These compounds include perchlorates and thiocyanate, which inhibit iodine transport into the thyroid, and a number of compounds that inhibit organification of iodine, including the metal cobalt and several classes of cyclic organic compounds, such as substituted phenols. Particularly concerning are the developmental effects of such alterations, given the important role of T₄ in CNS development. A recent study of electroplating workers with chronic cyanide exposure, which causes thiocyanate accumulation, demonstrated reduced serum T₄ and tri-iodothyronine (T₃), and elevated TSH concentrations relative to controls.⁶ Perchlorate has historically been used to treat Graves' disease, effectively lowering T₄ levels; however, it was discontinued due to a number of reports of aplastic anemia. Environmental perchlorate contamination of drinking water has been linked to reduced T₄ and increased TSH in newborns.⁷ While increased rates of congenital hypothyroidism have not been observed, this endpoint is not sensitive for detecting subclinical thyroid dysfunction.⁸ Two studies of workers with inhalational perchlorate exposure, in contrast, did not find evidence of altered thyroid function,^{9,10} although the applicability of these findings to

pediatric populations is unclear. More recent investigations of orally administered perchlorate in human volunteers have documented inhibition of I-123 uptake by the thyroid at low doses (0.01–0.043 mg/kg/day).^{11–13} These findings indicate inhibition of the sodium-iodide symporter, with mild changes in thyroid hormone levels at higher doses (0.5 mg/kg/day) in the short term.³ Additional health concerns regarding perchlorate have focused on rodent models, demonstrating a lowest observable adverse effect level (LOAEL) of 0.01 mg/kg/day based on brain morphometric and thyroid hormonal changes in rat pups, with thyroid follicular epithelial cell hyperplasia observed at 0.1 mg/kg/day.¹⁴ In aggregate, these investigations have led to recommendations for lowered reference doses, with proposed reference doses as low as 1 ppb for drinking water (Drinking Water Equivalent Level [DWEL]).¹⁴

The effect of ionizing radiation on the thyroid gland has also been appreciated for many years.¹⁵ Low to moderate doses of local irradiation to the gland, either through an external X-ray study or by absorption of radioactive iodine, have been responsible for the development of benign and malignant tumors (see Chapter 30.7). High doses of ionizing radiation are ablative and are the basis for one of the standard treatments for Graves' disease. To date, clinical studies do not suggest that the low, carcinogenic doses are associated with functional changes; hypothyroidism has not been described as a relevant effect of radiation exposure except in the setting of very high therapeutic doses.

More recently, the effects of environmental contaminants such as heavy metals, solvents, pesticides, and related compounds have been recognized as causing functional thyroid effects either clinically or in experimental animals. In humans, depressed levels of thyroid function have been correlated with exposures to lead, carbon disulfide, polybrominated biphenyls (PBBs), polychlorinated biphenyls (PCBs), dioxins, and furans. These agents have been shown to act by a variety of mechanisms in laboratory studies, including enhancement of T4 glucuronidation, and thus excretion, by PCBs, DDT, and chloroacetanilides; binding to serum thyroid hormone transport proteins by PCBs;¹⁶ and inhibition of peripheral T4 deiodination by methoxychlor.¹⁷ As with the goitrogens discussed above, the effects of disruption of thyroid homeostasis by these compounds during prenatal and postnatal development have been of particular concern because of the importance of thyroid hormone to normal brain development.¹⁸ During the first trimester of pregnancy, the developing embryo is totally dependent on maternal T4, and even subclinical decreases in the maternal free thyroxine index during early gestation have been associated with impaired psychomotor development and reduced IQ.¹⁸ The fetus begins to synthesize T4 around week 10 to 12 of gestation, but some T4 is still transported from the mother throughout gestation. Thus, the severe sequelae of congenital hypothyroidism are seen after birth, with the withdrawal of the maternal source of T4.⁴

Thyroid function in lead workers has been studied quite extensively. Results suggest mild depression of function in

chronically and heavily exposed adults,^{19,20} without substantial effects at lower levels.²¹ Challenge testing has suggested that the level of the lesion is at the hypothalamus, although neither pituitary nor direct thyroid effects, as predicted by animal studies, could be excluded. Significantly, a careful study of young inner-city children failed to reveal any relationship between lead exposure and thyroid function, although screening for such an effect in the face of childhood lead poisoning is recommended in view of the ramifications of even mild hypothyroidism on child development.²²

Early reports of depressed thyroid function in carbon disulfide-exposed workers have been neither clinically studied nor confirmed in more recent cohorts.²³ As is generally true for endocrine effects, other clinical effects of carbon disulfide poisoning, including neuropathy and cardiovascular disease, tend to dominate the clinical picture in the only available reports.

The study of the agricultural communities in Michigan accidentally exposed to PBBs in the 1970s provides the only report of an outbreak of non-goitrogenic thyroid dysfunction attributable to environmental contamination by chemicals.²⁴ Although sophisticated testing of those with depressed T4 levels was not conducted to establish the level of injury in the thyroid–pituitary–hypothalamic axis, the report of increased antithyroid antibodies serves as indirect evidence of a primary effect on the thyroid gland itself.

Studies of adult humans exposed to relatively high levels of PCBs provide conflicting data about the effects of these compounds on thyroid function. In adults who 16 years earlier had consumed cooking oil ('Yusho rice oil') contaminated with PCBs, serum T3 and T4 were elevated, but TSH and antithyroid antibodies were not changed compared to controls.²⁵ Serum PCBs did not correlate with T4 or T3 in that study. In contrast, a history of current or former occupational PCB exposure among transformer repairmen was associated with a lower T4 and T4-RT3 index compared to unexposed controls.²⁶ In the same study, adipose or serum PCB concentrations were not significantly associated with exposure, suggesting that exposure history may have been spurious or that the relationship between PCB body burden and thyroid function is not a linear one. A recent study of employees in a former PCB plant found increased thyroid volumes and increased prevalence of antithyroid antibodies in the employees compared to controls, but no differences in T4 or TSH levels.²⁷ Unlike the conflicting human data, experimental studies in adult rats demonstrate suppression of serum T4 by PCBs.¹⁶

Exposure to another class of chlorinated polyaromatic hydrocarbons, the dioxins, has also been associated with subclinical changes in thyroid hormone secretion in some human studies. There was a positive relationship between serum 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD) concentration and T4 and free T4 index, but not TSH or thyroid disease, in industrial workers exposed to TCDD contamination 15 years previously.²⁸ Similarly, another study of chemical workers also found a positive associa-

tion between serum TCDD concentration and T4, but not TSH.²⁹ In contrast, free T4 index did not differ between Operation Ranch Hand Vietnam veterans exposed to TCDD in Agent Orange and controls.²⁸

PCBs, like dioxins and furans, are highly persistent, lipophilic, organochlorine pollutants for which more than 90% of human exposure occurs via food intake, primarily meat, fish, and dairy products (see Chapter 45).³⁰ Breastfeeding can be an important source of exposure, accounting for 12% to 14% of the total PCB and dioxin intake in one study.³⁰ One recent study in children found a negative relationship between serum PCB levels and serum levels of free T3, and a positive correlation with TSH.³¹ A study of breast-fed Japanese infants found significant negative correlations between total dioxin equivalents contributed by PCBs, dioxins, and furans in the breast milk, and serum T4 and T3 levels.³² A Dutch study found a positive correlation between breast milk PCBs and dioxins and neonatal TSH, but no relationship with T4.³³ Another study of background level PCB exposure in the US, in contrast, found no significant correlation between maternal PCB levels and neonatal T4, T3, or TSH levels at birth.³⁴ The significance of small reductions in thyroid hormone levels observed in the former studies on the developing brain are not yet fully characterized. However, studies of human populations with prenatal and perinatal environmental PCB exposures demonstrate neurologic deficits that are consistent with a mechanism involving disruption of thyroid hormone homeostasis. These studies reported inverse relationships between various indices of PCB exposure and motor function, attention, IQ, and memory deficits.^{4,35} Moreover, animal studies have shown that maternal PCB exposure causes reduced T4 and T3 levels in fetal brains, as well as motor deficits and impaired learning.^{4,35}

Thyroid function has been studied in women exposed to cobalt-based paints.^{36,37} Cross-sectional blood tests suggest that one effect is dose-related elevation of T4, free T4, and the T4-to-T3 ratio, without a change in TSH levels or pituitary function. The results suggest reduced peripheral deiodination of T4 to T3, but the clinical significance of this observation is unclear.

For none of the settings in which human effects have been observed and reported are there adequate longitudinal data on the natural history or response to any intervention. Lead workers removed from further exposure appear to have gradual amelioration of depressed T4 levels. The effects of chelation or thyroid supplementation are unknown. The potential reversibility of lesions due to other exposures described above is also unknown, but at a minimum, removal of the affected individual from any further exposure would seem advisable once non-environmental causes have been excluded.

In addition to the effects that have been reported in workers and communities, experimental studies in animals suggest that the thyroid is potentially susceptible to injury from widely used chemicals. These include insecticides such as organophosphates, carbamates and organochlorines, fungicides, food colorants, and mercury.³⁸ It is premature to

recommend that exposed individuals be screened or otherwise evaluated for these effects outside research protocols. Nonetheless, exposure to these agents should be considered as potentially causal in patients who are identified with thyroid functional abnormalities when other established factors have been excluded.

DISORDERS OF ADRENAL FUNCTION

Very little is known about the effects of environmental agents on adrenal cortical or medullary function in humans. Occupationally, only workers heavily exposed to lead and PCBs have been studied.

Results of studies of lead-exposed workers suggest that secretion of corticosteroids is depressed in response to insulin-induced hypoglycemia and vasopressin; baseline levels of 17-hydroxy (glucocorticoid) and 17-keto (androgenic) steroids were low normal. Because response to administration of adrenocorticotrophic hormone (ACTH) was normal, it was presumed that the lesion was at the hypothalamic-pituitary level, but primary toxicity on the adrenal itself could not be excluded. Neither the clinical relevance nor the appropriate treatment for these lesions has been characterized. Importantly, all workers demonstrating these effects also had other evidence of lead toxicity, requiring all the workers to be removed from exposure and chelation therapy to be instituted in those more severely affected.

In a study of humans massively exposed to the pesticide gramoxone by ingestion, levels of adrenocortical hormones were measured and found to be markedly elevated in those who later died, but normal or low in survivors.³⁹ Whether this factor represents toxicity to the adrenal gland or axis or whether it is a non-specific response to systemic poisoning could not be ascertained; the effects of lower doses of this and related agents are unknown.

Current and former transformer repairmen exposed to PCBs were found to have lower urinary 17-hydroxycortisone excretion than controls.²⁶ Moreover, urinary 17-hydroxycortisone was negatively correlated with adipose tissue PCB concentration.²⁶ It is not known whether there was a concurrent effect on serum glucocorticoid concentrations, as they were not measured. Reduced urinary 17-hydroxycortisone may reflect a suppressive effect of PCBs on adrenal glucocorticoid secretion or synthesis, resulting in reduced serum levels of glucocorticoids.

Animal studies suggest that the adrenal gland may be more sensitive to environmental effects than the limited human data would suggest. A broad range of organochlorine, organophosphate, and carbamate pesticides has been tested, and evidence of histologic alterations in adrenocortical cells has been found; similar effects have been shown with ammonium sulfate fertilizer. The herbicide paraquat has been established to be a potent inhibitor of aldosterone synthesis in the adrenal gland, with action similar to the drugs spironolactone and metyrapone;⁴⁰ depression

of aldosterone secretion has been demonstrated in animals. Several organophosphates, including malathion and diazinon, have been shown to interfere with adrenomedullary function, causing enhanced secretion of epinephrine and norepinephrine, with resulting hyperglycemia, glycogen deposition in the liver, and exhaustion of adrenal stores of these amines.^{41,42} Mirex, toxaphene, and dioxin (2,3,7,8 TCDD) have been shown to cause direct suppression of glucocorticoid synthesis by the adrenal, with resultant hypoglycemia that could be reversed by cortisone administration.⁴³⁻⁴⁵ The solvent 1,1,1-trichloroethane suppresses plasma corticosterone and ACTH concentrations, possibly via an effect on hypothalamic corticotropin-releasing hormone (CRH) in rodents.⁴⁶ High doses relative to likely human environmental exposures have been used in these studies, so the relevance to humans remains unclear.

DISORDERS OF THE PITUITARY GLAND

Lead, styrene, and beryllium have been demonstrated to affect the pituitary gland of occupationally exposed workers. The data on lead have already been summarized earlier in the sections on thyroid and adrenal function. There is further evidence for an effect on the pituitary-gonadal axis (see Chapter 27.2). However, sophisticated testing of these workers failed to demonstrate any effects on growth hormone or prolactin secretion from the anterior pituitary or any evidence of posterior pituitary dysfunction.

The effect of styrene on hypothalamic-pituitary function has been studied in several groups of exposed workers. Although thyroid and gonadotropic hormones appeared to be unaffected by the exposure, baseline prolactin and growth hormone levels were elevated in a dose-dependent fashion.⁴⁷ Significantly, there was a very marked and dose-dependent enhancement of the prolactin response to thyrotropin-releasing hormone (TRH), suggesting the possibility of a defect in the normal counter-regulation of prolactin, which is controlled by hypothalamic dopamine.⁴⁸ These results suggest the possibility that styrene specifically depletes dopamine from the tuberoinfundibular portion of the hypothalamus. Depletion of dopamine in this portion of the hypothalamus following styrene inhalation has been demonstrated in experimental studies in the rabbit.⁴⁹

Notably, in occupational studies of pituitary function, workers experienced prominent, albeit vague, CNS complaints, suggesting that endocrine disturbance was not the first or sole toxicity resulting from the exposure. Although the clinical significance remains unclear, levels of prolactin observed in this condition could be a cause of galactorrhea, secondary infertility, or both in the appropriate exposure setting. Despite the hypothetical possibility of reduced fertility caused by hyperprolactinemia, a recent study found no effect of styrene exposure on time-to-pregnancy, an indicator of fertility, in men.⁵⁰

Patients with chronic beryllium disease due to beryllium exposure may exhibit granulomas in the pituitary gland

similar to those seen in sarcoidosis. However, functional disorders of the anterior and posterior pituitary gland similar to those seen occasionally in sarcoidosis have not been described in beryllium disease. Nonetheless, the occurrence of granulomas in this organ raises the possibility of functional defects that should be considered when they are clinically suggested.

In addition to the above-mentioned studies, limited human data suggest that pituitary secretion of the reproductive hormones luteinizing hormone (LH) and follicle-stimulating hormone (FSH) may be suppressed by occupational exposure to toluene^{51,52} and herbicides⁵³ and enhanced by occupational exposure to carbon disulfide.²³

Very little experimental work on pituitary responses to environmental agents has been conducted to date. Animal studies have demonstrated effects of the aromatic solvents toluene and xylene on pituitary hormone secretion; however, the results of these studies have been inconsistent. One study reported effects of toluene exposure on prolactin levels, but not on LH, FSH, TSH, or corticosterone concentrations,⁵⁴ while another reported effects on LH and FSH levels.⁵⁵ Xylenes were found to suppress both serum prolactin and corticosterone in rats in the third study.⁵⁶

DIABETES MELLITUS

It is evident from the above-mentioned effects of xenobiotics on the adrenal and pituitary glands that agents that enhance production or release of growth hormone or adrenomedullary amines could induce some degree of glucose intolerance. However, no human case nor animal model of diabetes that has developed via such a pathway has yet been described.

One single agent, the rodenticide Vacor (pyridyl N-p-nitrophenyl urea), has been implicated as a cause of diabetes mellitus after human ingestion.⁵⁷ Notably, glucose intolerance was the major clinical toxicity in reported cases, although autonomic and peripheral neuropathy with orthostatic hypotension were concomitantly observed. Animal studies have now documented the very strong binding of Vacor to pancreatic islet beta cells by a mechanism similar to that of the drug streptozocin. Whether this inhibition of insulin release may be reversible is unclear. Studied cases have demonstrated subsequent cytotoxic effects on the islet cells, and chronic insulin-dependent diabetes has resulted. Anti-islet cell antibodies have been measured in serum from some patients. It is unclear whether specific treatment early in toxicity, such as with the competitive binder streptozocin, may lead to a better outcome than supportive care alone.

Positive relationships have been observed between serum TCDD levels and both fasting serum glucose levels and risk of diabetes in workers exposed to chemicals contaminated with TCDD.⁵⁸ An association between TCDD levels and risk of diabetes mellitus has also been observed among US veterans of Operation Ranch Hand, who were exposed to TCDD in Agent Orange.⁵⁹ Interestingly, even among non-diabetic Ranch Hand veterans, there was a positive relationship between serum insulin and TCDD exposure category,

suggesting hyperinsulinemia as a possible mechanism for the development of diabetes in dioxin-exposed individuals.⁵⁹ Increased rates of diabetes-related mortality have been reported in female TCDD-exposed individuals in one study,⁶⁰ but not in two other studies.^{61,62} A large international study that combined 36 dioxin-exposed cohorts from 12 countries found an increased risk of mortality from diabetes, but did not reach statistical significance.⁶³ However, because most people with diabetes mellitus now survive for years after diagnosis, one would not necessarily expect to see an association with diabetes-related mortality even if there were a true association between dioxin exposure and risk of diabetes.

DISORDERS OF CALCIUM AND BONE METABOLISM

Calcium homeostasis and bone metabolism are under the control of the parathyroid hormone and the hepatic and renal metabolites of vitamin D. As well, the gastrointestinal tract, bone, and kidney are important target organs that determine the systemic impact of these hormones.

Virtually no data are available regarding the effect of toxins on the function of the parathyroid gland; one study of lead-exposed workers showed no effect. Although a variety of chemicals and ionizing radiation are capable of inducing parathyroid adenomas under appropriate experimental conditions, the relevance to human exposure is questionable. Hypoparathyroid states due to toxins have not been described in either humans or animals.

Vitamin D metabolism has been investigated in cases involving childhood lead poisoning because of the clinical observation of poor growth and abnormal bone structure in affected children.⁶⁴ The best evidence currently suggests that lead directly interferes with renal metabolism of 25-hydroxycholecalciferol to the more active 1,25-dihydroxy derivative. Whether supplementation with this metabolite could reverse some of the adverse sequelae of lead poisoning in this population has not been established.

Beryllium disease has been associated with hypercalcemia in a small number of patients. Although reports of vitamin D metabolism in this specific setting have not yet been published, it is likely that the hypercalcemia is related to that seen in other granulomatous disorders – namely, increased conversion of 25-hydroxycholecalciferol to the active moiety by hydroxylase in the granulomas, leading effectively to hypervitaminosis D. The administration of corticosteroids generally is satisfactory treatment for this metabolic complication.

Another environmental and occupational disease state associated with abnormalities of calcium metabolism in humans is chronic cadmium intoxication. Osteopenia is frequently seen in advanced cases, and it is often the first clinical manifestation (i.e., pathologic fractures) which is responsible for the Japanese name *itai-itai* (literally meaning 'ouch-ouch') for this condition. It is presumed that the bone disease occurs as a consequence of the renal tubular defect induced by prolonged exposure to cadmium, with subsequent metabolic acidosis, calcium loss, and bony

demineralization.⁶⁵ Recently, lower levels of cadmium exposure have been associated with reduced bone mineral density and osteoporosis in manufacturers of heat exchangers and in battery workers.^{66,67}

Recently, serum levels of p,p'-DDE, a metabolite of the organochlorine insecticide DDT, have been found to be negative predictors of bone mineral density in postmenopausal women.⁶⁸ The authors speculated that p,p'-DDE may affect bone density via its ability to potentially antagonize androgen receptor binding.

Beyond these reports, there are few experimental data by which to predict which other classes of toxins may have effects on vitamin D metabolism short of widespread systemic toxicity.

27.2 Disorders of Reproduction and Development

Ulrike Luderer, Mark R Cullen, Donald R Mattison

Extraordinary awareness, interest, and concern have arisen in the past three decades regarding the effects of physical activity and occupational and environmental exposures on human reproductive and developmental health. These factors have paralleled increased interest in reproductive health, motivated in part by an explosion of technology to enhance fertility and minimize adverse pregnancy outcomes. At the same time, the focus on reproduction and development has followed increased concerns about the effects of chemical, biologic, and physical hazards on health generally.

Certain unique social, scientific, and medical circumstances have contributed further to these concerns. Most obvious has been the enormous shift of women into the workforces of developed countries. Most women now work before, during, and after their pregnancies. Furthermore, the range of occupations undertaken by women has expanded to include virtually all of those formerly limited to men. Not surprisingly, issues such as the safety of occupational exposure standards for women of reproductive age, pregnant women and their fetuses, and the appropriate modifications of work practices and the work environment for the pregnant woman have challenged traditional approaches to occupational safety, which were developed in an earlier era.

More recently, the concern has been raised that environmental pollutants, at levels to which the general public is exposed, may be having adverse effects on human reproduction and development. Exposure to chemical pollutants that disrupt endocrine function by mechanisms such as binding to intracellular steroid receptors has been associated with reproductive failure and abnormal sexual differentiation in wildlife and laboratory species.¹ Such observations led to hypotheses that similar abnormalities in humans, including declining sperm counts and increased incidence of abnormal urogenital development, breast cancer, and testicular cancer, may be caused by environmental exposures to endocrine-disrupting chemicals.¹⁻⁴ These hypotheses have generated considerable controversy,^{5,6} and are currently under active investigation. Relevant research will be discussed in later sections of this chapter.

Unfortunately, these challenges uncovered a second aspect of the reproductive-environmental health problem, namely, the extraordinary paucity of useful information. Even today, information is available on reproductive and developmental effects for a relatively small number of physical, chemical, and biologic agents, and primarily for those effects that occur at high levels of exposure. Human epidemiologic studies are difficult to perform because of the sensitive nature of the information required, and the problems of classifying individuals based on their exposures during the often brief periods of biologic interest. Toxicologic studies are no less difficult to interpret given the differences between the reproductive biology of humans and experimental animals. The net effect is that even though the issue of reproductive and developmental health in the workplace has emerged as serious and promi-

nent, the availability of scientific and clinical data on which to make decisions remains limited.

In response to these realities, many employers, physicians, and regulators proposed that women who were pregnant or were capable of becoming pregnant should be removed from exposure to any hazard that could possibly affect fecundity, fertility, or the outcome of pregnancy. However, this approach was based on the mistaken premise that environmental agents would have their impacts only on fetuses in recognized pregnancies following exposure of the female. In fact, successful reproduction and development entails events in men and women that long precede recognized pregnancy as well as critical events in the fetus, placenta, and infant (Fig. 27.2.1).

Further, many harmful agents are known to have long half-lives in the body, whereas others, at least theoretically, could cause effects on target tissues that persist long after the agent itself has disappeared. Therefore, protection of reproductive and developmental health could not scientifically be viewed as a matter of limiting exposure to pregnant women alone, but must also include the infant after birth and men. Even if such policies could scientifically limit their focus to women, there remain the social issues raised by a health policy that overtly discriminates against the job rights of fecund or pregnant women, a view underscored by the United States Supreme Court in its 1991 decision of *United Auto Workers versus Johnson Controls, Inc.*, in which the majority found that federal law prohibits job discrimination purely on the basis of pregnancy or the ability to become pregnant.

This chapter (1) defines adverse reproductive and developmental health outcomes, (2) summarizes non-environmental risk factors, (3) reviews sources of agent-specific data, (4) provides listings of agents for which reasonably good data exist, (5) outlines clinical approaches to common reproductive and developmental health concerns, and (6) discusses workforce or population-based prevention strategies.

ADVERSE REPRODUCTIVE AND DEVELOPMENTAL HEALTH OUTCOMES

Because of the complexity of reproduction and development, there are multiple adverse reproductive outcomes in humans (Fig. 27.2.1). Although knowledge of the biologic bases of these events remains limited, some information exists regarding their background distribution in populations of interest (Table 27.2.1) and the factors that predispose to their occurrence.

Infertility and subfertility

Because the concept of fertility often is discussed imprecisely, some definitions are presented here. *Fecundity* is the capability of the male, female, or couple to produce

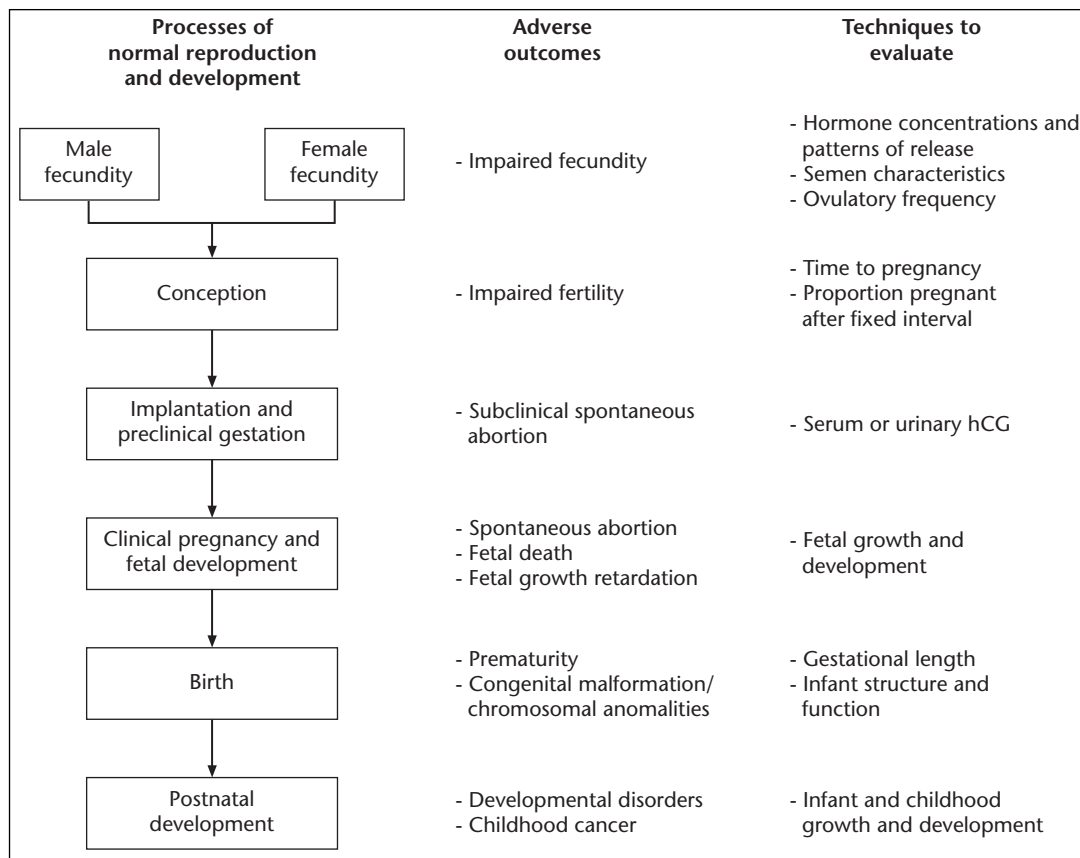

Figure 27.2.1: Normal processes of reproduction and development, representative adverse outcomes, and suggested techniques to evaluate the mechanism of the adverse outcome. For example, although subclinical spontaneous abortion may be initially manifest by increased time to pregnancy (impaired fertility), it is necessary to use urinary or serum measurement of the hCG to define early pregnancy and determine which conceptions failed to continue to develop.

Reproductive or developmental outcome	Percent
Infertility (of couples)	10–15
Preimplantation pregnancy loss	20–30
Spontaneous abortion (including clinically unrecognized)	15–50
Clinically recognized spontaneous abortion	10–15
Stillbirth (beyond 28 weeks)	<3
Premature, postmature, growth retardation	10
Birth defects	
identified at birth	3–5
identified over first year of life	5–15
Data from references 7, 8, 15–17.	

Table 27.2.1 Rates of adverse reproductive outcomes

offspring. It may be measured indirectly by such tests as a sperm count, ovulatory rate, endometrial biopsy; or more directly by measuring the conception rate of a couple followed over a fixed period of time. *Fertility* is the actual production of offspring by a couple. It is measured by recording live births over a particular time interval. *Subfertility* refers to a reduction in the expected birth rate due to factors other than choice, contraception use, or other clinical steps to diminish live births. It often is measured as a delay in the time that it takes to have a live birth during active attempts at pregnancy. *Infertility* is a couple's failure to achieve a clinically recognized pregnancy and usually is defined as one year of unsuccessful attempts. The basis for infertility or for subfertility may be the impairment of male or female fecundity, a problem with conception or implan-

tation, or some difficulty in carrying live births to term (see pathophysiology section). In practice, and for the purpose of this discussion, infertility usually is reserved for couples who have trouble conceiving (achieving a clinically recognized pregnancy); postconception problems are considered separately.

Six to fifteen percent of all couples are infertile.^{7,8} The bases for failure to conceive within a year of trying are roughly due one-third to male factors, one-third to female factors, and one-third to couple and unexplained factors.

The known factors associated with impaired male fecundity include chromosomally determined sterility (e.g., Klinefelter's syndrome [47, XXY], male Turner's or Noonan's syndrome [mosaic 46XY, 45X]), congenital cryptorchidism, endocrinopathies (e.g., pituitary or testicular failure), testicular infections (e.g., mumps orchitis), gonadotoxic drugs (e.g., antineoplastics, potent vitamin A derivatives), urologic disorders and duct obstructions, retrograde ejaculation, and varicocele. Increasing age seems to be associated with decreased fecundity in men as well as women.⁹

Factors associated with impaired female fecundity also include chromosomal, endocrine, and anatomic disturbances, gonadotoxic drugs, and increasing age. In women, common endocrine problems are ovarian failure and disorders of hormonal imbalance, such as the amenorrhea-hirsutism disorders and prolactin-secreting pituitary adenomas. Congenital (e.g., abnormal uterus) and acquired (e.g., from pelvic inflammatory disease or endometriosis) anatomic disturbances resulting in fallopian tube blockage, or failure of the fertilized egg to implant, are also common.

Diagnosis of one of the above-mentioned factors that are known to impair male and female fecundity does not necessarily rule out an environmental or occupational cause. For example, environmental agents may be the cause of chromosomal damage, endocrine abnormalities, or endometriosis.

Although there are large differences in fertility rates among different ethnic and racial groups, it appears most likely that these differences are based more on cultural and social factors than on biologic factors. There are lifestyle factors that impair fecundity and fertility. Tobacco use decreases the number of morphologically normal motile sperm in the ejaculate, impairs ovulation, tubal transport, and implantation, and reduces fecundity in both men and women.^{10,11} Alcohol and other substances that are abused may also impair fecundity or fertility. Two recent studies of the effect of moderate alcohol consumption demonstrated reduced fecundity in women, but not men.^{12,13} Caffeine consumption may be associated with reduced fecundity in non-smoking women.^{13,14} Starvation and very high levels of physical activity also reduce fecundity. The complexity of these exposures and other associated lifestyle factors complicates the characterization of causation.

Spontaneous abortion

The rate of spontaneous abortion in a population depends on the method of quantitation. About 10–15% of clinically recognized pregnancies are aborted, largely in the first trimester. Prospective studies using the specific and sensitive assays for human chorionic gonadotropin (hCG) for early pregnancy detection demonstrate that about 30–60% of implanted pregnancies end in spontaneous abortion.¹⁵ At present no accurate data exist on *preimplantation* pregnancy losses in natural pregnancies because there is no clinically available test for preimplantation pregnancy; however, a protein termed early pregnancy factor (EPF) shows promise as such a marker.¹⁶ Data are available from two prospective studies using daily measurements of EPF and hCG: in a study of natural pregnancies, 17% of EPF increases were not followed by hCG increases;¹⁶ in a study of in-vitro fertilizations, 31% of EPF rises were not followed by hCG rises,¹⁷ consistent with preimplantation loss. The significance of extremely early losses remains unclear, as does the range of factors that may influence their occurrence. Therefore, this discussion focuses on the factors that influence rates of clinically recognized spontaneous abortions.

Among the clinically recognized abortions, about half that come to pathologic evaluation are chromosomally abnormal, often remarkably so. This suggests that spontaneous abortion in these cases is biologically determined; the adverse health outcome is the fetal disorder, not its loss. There is little information on factors that determine the rate of these chromosomal abnormalities, nor is it known whether or not they are influenced by any of the factors that are associated with loss of apparently normal pregnancies.

The causes for loss in the first trimester of chromosomally normal fetuses are partially understood. There is a

strong age dependency, with spontaneous abortion more common in very young women (i.e., younger than 18 years of age) and older women, especially those older than 35 years of age, at which point the rate is about double; the effects of paternal age, if they do occur, are slight. Prior spontaneous abortion is a comparable risk factor, supporting the impression that some women miscarry repeatedly. Tobacco also is an important risk factor for early spontaneous abortion, with about a 50% increase seen in those women who smoke during pregnancy compared with those who quit before conception.^{18,19} The effect of moderate alcohol consumption is uncertain, with mixed results being generated from available studies once the effects of other known factors are accounted for.^{20,21} Similarly, nutritional factors, other than extreme malnourishment early in pregnancy, do not appear to be associated with an increased risk for early pregnancy loss, demonstrated by the rather good record of women with weight loss associated with hyperemesis gravidarum.

Late spontaneous abortion and fetal death

After the first trimester, spontaneous pregnancy losses are less common. In the second trimester, they are associated with anatomic problems of the mother, such as an incompetent cervix, severe disease of mother or fetus, or infection, such as urinary tract infection, cervical infection, or parvovirus, the cause of epidemic fifth disease in young children. An in-depth analysis of maternal diseases is beyond the scope of this text. Fetal disorders associated with fetal death in mid- and late pregnancy are discussed later in the section on fetal growth retardation. Brain injury, often occurring late in gestation as a complication of development (such as umbilical cord strangulation or compression), is another explicable cause of fetal death.

Fetal growth retardation

Fetal or intrauterine growth retardation refers to impaired growth of the fetus during development, which is measured by comparing the size of the fetus or infant to ethnic-appropriate, gender-specific data based on gestational age. A fetus or infant below the 10th percentile for age may be considered growth retarded. Accurate determination of gestational age is essential for the appropriate diagnosis of growth retardation.

Although growth retardation may be due to an underlying disease of the fetus itself, such as a genetic or chromosomal abnormality, or the presence of multiple fetuses, many cases represent established conditions including severe maternal malnutrition or illness; maternal use or abuse of tobacco, alcohol, or drugs; and exposure to teratogenic drugs or infections. The role of socioeconomic status beyond these specific factors is less clear, although a prior history of a pregnancy complicated by fetal growth retardation is a strong independent predictor.

Because of the difficulty in some cases in distinguishing fetal growth retardation from either genetically small size

(e.g., dwarfs, small parents) or prematurity, the precise incidence of fetal growth retardation is uncertain. Overall, about 1 in 16 live neonates in the United States weighs under 2500 g. Of these neonates, about 15–20% are believed to be term births with pure fetal growth retardation; the remainder are due to prematurity or a combination of prematurity and growth retardation.

Prematurity

Prematurity is defined as birth prior to 37 weeks' gestation; it is a clinical problem if the baby is small or significantly immature, especially in terms of lung development. Surprisingly little is known about the factors that precipitate premature delivery. Ascending urogenital infections are an important, largely preventable, cause of prematurity.²² Other causes include premature rupture of the membranes, or other maternal or fetal injury or disease. Among lifestyle factors, smoking is most clearly associated with prematurity. Prematurity also occurs more commonly among women of low socioeconomic status, those with less prenatal care, and those who drink alcohol, or abuse drugs during pregnancy. As with many reproductive outcomes, a history of a prior premature delivery is predictive of another.

Congenital malformations and chromosomal abnormalities

Depending on the length of observation and the precision of diagnosis, 3–5% of all live births are recognized as having either a congenital malformation or a chromosomal disorder, with an increasing number recognized after the first year of life. Although a very small fraction of these conditions can be traced to heritable genetic disease of the parents, the vast majority are acquired in the reproductive process itself and, hence, are subject to environmental effects (Table 27.2.2).

A chemical, physical, or biologic agent that causes a birth defect, gross chromosomal alteration, or functional deficit with expression at some point after birth is termed a teratogen or developmental toxicant. In general, established causes of birth defects are associated with particular syndromes, malformations, functional deficits, or patterns of developmental toxicity. This is most striking for the first well-characterized group of developmental toxicants, the infectious agents, which include rubella, syphilis, toxoplasmosis, and cytomegalovirus. Thyroid insufficiency in preg-

nancy or the use of antithyroid medications may result in cretinism. Other drugs also have been found to cause congenital malformations since the outbreak of phocomelia was recognized to be associated with use of the sedative thalidomide during the first trimester of pregnancy. Those drugs with established or suspected teratogenicity are listed in Table 27.2.3.

There are increasing data suggesting that at least some birth defects may be related to nutritional factors. Diets low in folic acid have been associated with neural tube defects, and supplementation with folic acid during the periconception period has been demonstrated to reduce the risk of these defects by about 50%.²³ To date, trials with folic acid and other vitamin supplements have not reduced the frequency of other common defects. Iodine is another essential nutrient for normal development, as evidenced by high rates of cretinism in areas with endemic goiter. Although nutritional supplementation may improve reproductive or developmental outcomes, excess exposure to some vitamins, notably vitamin A and its derivatives, is

Aminopterin
Androgens; testosterone
Aspirin; non-steroidal anti-inflammatory drugs†

Valproic acid
Vitamin A, isotretinoin, 13-cis-retinoic acid and etretinate
5-Fluorouracil

* Although this table lists drugs known or suspected to cause developmental toxicity, it is incomplete in several important ways: the adverse developmental effect is not defined; the risk for the adverse effect as a function of dose, duration of exposure, and timing of exposure with respect to pregnancy are not included; and the benefit of treatment of maternal, fetal, or pregnancy-related disease is not characterized. These and other factors need to be considered when counseling patients about the impact of these drugs on development. Adapted from references ^{24, 151}.

† Late third trimester use is associated with constriction of the ductus arteriosus. Use during the first and second trimesters is considered safe.

‡ Use during late pregnancy is associated with withdrawal syndromes in the neonate.

Combinations of estrogens and progestagens in oral contraceptive formulations have not been associated with increased risk of major malformations.

Table 27.2.3 Therapeutic drugs known or suspected to cause developmental toxicity*

associated with an increased risk for reproductive or developmental toxicity.²⁴ The importance (benefit and/or risk) of essential dietary minerals and overall protein and caloric intake has not been established.

Maternal disorders associated with an increased risk of congenital anomalies are diabetes mellitus, phenylketonuria, and hypothyroidism. Maternal age is also an important risk factor, especially for Down's syndrome and disorders of the CNS such as anencephaly and spina bifida. Alcoholism and substance abuse during pregnancy are associated with fetal developmental disorders that may be recognized as birth defects in extreme cases or as developmental disorders of childhood in more subtle presentations. At present, there are no compelling data to suggest that tobacco use is associated with birth defects.

Developmental delay and disability

A distressingly high proportion of children, perhaps up to 10%, experience some measurable delay in achievement of developmental milestones, as noted on routine well-baby checks or as determined by more specialized testing. These delays may be associated with evidence of structural neurologic damage, such as seizures, motor deficits, or systemic disorders, suggesting either metabolic or congenital disease. Most commonly, however, the delays are functional and are not easily classifiable into another disease category. When they are mild and compensated, the conditions are termed developmental delays. Persistent deficits are called developmental or learning disabilities.

When the losses are profound relative to age-specific standards, mental retardation is diagnosed. The cause of the vast majority of such cases is unknown. Clearly, children with prenatal disorders such as growth retardation and prematurity, exposure to known developmental toxicants, and traumas associated with labor and delivery that result in low Apgar scores are at higher risk. Intrauterine or postpartum infection may play a role in some cases. Because most of the normative standards for the developmental milestones are race and social class specific, poor and non-white children appear to have higher rates, but successes of early learning programs suggest these differences are likely artifactual. The roles of dietary and behavioral factors (i.e., nurture) remain speculative.

Childhood cancer

Acute leukemia occurs with an incidence of about 4 per 100,000 per year throughout the first 15 years of life. It occurs in very high frequency in children with Down's syndrome and other rare congenital disorders, including Fanconi's syndrome, Bloom's syndrome, and immunodeficiencies. Genetic factors are suggested by a high rate of concordance in identical twins early in life. Postpartum exposures to benzene, ionizing radiation, and other agents that injure the bone marrow also are established causes (see Chapter 30.3). Other causes, however, are not well defined; viral infections have been suggested but remain unproven.

Malignant brain tumors are slightly less common than leukemia after the first year of life. The causes of these tumors remain poorly understood. Other cancers of childhood are very rare, and little is known about causes other than genetic factors, which explain a high fraction of cases of Wilms' tumor of the kidney and retinoblastoma; both conditions may be transmitted by autosomal dominant suppressed genes with incomplete penetrance. The occurrence of cases with features of hereditary disease in the absence of positive family history suggests the occurrence of spontaneous mutation at the prezygotic phase, possibly due to environmental mutation.

PATHOPHYSIOLOGY: THE MECHANISTIC BASIS FOR REPRODUCTIVE AND DEVELOPMENTAL TOXICITY AND LABORATORY EVALUATION

The physiologic events that are responsible for normal reproductive and developmental events are summarized in Figure 27.2.1 and Table 27.2.1. A *reproductive toxicant* is a chemical, physical, or biologic agent that alters male or female fecundity or that affects couple-specific factors, resulting in an alteration in fertility. Such agents must act on the male, female, or couple at a stage that precedes clinically recognized pregnancy (Fig. 27.2.1). A *developmental toxicant* may act on male or female gametes before pregnancy, on the developing embryo/fetus during pregnancy, or on the developing infant/child after pregnancy.

Male fecundity

Three systems are required to function effectively to ensure normal male fecundity: (1) the hypothalamic-pituitary-gonadal (HPG) endocrine axis, (2) testicular spermatogenesis, and (3) the accessory gland and transport system of the genitalia. Each of these systems is potentially subject to injury by an environmental hazard, although far more is known about the potential vulnerability of the first two than the last one.

The endocrine axis includes the hypothalamic hormone, gonadotropin-releasing hormone (GnRH), the pituitary hormones, luteinizing hormone (LH), follicle-stimulating hormone (FSH), and testosterone, generated by the Leydig cells of the testes in response to LH. The system is controlled by a negative feedback loop. Testicular failure results in elevations of LH and FSH, whereas testosterone or other sex steroids, such as estrogens, or environmental agents that can mimic the effect of steroids on the pituitary can inappropriately turn off the production of these hormones, leading to decreased testosterone production.

Unlike the situation in females, the HPG axis in males functions more or less continuously, so that measurement of disruption usually can be determined by a small number of blood samples for these hormones. Measurement of LH concentrations and secretory patterns must be repeated

several times because the secretion of LH is pulsatile. Testosterone must be measured along with its binding hormone to determine free as well as total circulating hormone, because only the circulating hormone is active. Measurement of interfering steroids, such as estrogens and androgens (and xenobiotics, which are steroid agonists or antagonists), can be undertaken in urine and blood.

In general, the most important clinical effect of disruption of the HPG endocrine axis on male reproductive function is a reduction in male fecundity, either as a result of altered reproductive behavior, impaired sperm production or function, or both. Other manifestations may include testicular atrophy and feminization, but these problems are uncommon with environmental effects.

The second major component of the male reproductive tract required for normal fecundity is spermatogenesis, which occurs exclusively in the seminiferous tubules of the testes. In a cycle that takes about 70 days in humans, the primordial germ cells, called spermatogonia, mature to sperm under the obligate influences of testosterone and FSH. This maturation process requires both multiple mitoses, increasing the numbers of progenitor germ cells, and meiosis, producing the sperm with their haploid complement of chromosomes.

Interference with spermatogenesis can be detected in several ways. The most readily available method is semen analysis, with evaluation of the numbers, viability, morphology, and motility of sperm in an ejaculate studied immediately after production under defined conditions of abstinence (typically 48 hours). More precise information regarding lesions in spermatogenesis can be obtained by testicular biopsy, in which the stage of spermatogenesis affected may be identified. A variety of newer tests also have been developed, including in-vitro assays of sperm penetration of hamster eggs, and sperm attachment to and penetration of the zona pellucida, and the sperm chromatin structure assay (SCSA), which assesses the susceptibility of sperm chromatin to breakage.²⁵ The importance to male fecundity of defects noted on these tests remains unclear, although the tests are in use both experimentally and in the clinical evaluation of infertile couples.

Clinically, lesions in spermatogenesis may be expected to have an effect on male fecundity, although there is no requisite number of cells or other finding on analysis of semen that directly predicts fecundity; usually less than 20 million cells per mL is associated with a clinically recognized disturbance in fecundity (Fig. 27.2.2). Decreased percentages of motile and morphologically normal sperm are also associated with decreased male fecundity.²⁶ Although the natural history of injuries to spermatogenesis is agent and circumstance specific, serial studies of affected men have led to recognition that partial lesions or disruption in late meiotic stages are generally somewhat reversible after removal of the affected individual from exposure and passage of several full spermatogenic cycles (e.g., several 70-day periods), whereas destruction of spermatogonia or complete azoospermia often is irreversible.

It is also important to recognize that effects on spermatogenesis could have profound effects on the reproductive or

Figure 27.2.2: Relationship between sperm count and male fecundity. Data collected from human studies suggest that the sperm contribution to male fecundity is optimal at concentrations above 40 million/mL. When the sperm count falls below 20 million/mL, there is a rapid decline in male fecundity. Although the single parameter of sperm concentration in the ejaculate contributes to male fecundity, there are also other factors that play a role, including morphology and motility.^{26,149}

developmental processes beyond male fecundity. The selection of chromosomes for passage to the oocyte occurs during this process so that mutations, chromosomal aberrations, or some chromosomal selection process could occur during this period that could be expressed later, with effects ranging from spontaneous abortion to developmental defects, or even childhood cancer. There are no established examples of such effects in humans, but male-induced early pregnancy loss (spontaneous abortion) has been shown with mutagens like dibromochloropropane in mice.

The final component of the male reproductive tract is the storage and transport of sperm in the male genitalia. This system begins with the Sertoli cells in the testis, where spermatogenesis begins; destruction of the Sertoli cells results in irreversible loss of fecundity. The epididymis stores sperm for 2 to 3 weeks, during which time the sperm become functionally mature. The vas deferens, accessory glands, prostate, and seminal vesicles each add components to semen and assist in its proper and timely delivery. Although less well characterized than testicular lesions, injury or functional modification of these post-testicular organs would be expected to result in reduced fecundity. Toxic injury to these components of the male reproductive system may be evaluated by assessment of the composition of the seminal fluid, including pH, volume and the specific products of each gland.

As with the process of spermatogenesis, the final stages of storage and transport of seminal fluid create, at least theoretically, opportunities for male-mediated effects on reproduction beyond fecundity. Heavy metals and organic compounds have been measured in seminal fluid. These agents could have an impact on sperm DNA during sperm maturation. Alternatively, contamination of the ejaculate with environmental toxicants could have an impact on early

couple-specific factors, such as fertilization, or even affect the early zygote, resulting in disturbances of implantation or embryonic development. Further research is required to assess such effects and to date they have not been demonstrated in humans.

Female fecundity

As with males, female fecundity hinges on three systems: (1) the neuroendocrine gonadal axis, (2) oocyte development and release, and (3) the anatomic integrity of passages that allow sperm access to the oocyte and conceptus access to the uterus. Disorders of any component reduce female fecundity.

The human female neuroendocrine (hypothalamic-pituitary-ovary or HPO) axis is more complex than the male counterpart because of the added intricacy of temporal cycles. In order to facilitate the release of a mature oocyte (ovulation), LH and FSH concentrations must cycle, with suppression during menses, followed by a surge approximately 2 weeks later. Feedback by two ovarian hormones, estrogen and progesterone, produced by the supporting granulosa and thecal cells of the ovulatory follicle, are crucial to this orchestrated sequence. Also, the influence of hormones less consequential in males, such as prolactin, may sufficiently disturb this balance to disrupt the cycle. As in the male, LH, FSH, and sex steroid concentrations can be measured in the blood; however, in women, the concentrations must be assessed relative to the phase of the menstrual cycle in which the specimens were obtained.

Although the details of female reproductive physiology are beyond the scope of this text, the ramifications for evaluation of female fecundity can be summarized as follows. First, detection of a gross lesion in female fecundity is not difficult; anovulatory cycles may be recognized by the impact of hormones on the uterine endometrium, which is detectable by biopsy or by sequential hormonal analysis using repeated blood or urine specimens. On the other hand, localization of the lesions may be complex unless trophic hormones are persistently elevated, indicating ovarian failure. Another important ramification is the likelihood that many different types of toxicants, acting in diverse ways, would be predicted to upset normal function of this endocrine axis. In animals, a host of heavy metals and halogenated hydrocarbons are established causes of diminished female fecundity. In humans, only pharmacologic agents such as steroid hormones and antineoplastic drugs have been adequately studied, although other exposures, such as tobacco use, are known to impair female fecundity. Whatever the cause or locus of interference, females with abnormal neuroendocrine cycles have impaired fecundity; they also may have abnormal menses and disturbances in secondary sex characteristics.

The processes leading to the release of a mature oocyte prepared for fertilization also are complex. Unlike the male (who has an essentially unlimited supply of gametes), the female develops a finite set of oocytes in utero, supported by primordial follicles. At puberty, under the influence

of trophic stimulation, these follicles develop in small numbers, sequentially becoming antral or preovulatory. The time span from emergence of a follicle as preovulatory to actual ovulation is about 3 months. From this distinction, it becomes clear that agents that may injure primordial follicles, such as the drug cyclophosphamide or tobacco use, can shorten the female's reproductive life span (i.e., produce premature menopause), whereas agents that may affect preovulatory follicles may cause short-term infertility that may reverse when exposure ends.

The role of anatomic lesions in female fecundity is straightforward. Such lesions, either congenital (e.g., abnormal uterus) or acquired (e.g., postinfectious occlusion of fallopian tubes), prevent the sperm from fertilizing the oocyte. Generally, these lesions are identifiable with available imaging techniques and may be corrected surgically.

Conception and couple-specific factors

Up to one-third of all couples seeking consultation for infertility are found to have normal male and female fecundity; the problem may be attributable to couple-specific factors. The most common of these factors are behavioral, involving frequency, timing, and technique of intercourse and contraceptive use. Occupational stressors, such as shift work, overtime work, and factors affecting libido, may also be important.

Biologic factors may explain some portion of the couple-specific cases of infertility as well. An example is incompatibility of the seminal fluid with the female reproductive tract due to the presence of antibodies or some other spermicidal action. Techniques for detection of such conditions are highly specialized. At present, the role of occupational or environmental factors in such disorders has not been established.

Implantation and early gestation

Before even a single menstrual period has been missed, the conceptus enters the earliest stages of embryogenesis. The mechanisms that facilitate the cellular division, differentiation, cell migration, and programmed cell death during this period are only beginning to be understood; they are discussed together with fetal development in the next section. Unique to this very early stage is the need for continued support of the new embryo by the ovary, in its luteal phase postfertilization, and by the uterus, which must respond to hormone stimulation (for endometrial development and myometrial quiescence) to allow embryonic implantation. The conceptus itself, through production of hCG and other factors, shares biologic responsibility for the success of implantation and its survival in the earliest stages as well.

Because these events occur before recognition of pregnancy, little opportunity for study in humans has been available. Animal studies have elucidated the timing and endocrinologic aspects of the period immediately after conception, and recently the possible role of toxicants has begun to be studied. These studies demonstrate that

toxicant exposure during this window of development does not necessarily have an 'all or none' effect (death or no adverse effect), as previously assumed. They demonstrate that in addition to immediate death of the conceptus, exposures during this period can also cause a unique pattern of anatomical defects.²⁷ These results suggest that some previously unexplained human birth defects may be caused by exposures to toxicants or other stressors occurring prior to implantation. New techniques, such as the prospective monitoring of women with daily collections of urine, and sensitive and specific hormone assays, such as the newer assays for β -hCG, have also begun to shed light on the interval immediately after implantation in humans. For example, the longstanding prediction that a high proportion of embryos are lost during this period has proved to be true, perhaps as high as a half or more in some populations (see Table 27.2.1). It has also been learned that many women have normal pregnancies in the cycles immediately following such early losses, raising the question as to whether these are clinically important adverse reproductive outcomes.

Clinical pregnancy and fetal development

The remarkable sequence of events by which a single fertilized ovum develops into a well-differentiated fetus has been studied by embryologists for decades. Although the morphologic sequence has been clear for a long time, the cellular and molecular mechanisms that underlie the process are only just becoming clear, along with the myriad possibilities for disruption by endogenous and exogenous factors.

The major organ systems and anatomic structures are formed largely during the first trimester. Some landmark events and their approximate timing in human development are summarized in Table 27.2.4. A variety of biologic events appear to be crucial for normal development, including:

1. The presence of appropriate regulatory and structural genes.

Days from ovulation	Biologic event
1	Conception
5–7	Implantation begins
15	First missed menstrual period
18–19	Neural plate forms
20–21	First somite
23	Primordia of eye and ear
24–27	Neuropores close
27–30	Limb buds develop
29–32	Optic cup, lens form
33	Crown–rump length about 7 mm
37	Crown–rump length about 9 mm
38–42	Critical period for upper limb development
46–47	Cardiac chambers form
56–58	Palate closes
60–70	Fusion of urogenital folds, formation of external genitalia
84	Second trimester begins

Table 27.2.4 Early developmental milestones for the human fetus

2. Effective cell–cell communication via gap junctions and other surface molecules.
3. Appropriate exogenous stimuli by physiologic morphogens allowing specific cells to move, differentiate, and die based on their relative locations.
4. Adequate nutritional support allowing growth and survival.

It is obvious, therefore, that a wide range of possibilities exist for interference with development, and further, that the importance of these factors is time dependent. In other words, agents that may disrupt development at one stage may not have an impact earlier or later. Moreover, disruption of one of these vital elements may have very different clinical expressions depending on timing.

Although a detailed discussion of the mechanisms of developmental toxicity is beyond the scope of this text, some examples are illuminating. First, it is clear that major chromosomal anomalies, of whatever cause, could devastate the process of development if the genes that program the sequences of cell growth, differentiation, movement, and death are missing or abnormal. These problems would be expected to be lethal in a high proportion of cases, explaining why a high fraction of early spontaneous abortions are chromosomally abnormal. It also explains the multiple defects in those fetuses that survive, as well as the lethal or teratogenic effects of antimetabolites, such as antineoplastic drugs or other potent mutagens. Agents that interfere with regulatory genes, which determine the proper sequence for cellular events, also may be developmental toxicants. Transgenic experiments have proved the importance of these sequences, as well as the integrity of the genetic expression. Developmental toxicants, like vitamin A derivatives and the synthetic estrogen diethylstilbestrol (DES), act in part by altering normal regulatory gene expression or the effect of regulatory gene products.

Interference with cellular communication also may result in developmental toxicity. This problem may explain the action of certain teratogenic drugs, such as hydantoin and warfarin. Interestingly, in-vitro data suggest that certain environmental toxicants of interest, such as the ethylene glycol ethers, may disrupt cellular gap junctions.²⁸

Interference with physiologic signals for cell behavior is another mechanism for effects produced by occupational and environmental hazards. Important physiologic agents in this regard include retinoic acid and thyroid hormone, likely explaining the important effects of agonists or antagonists of these endogenous compounds.

Disruption of nutritional support also may explain developmental toxicity, as well as growth retardation, during later stages of development. The crucial need for sources of energy in all cells, as well as appropriate maintenance of tissue osmolarity and pH, may explain why certain inborn errors of carbohydrate metabolism are devastating, as well as why deprivation of B vitamins, such as folic acid or riboflavin, may be teratogenic.

After essential organogenesis is complete, largely during the first trimester, the possibilities for environmental factors to affect the gross structure of the fetus are reduced. At this stage, the fetus is subject to many influences,

requiring continuous delivery of nutrients by the placenta, and avoidance of toxicants that may cause systemic or specific organ system dysfunction. The central nervous system, which is continuing to develop and establish new cell–cell interactions (and will for many years postpartum), and the external genitalia, which are also continuing to develop during this period, are especially vulnerable to intoxication at this stage. Further, from this period through delivery, the fetus is dependent on preservation of its status in utero to allow the fullest maturation of its organs, such as the lungs and gastrointestinal tract, which would be vulnerable to the outside environment should premature delivery occur.

Sources of fetal susceptibility during the second and third trimesters include: (1) the placental supply of nutrients; (2) toxicants that may enter the fetus through the placenta, especially neurotoxicants; and (3) factors that may lead to prematurity. The first two susceptibility factors are reasonably well understood. The human placenta allows passage of a wide range of materials at rates determined by their molecular weights, lipid solubility, and other characteristics. These materials include drugs and chemicals to which women may be exposed during pregnancy. These may, on the one hand, interfere with delivery of necessary nutrients, as with asphyxiants or placental toxicants such as cadmium, or they may cause fetal toxicity directly, as with lead and organic mercury. It should also be noted that the fetus may be exposed by means other than the placental blood supply to certain hazards, especially physical hazards such as radiation, noise, heat, and injury, but the effects are comparable to transplacental sources of harm during this period.

The clinical effects of transplacental injury during the second and third trimesters may be varied and may not be apparent, either in utero or at birth. Unless a devastating insult occurs, such as fetal alcohol syndrome, the outcomes include growth retardation and developmental disruptions. Although evidence of transplacental exposure can be documented via cord blood analysis if the exposure is persistent or ongoing, such analysis is not recommended for routine clinical purposes. The placenta and body fluids of the newborn are other areas where such exposure could be confirmed, if desired.

Childbirth

A variety of adverse events may occur at or near the time of delivery, including stillbirth, fetal injury, or perinatal death. As noted, the most common reasons for these complications are pre-existing disease in the mother or the fetus or an obstetric catastrophe, as occurs with placental anomalies, multiple fetuses, gross prematurity, and cord strangulation. Rarely, extrinsic events or hazards such as overwhelming injury to the mother or near-lethal intoxication may be implicated.

Postnatal development

After birth, the infant is directly vulnerable to environmental exposures, such as inhalation or ingestion of

contaminants brought home by the parents; ingestion of household poisons, such as lead or mercury in paints; and exposure to indoor and outdoor pollutants. As discussed in Chapter 10, the newborn and infant may have both unique exposures and sensitivity to some of these agents. The present discussion is limited to effects that result from the reproductive process itself, i.e., exposures that have occurred in utero or before conception. One unique and important source of postpartum exposure and risk that is related to reproduction, ingestion of breast milk during lactation, is discussed subsequently.

It has been noted that many effects of hazardous exposures during reproduction or development may not be recognized until after birth. For most cases, this is because the effect is sufficiently subtle or preclinical that it was not noticed at birth. In contrast, the manifestation of abnormal neurologic development and the occurrence of childhood cancer may require additional biologic events after birth. Each of these conditions has become the subject of serious inquiry.

The possibility that exposures during pregnancy could have an impact on development of the CNS long after birth is suggested by two factors. First, many CNS toxicants are long lived in the body; hence, they are likely to persist after prenatal exposures. Second, unlike other major organs that mature largely before birth, the CNS continues active development over a period of years. Although little is known about how agents may disrupt this process at the cellular level (as opposed to causing cell injury), or even whether the effects that emerge after birth represent a true *de novo* injury or merely inadequate repair of prior effects, at least two important agents, lead and polychlorinated biphenyls (PCBs), have been demonstrated to result in ongoing dysfunction in humans, measurable at 5–10 years of age. Unfortunately, there is no way to distinguish these causes of impairment from the myriad other causes for learning deficits unless other indications of poisoning by the same agents are apparent.

The fact that prenatal environmental factors could be causes of childhood or early adulthood cancer was recognized two decades ago, when females exposed in utero to DES had an increased risk of vaginal adenocarcinoma. Knowledge of the mechanisms of carcinogenesis has further enhanced interest, because two cancers of childhood, Wilms' tumor of the kidney and retinoblastoma, are often associated with the presence of a mutation of tumor suppressor genes. The possible mechanisms for reproductively or developmentally mediated carcinogenesis include:

1. Mutations of male or female gametes due to preconception exposures.
2. Somatic mutation occurring shortly after fertilization due to male or female parental exposures.
3. Transplacental or direct in utero exposure to mutagens or carcinogens from maternal exposure.
4. Transplacental injury to target tissue, changing its postpartum susceptibility to transformation.

While the fourth mechanism has been associated with an established human environmental exemplar, namely DES,

epidemiologic studies implicating parental exposures suggest that the other mechanisms may also be relevant.

Lactation

Breast feeding has been extolled in both developed and developing countries as the most healthful way to nourish newborns and infants. Unfortunately, breast milk also may be a source of harmful substances to which the mother has been exposed before, during, and after pregnancy.

Knowledge of the physiology of lactation allows some reasonable prediction of what types of materials will be concentrated in milk. Factors that enhance concentration include low molecular weight, high pK (i.e., basic), low polarity (i.e., neutral), and fat solubility. The most significant predictor of a substance's milk content is the maternal blood or fat level of the substance, but for a given toxicant, milk may have as little as 1% or as much as 100-fold the level in the mother's plasma.

The most significant concerns regarding environmental exposures from breast milk have been heavy metals, halogenated solvents, pesticides, PCBs and dioxin (Table 27.2.5).²⁹⁻³¹ Not only are these materials highly concentrated in milk, as would be predicted, they also are long lived in maternal tissues and potentially very toxic.

Studies of large populations (Table 27.2.5) have not suggested that typical levels in milk approach those known to be associated with harm from these agents, even in the very vulnerable newborn age group, who have no other source of nutrition. Obviously, this is not the case in areas where there is significant past, ongoing, or other excessive maternal exposure or endemic contamination. In such cases, the level of the potential toxicant and ongoing exposure to the mother can be quantified, ideally before neona-

tal exposure occurs. If necessary, levels in the mother's milk itself can be measured, although these measurements are expensive and not widely available. Once exposure through milk has occurred, the most important information, i.e., the dose transmitted to the infant, can be obtained by sampling the baby's blood or other relevant tissue.

DATABASES FOR EVALUATING ENVIRONMENTAL AND OCCUPATIONAL REPRODUCTIVE AND DEVELOPMENTAL HAZARDS

In order to develop rational occupational health policies to reduce reproductive and developmental toxicity, information on effects in animals and human responses to exposure is essential. Unfortunately, there are substantial gaps in these important data.

Human epidemiology and clinical studies

Despite the fact that adverse reproductive events are extremely frequent in the population (see Table 27.2.1), the study of the effects of occupational and environmental factors has been very difficult. At the most conspicuous level, vital records of the kind that have been crucial for the study of mortality and cancer are not well maintained; early reproductive failures such as infertility and spontaneous abortions are not documented in any consistent fashion, nor are they even recognized with any uniformity. Later and less common adverse outcomes are documented but are rarely systematically available for analysis, although some birth defect registries have recently been developed to facilitate research. In the meantime, studies of events such as fetal deaths, growth retardation, and birth defects are difficult to perform, because the numbers of such events in any defined exposed population are small; case-control studies are hampered by a lack of knowledge of exposures within the larger population to all but the most conspicuous hazards, such as physical stressors.

Even if the events could be easily and consistently identified and verified, establishing exposure status is a formidable barrier. Not only the nature of exposure but its timing are crucial in classifying risk for any given outcome of interest. Further, for practical reasons, most studies have been retrospective, relying on recall of past exposures and confounding risk factors, with the potential for recall bias. Combined with the very sensitive nature of the information being gathered, it is not surprising that the performance of such studies has been limited.

In order to circumvent some of these difficulties, more recent epidemiologic studies have sought subtler endpoints that might be more readily discernible in exposed populations, with use of biomarkers of exposed effect. The best established and most straightforward methods are semen analysis and serum hormone measurements. More recent studies have prospectively collected daily urine samples

Compound	Per cent quantifiable‡	Range of means reported (ppm milk fat)
All DDT	70–100	
p,p'-DDT		0.2–4.3
p,p'-DDE		1.2–14.7
Dieldrin	0.04–100	0.05–0.24
Lindane and isomers	4–68	
γ-HCH		0.008–0.08
α-HCH		0.003–0.02
β-HCH		0.27–0.53
HCB		0.04
Heptachlor and heptachlor epoxide	25–100	0.035–0.13
Oxychlordane and chlordane	46–100	0.05–0.12
PCBs	20–100	0.8–1.5

* These data represent pesticide concentrations in breast milk that have been gathered by a range of analytic approaches over a period of 4 decades.

‡ The per cent of samples in which quantifiable levels of the indicated pesticide were observable. Note that these percentages are likely to vary with the analytical method used.

DDE = 1,1-Dichloro-2,2-bis (p = chlorophenyl ethylene); HCB = hexachlorobenzene; HCH = hexachlorocyclohexane; PCB = polychlorinated biphenyls.

Table 27.2.5 Breast milk pesticide concentrations reported in the United States*

from cohorts of women exposed to various hazards, for analysis of preclinical spontaneous abortions and menstrual cycle abnormalities. Endpoints for human epidemiologic studies that are currently considered relevant for assessing reproductive and developmental effects are summarized in Table 27.2.6, along with some endpoints that are being evaluated in more recent studies.

Application to clinical practice of the existing limited body of epidemiologic data should be carried out cautiously. Although relevance to humans is obviously not an issue, quality, in terms of classification of exposure, control of confounding bias, and occurrence of biases are important. Further, the direct relationship between the populations studied and the individual or group for whom the data are applied must also be considered before the results are interpreted by the practitioner.

Experimental studies in animals

As with other effects of environmental hazards, animal studies form a major portion of our knowledge base about which

agents may be harmful to humans, at what doses, and by what mechanisms. Because of the difficulty of studying reproductive and developmental hazards in humans, animal experiments are crucial to our ability to predict effects.³²

Unfortunately, there are serious limitations to animal experimentation in this arena as well. The most important issues are the following.

1. The timing of exposure relative to the timing of vulnerable reproductive or developmental processes is extremely important (see Table 27.2.4). Large doses of a toxicant could be harmless if delivered before or after a crucial event, like the formation of a body part or organ, whereas very small doses could be devastating if delivered at a crucial moment. For this reason, no single experiment can, in and of itself, exclude the possibility of a harmful effect for many agents that are short-lived in the body. Reproductive and developmental effects are likely to differ, depending on the timing of the exposure.

2. The central concept of a progressive, continuous dose–response relationship, which underlies all of toxicology (see Chapter 5), does not apply directly or simply to many situations in reproductive and developmental toxicology. Not only does timing alter responsiveness but the interactions between the parent and offspring also may alter dose–response relations. For example, at a very high dose, the primary effect of a toxicant may be maternal harm, with possible fetal death. At a lower dose, sublethal but possibly more relevant effects, such as teratogenesis, may be seen; further, only at doses below those that directly impair development of the fetus might effects such as mutagenesis or carcinogenesis become evident. Thus, interpretation of animal studies requires evaluation of different dose ranges, which cause different effects at different points in time.

3. Extrapolation from various animal species to humans presents challenges. In addition to the differences between species that affect all studies in toxicology (e.g., absorption, distribution, metabolism, elimination), reproductive patterns differ among the mammalian species; only primates simulate the human pattern very closely. For this reason, many relevant endpoints in animals, such as fetal resorptions, have no clear human counterpart, and many phases of human reproduction, such as menstrual cycle length, have no obvious animal analog in the species most available for study. Extrapolation of effects from one species to another, therefore, has limitations, despite being crucial for predicting human responses and protecting public health. A comparison between human and animal responses to pharmacologic agents (for which there are far better human data than for environmental agents) is instructive.³² A total of 203 drugs were evaluated, of which 38 were known to cause birth defects or other developmental disturbances in humans, whereas 165 were deemed safe. Of the 38 harmful drugs, 37 had been proved to have positive responses in some experimental model. On the other hand, 118 of the 165 safe drugs also had positive responses in some animal experiments. The high negative predictive value of animal tests is demonstrated by the fact that of 48 negative results in animals all but one proved

Endpoints that are evidence of a human hazard

Couple specific

- Infertility: absence of pregnancies
- Subfertility: increased time to pregnancy or decreased standardized fertility ratio (lower birth rate)

Female specific

- Decreased reproductive life span: delay in puberty or premature menopause
- Menstrual dysfunction: anovulatory cycles or dysfunctional cycles
- Abnormal reproductive hormone concentrations

Male specific

- Abnormal semen analysis: decreased sperm count or abnormal sperm viability or morphology
- Abnormal reproductive hormone concentrations

Fetal/developmental

- Increased spontaneous abortion rate (clinical or preclinical pregnancies)
- Increased rate of fetal death
- Prematurity/growth retardation: smaller live births
- Increase in rate of birth defects or congenital anomalies
- Decreased age-specific function of offspring, e.g., childhood neuropsychologic performance
- Increased rate of childhood disease, e.g., cancer

Endpoints suggestive of human hazard

Couple specific

- Decreased coital frequency
- Increase in antisperm antibodies
- Abnormal postcoital test for sperm motility

Female specific

- Decreased libido
- Abnormal menstrual cycle lengths
- Changes in reproductive hormone levels within the normal ranges

Male specific

- Decreased libido
- Minor changes in sperm morphology or viability
- Decrease in sperm function on in vitro tests
- Changes in reproductive hormone levels within the normal ranges

Fetal/developmental

- Increased rate of disorders of pregnancy, e.g., pre-eclampsia

Table 27.2.6 Endpoints of human epidemiologic studies that support or suggest evidence of a reproductive or developmental toxicant

safe. On the other hand, the tests have limited positive predictive value; of 155 drugs that tested positive, only 37 were truly teratogenic for humans.

This is not to imply that animals are uniformly, or even consistently, more sensitive to reproductive hazards than humans. For example, mice and rats proved very insensitive to the notorious drug thalidomide, although rabbits are sensitive to the agent. Conversely, the widely distributed polycyclic aromatic hydrocarbons are potent ovarian toxicants in many species, but humans appear relatively insensitive by comparison. Because of such interspecies and interindividual variability in sensitivity to toxicants, risk assessors often apply 'uncertainty factors' or 'safety factors' when extrapolating from animal data to humans. Frequently, two factors of 10 are applied, one to account for interindividual variability and the other for inter-species variability. For example, if the dose level at which no reproductive toxicity occurs in animals (no observed adverse effect level, NOAEL) for a compound is 5 mg/kg, the estimated human NOAEL for reproductive toxicity might be interpreted as 0.05 mg/kg. If animal studies do not provide a dose level at which no effects occur, an additional uncertainty factor of 10 is often applied to the lowest dose level studied (lowest observed adverse effect level, LOAEL).

4. Perhaps the most serious limitation of toxicology for the practitioner remains the dearth of testing altogether. Analyses performed for the State of California in its attempt to develop a prospective control policy for reproductive and developmental toxicants ('Proposition 65') revealed that only a small fraction of even the highest volume chemicals and other environmental pollutants had undergone sufficient toxicologic study to allow inference to human risk;^{33,34} similar observations have more recently been made by the US Environmental Protection Agency's Endocrine Disrupters Screening and Testing Advisory Committee.³⁵

Despite these problems, data from animal experiments remain central to the practitioner's task of clinical evaluation and prevention because they form the bulk of the available information. Because most practitioners have little experience in the design and conduct of such experiments, two issues should guide judgment when these elements are reviewed in relation to a particular case or problem. First, the study should be of reasonable design. Doses large enough to demonstrate an effect, as well as doses comparable to those humans could receive, should have been delivered at times that make sense relative to the endpoints evaluated, and the study's statistical power should be sufficient to reasonably exclude chance as an explanation for results. For developmental effects, greater weight should be given to studies in which the developmental endpoints are affected selectively.

Equally important in the interpretation of experimental animal data for evaluation of human risk is the particular endpoint chosen. As noted earlier, many consequences that may occur in animals have no obvious counterpart in humans, or none that can be easily interpreted. Table 27.2.7 lists those endpoints in animal studies that are

Endpoints considered to have predictive value for identifying human reproductive and developmental toxicants

Breeding studies

- Reduced mating indices (proportion of males or females exposed who mated)
- Reduced fertility indices (proportion of males or females exposed who succeeded in producing pregnancy or becoming pregnant)
- Reduced gestation index (proportion of pregnant females producing live offspring)
- Lower number of implantations
- Higher number of preimplantation and postimplantation losses
- Lower litter size at birth
- Reduced live birth index (proportion of all fetuses born live)
- Reduced survival indices (proportion live at one point in time after birth compared with an earlier time after birth)
- Decreased reproductive capacity of offspring (rebred for a second generation)
- Increased malformations or disease in offspring (see fetal studies, later)

Male studies

- Azoospermia
- Oligospermia
- Disruption of sperm motility or morphology

Female studies

- Estrous cycle disruption
- Decreased numbers of ovarian follicles or oocytes
- Decreased reproductive period (delay in puberty, early menopause)
- Uterine disruption histologically

Fetal studies

- Fetal deaths
- Fetal malformations

Endpoints suggestive of possible human reproductive or developmental toxicants

Breeding studies

- Decreased weight of offspring

Male/female studies

- Histologic change in gonads without germ cell loss
- Decreased gonadal, uterine or accessory organ weight
- Altered endocrine function

Fetal studies

- Growth retardation
- Developmental variations
- Functional deficits

Table 27.2.7 Endpoints of animal experiments with predictive value for human reproductive and developmental toxicity

considered highly predictive and those that are considered potentially predictive of human reproductive or developmental effects. These endpoints are listed according to whether they are detected in breeding studies (in which the male, female or both have been exposed), female exposure and female endpoints, or male exposure and male endpoint studies. Although there may be some specificity of the outcome of these studies for particular human effects, the reader is cautioned to remember that agents with reproductive or developmental toxicity may have different effects in humans than in animals and may, in fact, have more than one effect depending on dose and timing of exposure.

Other tools

Because the combined data from human and animal reproductive and developmental toxicity studies are so limited, the practitioner often must consider other forms

of information in clinical decision making. In general, these sources involve drawing inferences about hazards for which there is some non-reproductive animal or in-vitro data suggesting a mechanism of action that may be relevant to a reproductive or developmental endpoint. For example, in-vitro data may suggest that a compound is highly mutagenic, which would make it a suspect reproductive or developmental hazard by inference. Similarly, a new compound with affinity to steroid receptors, either before or after metabolism, would merit suspicion even prior to any reproductive or developmental toxicity testing. Recognition of the usefulness of in-vitro data for screening large numbers of compounds for their potential to disrupt endocrine and reproductive function recently led the Endocrine Disrupters Screening and Testing Advisory Committee to recommend a battery of screening tests that include in-vitro assays of receptor binding, gene expression, and steroidogenesis.³⁵ Generic knowledge about the chemistry of a possible hazard, such as knowledge that it is highly fat soluble and of low molecular weight, hence highly likely to be transmitted to an infant in breast milk, also could be of interest.

CLASSIFICATION OF HUMAN DISORDERS OF REPRODUCTION AND DEVELOPMENT

The following sections discuss the established and suspected occupational and environmental causes of the major disturbances of reproduction and development. For each disorder, male and female exposure risks associated with the outcome are discussed separately. Also for each disorder, emphasis is placed on the timing and dose of exposure of the parent relative to that outcome, to the extent that it is known.

Infertility and subfertility

Male exposures

Several chemical and physical factors in widespread use have been determined to decrease male fecundity in humans through occupational or environmental exposure. These factors are summarized in Table 27.2.8.

Although the potential for radiation injury and medicinal use of drugs to cause reduced fecundity had been appreciated for years, the occurrence of epidemic infertility among men manufacturing DBCP in California in the early 1970s demonstrated that male reproductive effects might be the only manifestation of a workplace hazard. Although other clinical effects from the hazards listed in Table 27.2.8 may coexist with fertility loss, each agent has the potential to impair fecundity with no other overt evidence of toxicity.

Review of Table 27.2.8 also demonstrates that the exposures that have been demonstrated to impair male fecundity are relatively high levels associated with manufacturing or occupational use of the chemical. Low-dose exposures that may occur from environmental contact

Hazard	Setting of established risk
<i>Metals</i>	
Lead	Occupational uses
<i>Pesticides</i>	
DBCP	Chemical manufacture and pesticide application
EDB	Chemical manufacture
Chlordecone	Chemical manufacture
<i>Solvents</i>	
Ethylene glycol ethers	Occupational uses
Carbon disulfide	Occupational uses
2-bromopropane	Electronics industry
<i>Pharmaceuticals</i>	
Estrogens	Drug manufacture
<i>Physical agents</i>	
Ionizing radiation	Occupational accidents
Heat	Occupational exposures

DBCP = Dibromochloropropane; EDB = Ethylenedibromide.

Table 27.2.8 Hazards that have been determined to reduce human male fecundity

through food or water have not generally been shown to be significant. A report of declining sperm counts over the past half century in humans, which was later hypothesized to be caused by exposure to estrogenic pollutants at levels present in the general environment, has raised the possibility of more widespread effects of toxicants on male fecundity.^{3,36} The study was criticized for its statistical methods and the fact that it combined sperm count data obtained in different laboratories using different methodologies.^{6,37} More recent studies have demonstrated declining sperm counts in some parts of the world, but not others (reviewed by Daston et al.⁹), suggesting that environmental factors likely do affect sperm counts, but that there is not one overriding environmental factor affecting them worldwide.

Mechanisms for injury by each of the various hazards are incompletely known in general, and likely differ, but in each case, they are associated with a reduction in the numbers or quality, or both, of sperm produced. Lead appears to have effects on both the HPG endocrine axis and directly on the germinal epithelium of the testis.³⁸ DBCP and the structurally related solvent, 2-bromopropane, are directly toxic to spermatogonia, with secondary increases in the levels of the trophic hormones.³⁹⁻⁴² Complete destruction of the spermatogonia would be expected to result in irreversible azoospermia, and this has indeed been observed in the most severely intoxicated DBCP workers. Glycol ether solvents,^{43,44} in contrast, appear to affect the more mature spermatids, and therefore the effects are reversible after exposure cessation. Heat⁴⁵ and ionizing radiation^{46,47} also appear to have effects limited to spermatogenesis, with well-preserved HPG endocrine axis function. Exposure to estrogens in oral contraceptive manufacture⁴⁸ suppresses the HPG axis, resulting in suppression of gonadal function in male workers. Ethylene dibromide appears to affect semen quality in men primarily by actions downstream from the testis, in the accessory sex glands.^{49,50}

The widely used aromatic solvents have received much attention as possible reproductive toxicants.⁵¹ Two

epidemiological studies suggest that the solvent toluene may act on the HPG axis in exposed workers to suppress LH and FSH secretion, with secondary testosterone suppression.^{52,53} Acute controlled exposures to toluene had minimal effects on LH mean levels and no effect on FSH, suggesting that the occupational effects are related to chronic exposure.⁵⁴ The effects on the HPG axis observed in these studies were within the normal ranges, so perhaps it is not surprising that time-to-pregnancy in toluene-exposed workers did not differ from that of unexposed workers.⁵⁵ Occupational exposure to another aromatic solvent, styrene, also did not affect fecundity in workers in the reinforced plastics industry.⁵⁶

Although the number of agents with well-characterized effects on male fecundity is small, there are several important hazards that are suspected to affect spermatogenesis based on animal experiments and some human reports. Important agents include organophosphate insecticides,^{57,58} metals (boron, cadmium, mercury, chromium), anesthetic agents (nitrous oxide, halothane), the solvent n-hexane,⁵⁹ ethylene oxide,⁶⁰ chloroprene, and epichlorhydrin. Of note, a recent study found no effects of occupational metal exposure in the form of welding on male fecundity.⁶¹ Based on animal studies, postspermatogenic effects on the excurrent ducts appear to be involved in the mechanisms by which agents like ethane dimethanesulfonate,⁶² alpha-chlorohydrin, epichlorohydrin, methyl chloride, sulfasalazines, and the imidazoles interfere with male fecundity.⁶³ Many pharmacologic agents, such as adrenergic and cholinergic antagonists, interfere with the transport function of the male urogenital tract and, thus, have an indirect impact on fecundity.

Much recent work has focused on the effects of in-utero exposure to toxicants on the development of the reproductive system and subsequent reproductive function during adulthood. DES is currently the only agent proved to adversely affect human reproductive system development with in-utero exposure. However, animal studies demonstrate adverse effects of in-utero exposure to a variety of chemicals on male reproductive system development and adult function at lower doses than are toxic to the adult male. These include phthalate ester plasticizers,⁶⁴ dioxins,⁶⁵ the fungicide vinclozolin,⁶⁶ p,p'-DDE, a metabolite of the insecticide DDT,⁶⁶ and the insecticide methoxychlor.⁶⁷ Several of these compounds act as antiandrogens (p,p'-DDE, vinclozolin, phthalates), exerting significant adverse effects on accessory sex gland development.

Female exposure

Historically, the female reproductive system has been more difficult than the male reproductive system to investigate in humans because there is no counterpart single assay to semen analysis that can be obtained non-invasively. During the last 10 years, this imbalance has begun to be remedied through the use of new epidemiological techniques such as studies of time-to-pregnancy. Using this methodology, dental hygienists exposed to nitrous oxide were found to have a dose-related decrement in fecundity.⁶⁸ Since that study, nitrous oxide exposure and shift

Hazard	Setting of established risk
Solvents	
Toluene	Occupational uses
2-bromopropane	Electronics industry
Nitrous oxide	Hospital work
Antineoplastic drugs	Therapeutic uses
Physical agents	
Ionizing radiation	Occupational accidents
	Therapeutic uses
Shift work	Occupational exposures

Table 27.2.9 Hazards associated with reduced human female fecundity

work in midwives,⁶⁹ and exposure to formaldehyde,⁷⁰ toluene,⁵⁵ and high occupational energy expenditure (physical activity) combined with night work⁷¹ were also associated with reduced fecundity in women. In contrast, exposures to antineoplastic drugs and anesthetic gases⁷¹ were not found to reduce fecundity in hospital workers. Agents which have been associated with reduced female fecundity are summarized in Table 27.2.9.

In 1996, Korean researchers reported female reproductive dysfunction (amenorrhea, low estradiol and high FSH and LH levels) in electronics workers exposed to 2-bromopropane (2-BP), a solvent structurally related to DBCP, that had been introduced to replace ozone-depleting chlorofluorocarbons.⁴² Subsequently, 2-BP was shown to reduce estrous cycling and fertility in rats.⁷² In experimental animals, including primates, lead suppresses fecundity, probably by a combined effect on HPO axis endocrine function and direct ovarian or oocyte toxicity. However, this process has never been demonstrated in a human population. Similarly, animal data have suggested that ionizing radiation in high doses destroys primordial oocytes. Although premature menopause has been documented in women receiving therapeutic doses (i.e., >2.5 Gy), few studies have been conducted to explore the effect.⁴⁷

The reproductive effects of many members of the large class of organochlorine chemicals have been extensively studied. PCBs and estrogenic organochlorine compounds appear capable of disrupting female fecundity based on endocrine effects on the timing of HPO axis hormonal function, but infertility, per se, has not been documented among women who have been exposed. Taiwanese and Japanese women who consumed cooking oil contaminated with PCBs and furans have more menstrual abnormalities, but not higher rates of infertility, than control women.⁷³ A recent large retrospective study of women exposed to PCBs, heavy metals, and other contaminants by consuming Great Lakes fish, found no effect on fecundity.⁷⁴ Limited data have linked exposure to dioxins in monkeys and in a nude-mouse model to endometriosis, a disease frequently associated with infertility in women.^{75,76}

As in males, animal studies have demonstrated effects of in-utero exposures to toxicants on reproductive system function in adulthood in females as well. Gestational exposure to the insecticide methoxychlor⁶⁷ and to dioxin⁷⁷ are the most well-studied examples.

Spontaneous abortions

Female exposures

Despite the methodologic problems in studying spontaneous abortions (SAB), a variety of hazards and occupations have been associated with an increased risk for this complication in human populations. Although there remain uncertainties, the associations that are presently accepted as most likely to cause SAB are summarized in Table 27.2.10.

Healthcare workers have been extensively studied, and increase SAB risk has been associated with exposure to antineoplastic agents,⁷⁸ anesthetic gases, and ethylene oxide. Although the preponderance of evidence supports these associations, not all studies have yielded consistent results. One interpretation is that only high levels of exposure enhance the risk for SAB, with lesser exposures showing no effects. Ethylene oxide studies support this interpretation. Women who were engaged in sterilizing instruments using ethylene oxide during pregnancy had elevated risks of SAB in two studies,^{79,80} whereas women who handled instruments after sterilization did not.⁸¹ Similarly, exposure to anesthetic gases was significantly associated with SAB in older studies performed prior to use of scavenging equipment of waste gas, but not in more recent studies performed after the introduction of scavenging equipment. A recent study directly compared SAB risks in dental assistants exposed to the anesthetic gas nitrous oxide in the presence or absence of scavenging systems. Women in the unscavenged group had elevated risk, whereas the risk for the women in the scavenged group was not distinguishable from the unexposed women.⁸² It is also possible that other exposures of these women, such as the physical and other stresses of their jobs, also may account for some differences among studies.

The data for metals are surprisingly limited given their ubiquitous nature in the workplace and environment. Many older descriptive studies documented that women exposed to lead at work experienced SABs frequently,

but classification of exposures was limited and confounded by other lead effects that were difficult to evaluate; studies of environmentally exposed women have not been impressive regarding the risk for spontaneous abortion. The findings regarding mercury, a reproductive toxicant in animals, have not been consistent. The study described above, that identified waste nitrous oxide as a cause of increased spontaneous abortion, did not find an elevated risk for mercury exposure in dental assistants.⁸²

Extensive epidemiologic literature exists on solvents, with the weight of the evidence suggesting that occupational solvent exposure in general is associated with increased risk of spontaneous abortion.^{83,84} Identifying which specific solvents or classes of solvents are the culprits has proven more difficult, with the possible exception of the ethylene glycol ethers, which are potent reproductive toxicants in animals, and the aromatic solvents toluene and benzene. Multiple studies of the semiconductor industry have all found excesses of spontaneous abortions among women exposed to ethylene glycol ethers in computer chip production.⁸⁵⁻⁸⁸ However, these data must be interpreted cautiously because the solvent exposures in this setting are generally low and the environment is replete with other physical and chemical hazards that may confound the association of up to a doubled risk for first trimester spontaneous abortion. Studies of laboratory workers,⁸⁹ electronics workers,⁹⁰ and petrochemical workers⁹¹ have implicated aromatic solvents as potential causes of SAB. The solvent perchloroethylene has also been associated with increased risk of SAB in a study of dry-cleaning workers.⁹²

The associations between spontaneous fetal loss and both PCBs and pesticides are based on studies of women who have been very heavily exposed. Increased spontaneous abortion was one of the outcomes noted among women poisoned by PCBs in the infamous rice-oil contamination episodes in Japan and Taiwan (see Chapters 44 and 45). Fetal loss after pesticide poisoning has been widely described in case reports, but usually after the mother herself is poisoned. There are few human studies that incriminate either occupational or ambient environmental levels of exposures in humans for this endpoint, although many widely used compounds are suspected based on animal effects. A recent study in Turkey found that the rate of self-reported SAB increased with increasing serum levels of the fungicide hexachlorobenzene in women who had been intoxicated with the pesticide during the 1950s and in control women.⁹³ A relationship between occupational exposure to pesticides and SAB is also suggested by a recent case-control study which found that women who worked in agriculture or lived on farms were at increased risk for infertility.⁹⁴

The data on physical activity are extensive and controversial. The evidence is strongest for shiftwork (night shifts or rotating shifts), which was associated with elevated risk of SAB in six of nine studies.⁹⁵ Some, but not all, studies have shown that heavy lifting, standing 8 or more hours per day, and physically heavy work increased the risk for spontaneous abortion.⁹⁶ In contrast, many studies of leisure time exercise did not find an increase in SAB rate,

Hazard	Setting of established risk
Medical hazards	
Antineoplastic drugs	Oncology nurses
Anesthetic gases	Operating room personnel
Nitrous oxide	Dental assistants
Ethylene oxide	Sterilizer operators
Metals	
Lead	Occupational uses
Solvents	
Ethylene glycol ethers	Semiconductor manufacture
Aromatic solvents	Occupational use
Mixed organic solvents	Occupational use
Other chemicals	
PCBs	Heavy food contamination
Pesticides	Accidental poisoning
Physical agents	
Heavy labor	
Shift work	

Table 27.2.10 Hazards associated with increased risk for spontaneous abortion or fetal death after female exposure

and some even found protective effects.⁹⁶ This apparent contradiction may be explained by various factors, including the much longer duration of occupational exposures compared to leisure exposures, and differences in the fitness levels and socioeconomic status of the women in the two kinds of studies. Few data exist on exposure to noise, vibration, heat, and cold and rates of SAB.

Several widespread physical factors are less likely to be important causes of spontaneous abortion at typical exposures found in occupational or environmental settings, including background ionizing radiation, non-ionizing radiation, and the use of video display terminals. While high doses of radiation during the first 8 weeks of pregnancy, as experienced by victims of the atomic bomb blast in Japan, clearly cause SAB, lower occupational and environmental doses do not.⁹⁷ Non-ionizing, electromagnetic radiation from occupational exposure to video display terminals^{98,99} and magnetic resonance imaging machines,⁷ and residence in houses with high current configurations (wire codes)¹⁰⁰ have not been found to increase risk of SAB. A few exposures, such as use of electric blankets during the first trimester of pregnancy and occupational exposure to microwave radiation, have been associated with increased SAB risk,^{100,101} and reproductive effects of non-ionizing radiation remain under intensive investigation.

Psychological stress has received increasing attention as a cause of adverse pregnancy outcomes. In the only study to look at the effect of stress on spontaneous abortion rates, major negative life events were associated with increased risk of chromosomally normal SABs compared to chromosomally abnormal SABs.¹⁰²

Male exposures

As noted earlier, there are some theoretical ways in which male exposure could enhance risk for spontaneous abortion. It is important to note that animal studies have demonstrated these effects, predominantly for those chemicals that produce mutations or other types of sperm and somatic cell DNA damage. Several studies have noted increased spontaneous abortions in spouses of men exposed to various suspect agents, such as lead, solvents,¹⁰³ and mercury. However, none has been confirmed or further elucidated mechanistically at this time. A recent large study of male welders did not confirm previous findings that this common paternal exposure causes SAB in wives of exposed men.¹⁰⁴

Fetal growth retardation and prematurity

Female exposures

Given the rising awareness of the associations between these developmental endpoints and infant and childhood morbidity and mortality, there is great interest in identifying preventable environmental causes. Unfortunately, few have been found to date.

Lead is probably the best appreciated preventable exposure. Women exposed occupationally during gestation have

had documented smaller and often premature offspring.¹⁰⁵ In addition, the same exposures are associated with various birth defects and childhood developmental abnormalities consistent with direct fetal exposure in utero and associated tissue disruption. Lead exposure in utero has also been associated with reduced postnatal growth rates.¹⁰⁶

Children born to women exposed to PCBs during food-borne outbreaks also had smaller offspring, although the infants were not obviously premature. Other stigmata of exposure in these children included skin discoloration and other evidence of ectodermal dysplasia. Small dose-related effects on birth weight also have been documented in areas of heavier environmental exposure via contaminated fish.¹⁰⁷

Another well-defined cause of fetal growth retardation is external (gamma or x-ray) ionizing radiation, which also is a cause of birth defects. The fetus is especially sensitive in the second part of the first trimester and early second trimester. Although the dose-response for this effect is not well established, it is a clear risk after accidental exposures in the range of 0.05–0.5 Gy (5–50 rad). What is less clear is the risk at levels just below this limit, which are most likely to be found in the workplace. Since 5 rads is the allowable dose per year for non-pregnant workers in many places, exposures in this range are not rare. Radionuclide exposures that might occur in the workplace or environmentally have not generally shown potential for causing growth retardation. Only radioactive iodide has been well established as a cause of fetal injury and then only after large (i.e., therapeutic) exposure doses.

Exposures among healthcare workers have recently been associated with low birth weight and prematurity. Midwives with nitrous oxide exposure during pregnancy were found to have higher rates of low birth weight.⁶⁹ Dental assistants exposed to the sterilant ethylene oxide had non-significantly elevated risk of preterm birth.⁸⁰

Knowledge of the effects of alcohol on fetal growth has raised many concerns about solvent exposures, especially those occurring occupationally. Although these are biologically realistic concerns, data gathered to date suggest only an increased risk for maternal pre-eclampsia by an unknown mechanism.¹⁰⁸ In mothers who develop this complication, growth retardation and prematurity are probably more likely.

Similarly, knowledge of the risks to fetal growth of cigarette smoking in pregnancy have raised concerns about exposures to carbon monoxide and other asphyxiants. However, evidence of fetal injury, including growth retardation, has been shown only after episodes of maternal intoxication.

On the other hand, the very much lower levels of ambient oxygen associated with high altitude do result in babies of smaller weight, which is of unclear consequence. Further, fetal toxicity has been documented anecdotally in women who experience pressure changes associated with deep sea diving, and increased fetal mortality was demonstrated in a sheep model for maternal-fetal bends.¹⁰⁹

As with spontaneous abortions, there is an extensive amount of literature evaluating physical activity late in

pregnancy and the risk for delivery of small or premature babies. Taken together, the weight of the evidence does not support a large effect of physical activity on birth weight.¹¹⁰⁻¹¹³ While physical activity per se does not appear to increase risk of prematurity,^{112,113} high energy expenditure combined with high work speed,¹¹¹ prolonged standing, and long working hours¹¹⁰ were more consistently associated with preterm birth.

Male exposures

There are no established factors that relate these outcomes to male exposures. There are suggestions that the spouses of male workers exposed to lead may have smaller offspring than others, but the possibility that these women were also exposed, either at the worksite or by indirect exposure via contaminated clothing, is difficult to exclude.

Birth defects

Female exposures

Possibly the most dreaded concern about environmental exposure is the likelihood of risk for birth defects. Thus far, only a few hazards have been associated definitively with birth defects. Known associations are summarized in Table 27.2.11.

Most of the well-described human environmental developmental toxicants have been recognized after an environmental disaster or epidemic, with presumably high levels of exposure to the causal agent, often with associated maternal morbidity as well. Although in each case there is incontrovertible evidence of effects on humans at high doses and a parallel animal model, the dose–response relationship at low exposure levels remains uncertain, which may be important in counseling pregnant women who seek advice after an exposure has occurred. Historic reports and isolated descriptions of babies born to women

occupationally exposed to lead document frequent occurrences of various defects including CNS disorders and urorectal malformations similar to patterns seen in some experimental models of lead-induced teratogenesis.¹¹⁴ The effects at doses that would be expected to occur in working women under current lead standards are less certain. At least one large study found an overall excess of minor anomalies of various kinds, whereas other studies have not identified such excesses.

Methyl mercury developmental toxicity was first described during the 1950s after residents around Minamata Bay in Japan consumed fish contaminated with methyl mercury that formed from industrial discharge of mercury into the water. Affected offspring had microcephaly, limb deformities, cerebral palsy, mental retardation, and other defects.¹¹⁵ Similar outcomes have been seen following other mass poisoning episodes. During the past decade, concern has emerged that levels of methyl mercury found in large, predatory fish such as tuna may pose a developmental hazard in populations who regularly consume large quantities of fish. These studies have focused mainly on neurodevelopmental deficits that are not apparent at birth, and are discussed in the subsequent section.

Similar to the situation with methyl mercury, the risk of birth defects in humans following PCB exposure was first appreciated after two mass poisoning episodes in which cooking oil was contaminated with PCBs.¹¹⁶ Also similar to the situation with methyl mercury, much attention has focused on possible developmental effects of lower levels of PCB exposure due to consumption of contaminated fish. These studies are also discussed below.

The well-known adverse developmental effects of ethanol and toluene abuse¹¹⁷ have generated concern that occupational exposure to these and other solvents may also increase risk for birth defects. Thus far, occupational exposures to either of these solvents, which tend to be orders of magnitude lower than with abuse, have not been associated with birth defects. Although many other solvents are developmental toxicants in animals, few human studies have demonstrated increased rates of malformations with occupational solvent exposure. This is likely due both to the rarity of major malformations and to the relatively lower doses to which humans are exposed. Recently, a large multicenter European group reported increased risk for congenital malformations among women exposed to glycol ether solvents during the first trimester of pregnancy.¹¹⁸ A significantly elevated odds ratio for major malformations and solvent exposure was reported in a meta-analysis of studies on solvent exposure.⁸³

Over the past decade, much attention has been paid to the effects of low-level environmental exposures to agents that act by disrupting endocrine function on in-utero development. Compounds that act as antiandrogens or estrogen agonists have been shown to cause malformations of the urogenital system in laboratory animals, and the hypothesis has been put forward that in-utero exposure to environmental pollutants may be responsible for the increasing incidence of abnormalities of human male urogenital development, such as cryptorchidism and

Hazard	Identified defects	Reported setting
Metals		
Lead	Various patterns	Occupational, environmental
Methyl mercury	Psychomotor retardation (seizures, paresis, mental retardation)	Food-borne contamination
Solvents		
Toluene	Microcephaly, craniofacial anomalies	Glue sniffing
Ethanol	Microcephaly, craniofacial anomalies	Abuse
Glycol ethers	Various patterns	Occupational
Other chemicals		
PCBs	Ectodermal dysplasia (dermal pigmentation, dystrophic nails, mucosal dysplasia, mental retardation)	Food-borne contamination
Physical hazards		
Ionizing radiation	Microcephaly	Atomic blast
Heat	Neural tube defects	

Table 27.2.11 Hazards that cause developmental toxicity after maternal exposure

hypospadias.⁴ Only a few epidemiological studies have been completed so far. One demonstrated an increased risk of cryptorchidism, but not hypospadias, in the sons of female gardeners.¹¹⁹ An ecological study found high rates of surgery to correct cryptorchidism in municipalities with high rates of pesticide use.¹²⁰

Male exposures

Female spouses of workers exposed to lead, solvents, and anesthetic gases have all been reported to have excesses of birth defects in isolated studies. However, none of these observations has been duplicated, nor has a clear model emerged, so at present there are no established or highly suspect male-mediated teratogenic hazards. However, it should be borne in mind that this possibility has not been readily evaluable in the environmental disaster situations in which most female-mediated causes were discovered because men and women were, in general, both exposed simultaneously.

Impaired postpartum development

Female exposures, including breast milk

Four important developmental toxicants are associated with delays in CNS development: lead,¹²¹ PCBs,^{116,122} methyl mercury,¹¹⁵ and ionizing radiation.^{97,123} Controversy exists over whether environmental exposures to the general population, such as from eating fish that contain low levels of PCBs or methyl mercury, pose a measurable risk to CNS development. Carefully conducted longitudinal studies suggest that subtle changes in outcomes such as intelligence quotient, learning, and behavior may be detectable following these exposures on a population basis, though not on an individual basis. Children whose mothers consumed Lake Michigan fish during pregnancy continued to have cognitive deficits through 11 years of age that correlated with cord blood PCB concentrations.^{124,125} Data from studies of two populations of women that consumed ocean fish, containing background levels of methyl mercury, daily during pregnancy have produced conflicting results. Reports from the Faroe Islands study demonstrated subtle dose-related effects on motor function, language, and memory even at 7 years of age,^{126,127} whereas the Seychelles Islands study did not report adverse effects through 5.5 years of age.¹²⁸ One caveat with these studies, as with any epidemiological study of environmental exposures, is that the measured exposure (PCB or mercury concentrations) represents one of numerous potential exposures. It is possible that the observed effects are due to an unmeasured exposure that is present in similar proportions to the measured exposure.

With ionizing radiation exposure, typically delivered between weeks 7–16 in utero, the cause of persistent deficits is likely inability to compensate for early diffuse injury. With chemical causes, the pathogenesis is more complicated because the toxicants themselves persist for long periods in the fetus and child and in the target CNS tissue, suggesting that ongoing neurologic injury may

occur through early childhood. Of clear therapeutic importance in this regard is the possibility of further postpartum exposures to the causal agent. For lead, the source generally is the home environment, including drinking water, paint, and dust. For methyl mercury and PCBs, breast milk is also a source of concern, because each agent is well concentrated in milk. In fact, anecdotal evidence suggests that postpartum exposures to mercury and PCBs in breast milk alone may cause CNS deficits, but few cases have been available for study in which exposure to the mother began, *de novo*, postpartum.

Of interest, organic solvents, except in the setting of glue sniffing, have not been shown to cause chronic neurologic or developmental impairment in children when mothers have been exposed during pregnancy or breast feeding.¹²⁹ Evidence for other neurotoxicants, such as various pesticides, is too limited to judge risk.

Male exposures

Presently no model for male transmission of a developmental lesion has been demonstrated involving exposure prior to birth. Of course, the possibility of contamination of children from paternal work materials, such as indirect para-occupational exposures from clothing remains of concern for such hazards as lead and pesticides, and other toxicants.

Childhood cancer

Female exposures

Although in-utero exposure to carcinogenic or mutagenic agents may be substantial when pregnant women are occupationally or environmentally exposed, there is very little data documenting increased risks for childhood cancer as a result. The single situation for which transplacental carcinogenesis has been unequivocally proved is for DES. Taken medicinally by mouth, this agent confers a substantial risk of a rare vaginal adenocarcinoma in female offspring after puberty.¹³⁰ No counterpart has been shown in women exposed to estrogens at work, although this is clearly a concern.

Several studies also have demonstrated risk for childhood leukemia in offspring of women exposed medically to ionizing radiation. Surprisingly, however, follow-up studies of atomic blast victims have not demonstrated a high rate of leukemia in children exposed to very high doses of radiation in utero, although increased risks of several cancers have been reported among individuals exposed to high doses of radiation in utero or during childhood compared to individuals exposed as adults.¹⁵²

Increased risk of childhood brain tumor has been associated with nitrosamine exposure due to maternal consumption of cured meats during pregnancy in some studies,^{131,132} but not in others.¹³³ Elevated risk of brain tumors has also been observed in children whose mothers were exposed to farm animals during pregnancy.¹³⁴ Of note, two recent studies have *not* substantiated an association between maternal exposure to electromagnetic fields during gestation and childhood brain tumor risk.^{135,136}

Beyond these examples, other evidences of childhood cancer risk from maternal exposures before or during pregnancy have not been demonstrated, although some epidemiologic studies have reported higher rates of solvent exposures during pregnancy in mothers of children with brain tumors and an association between agricultural work and childhood leukemia.¹³⁷

Male exposures

The availability of cancer registries that provide information on parental occupations has led to the investigation of the relationship between paternal occupation and rates of the common childhood cancers. Employment in occupations with exposures to motor vehicle exhaust and pesticides have been linked to childhood leukemia, albeit inconsistently. A highly publicized study found a similar link with paternal exposure to ionizing radiation at an English nuclear power plant; however, subsequent studies have not substantiated this association, and it is at odds with the experience of atomic blast victims.⁹⁷

In several studies, brain tumors have been associated with paternal work in agriculture and aircraft industries and with painting. A previous association between pre-conception paternal exposure to electromagnetic fields and childhood brain tumor risk has not been substantiated.¹³⁸ Somewhat more consistently, several studies have found metal work, especially auto body and auto mechanic work, and welding, to be more common among fathers of children with Wilms' tumor and other brain tumors.^{138,139} Similar associations have been noted with retinoblastoma and hepatoblastoma.

At present, none of these associations can yet be considered causal. Nonetheless, some consistency in pattern and a biologic basis for plausibility make this a fruitful area for future preventive investigations and underscore the importance of male factors in healthful reproduction.

CLINICAL EVALUATION OF PATIENTS WITH REPRODUCTIVE AND DEVELOPMENTAL RISKS AND DISORDERS

There are four clinical contexts in which individuals or couples typically seek medical advice regarding environmental and occupational effects on reproduction or development, or in which the practitioner should consider the possibility of such effects. These are: (1) infertile couples, (2) couples or women planning pregnancy or who are newly conceiving, (3) pregnant women or their partners who have had an exposure to an environmental hazard of concern before or during pregnancy, and (4) couples or women who have experienced an adverse reproductive or developmental outcome.

For each of these clinical situations, the practitioner will want to consult additional sources of information about the possible reproductive hazards that are identified. These

include books^{7,140-142} electronic databases,¹⁴³⁻¹⁴⁵ and articles, including those referenced in this chapter.

Infertile couples

The standard approach to the evaluation and management of infertility involves a detailed medical and reproductive history of both parents and the use of laboratory tests, such as semen analysis and evaluation of female hormonal cycling and anatomy as appropriate to identify the physiologic basis for reproductive failure. Prior to identifying the apparent problem, it is difficult to evaluate or manipulate environmental or occupational factors meaningfully.

When the male partner has been demonstrated to have a low sperm count or otherwise abnormal sperm, it is appropriate to consider the common causes of testicular dysfunction and to review the male exposure history in detail, with emphasis on exposures within the past year, especially current ones. Any possible exposure to the hazards reviewed in Table 27.2.8 should form the basis for further consideration, irrespective of the possibility of another non-environmental risk. Furthermore, if no other risk factors are identified, suspect agents of interest, such as those mentioned in the section on hazards to male fertility, should be considered.

If an established or possible suspect exposure is identified, it is reasonable to attempt to further qualify, and if possible, quantify the intensity of exposure (e.g., by blood or urine testing where applicable) before establishing an intervention plan. The choice of how to proceed depends on this investigation, with the clinician establishing some estimate of the likelihood that the environmental factor is important based on the agent, the intensity of exposure, and the coexistence of other risks.

Having established some reasonable likelihood of effect, the next step is an intervention trial, removing the man from further exposure. Before such a plan is undertaken, at least two preintervention semen specimens should be obtained for analysis because of intrinsic variability. If azoospermia is demonstrated twice, a trial still is reasonable but the prognosis for recovery is poor, which should be considered in further planning; assessment of the role of prior exposures is a separate task, which is discussed later. After discussing the economic and personal ramifications with the patient, the therapeutic trial of removal should be continued for 6–12 months (2–5 cycles of spermatogenesis) before any judgment is made, with repeat semen analysis performed bimonthly. The choice as to whether to continue attempting pregnancy during this interval depends on other properties of the hazard, such as the potential for other male-mediated effects. In the case of lead, at least, deferral may be the conservative choice.

If there is no improvement after a year, a period of continued removal may be scientifically reasonable (depending on, for example, body burden and disposition) but, practically speaking, is far less likely to be successful. At this stage, other factors should be given greater weight and the likelihood of trial failure added to the therapeutic equation.

Infertility of the female is far less readily evaluated, in part because so little is known about factors that may cause it, and in part because there is no counterpart to semen for ready analysis. Further, not only are few factors studied but the physiologic basis for possible environmental effects remains unclear, such as whether hazards act only by disrupting ovulation or may cause loss of fecundity at a later stage, such as during tubal transport or implantation.

The approach for women, therefore, is based on a more global perspective of the situation. If other female or couple-specific factors are not identified, it is reasonable to consider removing the woman from any environmental exposure that has been strongly associated with adverse outcomes (Table 27.2.9); indeed, this would be appropriate advice for the fertile couple as well. For agents less strongly associated with reproductive risk, the choice is more difficult and depends on the availability of other therapeutic options and the informed choice of the woman. In every case, it is very important that the patient appreciate how little is known about occupational risks to female fecundity and, therefore, that removal from the workplace or affected environment has only a small likelihood of remedy. On the other hand, it is not unreasonable to emphasize the risks to the pregnancy or offspring if conception is successful within the exposed environment.

If a therapeutic trial of removal of the individual from the workplace is undertaken, the duration and endpoint should also be considered. If cycles are anovulatory, it is reasonable to wait for at least 6–12 months, because the preovulatory maturation of the corpus luteum takes about 3 months. If the trial is based on anovulation, direct or indirect hormonal evaluation is essential to establish the basis for success or failure. For women who are infertile despite normal ovulation, the only reasonable endpoint is conception.

Couples or women planning conception or who are newly pregnant

Advising prospective parents about environmental risks begins by establishing a detailed profile of non-environmental factors that may be relevant and understanding the concerns and questions of the couple or woman patient. Has there been a prior adverse outcome in the history of the patient or a coworker or colleague? Has there been a specific exposure or risk of concern? Are there hidden fears about pregnancy that may be focused on the environment or workplace? If the answer to any of these is yes, the specific issues and circumstances should be directly addressed and resolved.

If there is no extraordinary basis for concern, the general principles of preventive care are appropriate. Occupational, avocational, and other ambient environmental exposures should be noted, with special attention to factors summarized in Tables 27.2.10 and 27.2.11, and suspected agents described in the sections on effects of exposures during pregnancy. If there is potential exposure to any of these hazards, opportunities for prevention should be reviewed, which may be as simple as modifying a normal or chosen activity, such

as a hobby involving pesticides, metals, or solvents, or as complex as planning a job modification. The need for developing a detailed or expansive database is often inverse to the patient's willingness or ability to modify or discontinue exposure. For example, it may be reasonable to recommend that a pregnant woman suspend use of garden chemicals during the period of pregnancy and breast feeding without much investigation, whereas considerable information might be necessary before advising an agricultural worker or horticulturist in the same situation.

For exposures whose elimination or control is not easily accomplished, a more formal investigation including risk assessment and control strategy is indicated. Each potential exposure of interest and its dose should be identified to the greatest extent possible, because high or uncontrolled occupational exposures merit steps very different from trace environmental contamination, a point that is crucial for the patient to understand as well. Also, the potential for postpartum exposure to the agent in breast milk should be evaluated based on the principles listed earlier.

Next, the database for each hazard should be reviewed, starting with the discussions in the preceding sections. The clinician may need to consult more detailed sources referenced above. With that information in hand, physician and patient together can proceed to establish the third element of the equation, the options for control. In this setting, these options include not only the factors normally considered in occupational and environmental health practice, such as a job change or use of personal protective equipment, but also certain alternatives, such as considering bottle feeding rather than breast feeding, or a choice to modify exposures for a specific limited period of time. For each control strategy, the two important aspects of concern are the effectiveness of the approach to reduce exposure and the acceptability of the approach to the patient, employer, or both.

Once the relevant exposures are deciphered, databases obtained, and control options ranked, the choices for preventive management of a pregnancy may be undertaken. There are no definite rules, although elimination or strict and rigid control of the known and suspected factors is highly desirable. Similarly, because maternal illness itself is a risk factor for the fetus, occupational or environmental risks of sufficient magnitude to make the mother systemically ill, such as with solvent intoxication or metal fumes, are best completely avoided or rigidly controlled. Management of physical stresses, although included in the tables, are less straightforward because we presently lack adequate dose–response information; strenuous labor, cold, noise, vibration, and shift work are best curtailed, if possible, after the second trimester.

Beyond these basic principles, there is wide latitude for choice, depending on the preferences of the patient. Although it is appropriate for the clinician to be conservative and generally risk averse, strong or sweeping generalizations to avoid everything, which may be reasonable when advising about use of medications that are not important in the treatment of life-threatening disease, are not easily adopted to environmental and occupational factors. Rather, more hazard-specific and balanced information is likely to be of

most use to the patient, although gathering this information is far more demanding of the time and thoughtfulness of the clinician.

Pregnant women who have been exposed to a hazard

Sometimes, women or couples consider the possibility of adverse effects from the environment *after* there has been an exposure of concern. Unlike the preventive setting described earlier, this situation demands a very specific and goal-directed role for the clinician, centered on a single specific task of risk assessment. At the outset, it must be appreciated that there will ultimately be only three options for subsequent action: reassurance, cessation of exposure, or recommendation for therapeutic termination of pregnancy.

After establishing the basis for concern, the first challenge is determining the risk of an adverse outcome based on knowledge of the exposure. As always, this begins with the determination of what actual hazard was involved, the timing of exposure with respect to the pregnancy, some estimate of dose, and a characterization of other factors that may modify risk. Almost invariably, these facts must be reconstructed from the patient's history; occasionally, a toxicant or its metabolites can be measured directly in the parent.

Once an exposure is verified and an estimate of dose and timing with respect to pregnancy is made, the possibility of a measurable effect on the pregnancy must be determined using the available databases. Given the gravity of the situation, it is advisable to obtain the most complete and current information available for that toxicant. The information in this text may serve as a guide, but it should be supplemented by the most current animal and human data available, except in a case of gross overexposure to a well-characterized hazard such as lead or methyl mercury.

If it appears possible that the exposure at its estimated dose may have an impact on the outcome of the pregnancy, then the timing of exposure should be assessed. Similarly, exposures that occur in the second trimester and beyond are unlikely to cause fetal malformations, although growth and development of the fetus remain at risk.

If after review of exposure, dose, and timing there is still basis for concern about the outcome of the pregnancy, then it becomes important to quantify the concern. For example, exposures that occur in the second trimester and beyond are unlikely to cause gross fetal malformations, although growth and development of the fetus remain at risk. Using conservative estimates from the available data, how likely is the outcome of concern to occur? For childhood cancers or fetal malformations, these are best expressed as straight probabilities of an all-or-nothing outcome. For developmental or growth effects, these possibilities may be conceptualized on a continuous scale from minimal to severe; however, inherent uncertainties often limit specific characterization.

As noted, the real challenge in this situation is that, at the end, the choices for action are extremely limited. Although there may be some small room for action, such as taking

steps to hasten removal of a toxicant or reduce later exposures, the basic choice comes down to therapeutic abortion versus reassurance. Because there is almost always some degree of uncertainty regarding the risk of an adverse developmental outcome and because many people have very strong pre-existing feelings towards therapeutic abortion, the clinician in these situations must present choices in the clearest and most distinct way possible. It is best for the clinician to very clearly delineate the risks and associated uncertainties, to present pregnancy termination as an option in cases with very high risks of developmental effects, to provide reassurance for continuation of pregnancy in the majority of cases in which the risk is small, and, perhaps most importantly, to be supportive of what ultimately must be the patient's choice.

Patients who have had adverse outcomes

Evaluation of a couple who has experienced an adverse reproductive outcome in the past may be important for two reasons: (1) concern about future pregnancies; and (2) attribution for medical-legal purposes. When the medical-legal issues are involved, the approaches are similar to those used to evaluate any environmental or occupational injury or illness, using the principles outlined in Chapter 3 of this text and the data provided earlier, as supplemented by other detailed and updated sources of information.

Evaluation of a prior event for the purpose of subsequent reproductive planning requires a somewhat different formulation. In general, patients who have had a prior adverse outcome, such as a developmentally abnormal child, fear a recurrence based on some underlying, immutable risk factor such as genetics. Recognition of a preventable or remediable basis for prior risk could provide a basis for reassurance and optimism about future pregnancies. However, depending on the circumstances surrounding exposure with the previous pregnancy, issues of self-blame and regret may complicate the benefit of this message.

Although it is important to decipher the patient's actual agenda in seeking consultation around an adverse event, it is best to separate the past and the future. First, one can evaluate the likelihood that a defined exposure may have been responsible for a prior adverse outcome. Second, based on this calculation and all other available information about the couple, such as current environment, persistence of prior exposures in the body, and results of genetic or other evaluations that have occurred, the prospects for the future can be estimated. The possibility of an immutable risk needs to be specifically considered in the patient's interest, so that referral for genetic or other appropriate counseling can be undertaken.

After these steps are complete, the general preventive approach for future pregnancies can be laid out as described earlier, modified by the special knowledge about the past and the unique perspective the patient will undoubtedly have because of it. Importantly, the recommendation for the future may appear to contradict the verdict on the past, a paradox the clinician must anticipate and be prepared to

explain. For example, a couple may have just lost a 2-year-old child to leukemia, which they might attribute to low-level ionizing radiation exposure to the father in the year prior to conception. Although support for this possibility in the current literature is small, advising the couple to reduce or eliminate such exposures prior to the next conception would not be unreasonably risk averse. In such a case, however, it would also be very important to be certain that an underlying heritable risk, such as Fanconi's syndrome, is not a factor.

PREVENTION OF REPRODUCTIVE AND DEVELOPMENTAL RISKS IN AN OCCUPATIONAL SETTING

One of the foremost challenges for corporations in the United States and other developed countries has been the development of reproductive and developmental health policies consistent with good preventive principles, existing exposure regulations, and the law. Although our knowledge of reproductive and developmental effects of hazards suggest possibly differential effects on each parent and fetus, United States law, subsequent to the case of Johnson Controls, requires women be given the right to work in any place where men may work, as long as they are adequately

informed about possible fetal risks should they get pregnant. In other words, gender-specific administrative controls may not be used to prevent reproductive or developmental harm.¹⁴⁶ In this section, we outline some approaches that may accomplish the goals of preventive reproductive health while adhering to these social mandates (Fig. 27.2.3). There are four key components that we recommend for institution in all workplaces and other defined organizations.

1. *Primary control of hazards to levels safe for men and non-pregnant and pregnant women.* Although existing occupational standards have not, in general, required exposures be reduced to levels believed to minimize risks to reproduction and development, such levels are definable and achievable in many, if not most, workplaces by engineering controls; they may be achievable in all, with the addition of personal protective equipment and administrative controls.¹⁴⁷ The adherence to such strict standards, which are gender neutral and as safe as possible for reproduction and development, is the cornerstone of an effective plan.

2. *Hazard identification.* All agents known or suspected to present a risk for reproduction or development should be identified clearly as such and well marked within the work environment, so that inadvertent exposures become far less likely.

3. *Reproductive and developmental health education.* Because the existing standards have not been calculated to

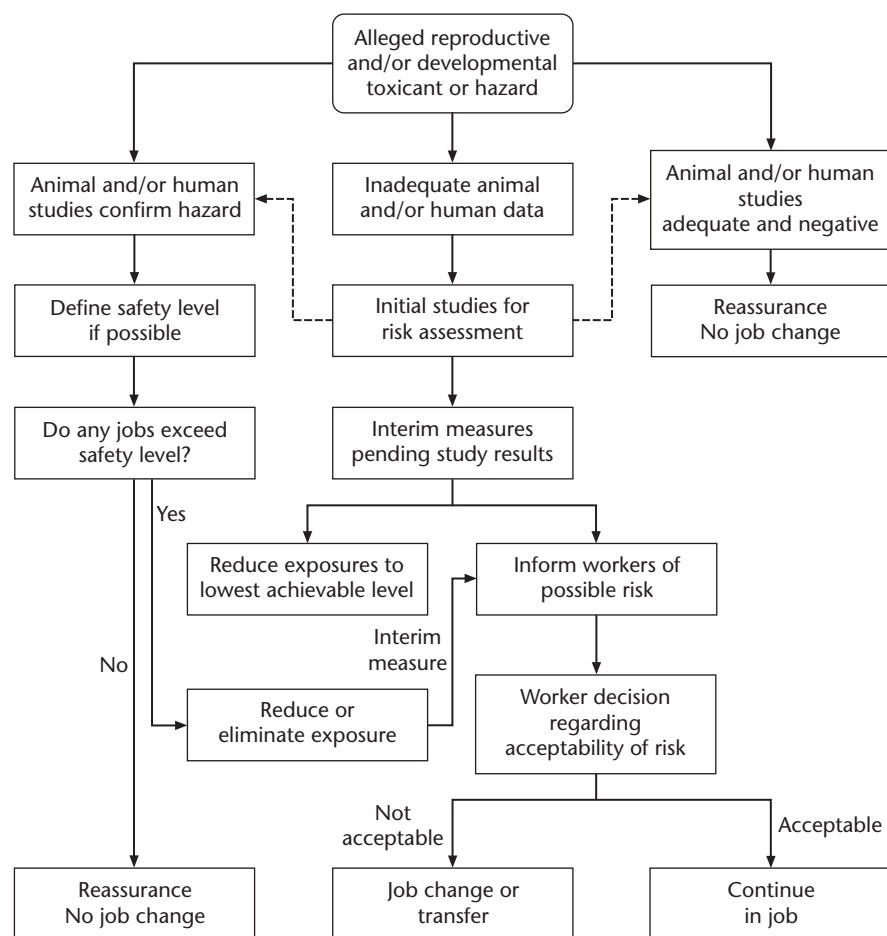

Figure 27.2.3: Proposed scheme for management of reproductive and developmental toxicants in the occupational setting. Many occupational exposures fall in the category identified as 'inadequate animal and/or human data'. In this case, it will be necessary to gather additional information as well as put interim measures in place to both inform and protect the workers. Exposures should be reduced to the lowest level achievable using engineering controls and personal protective equipment. The workers also must be informed that the exposure may pose a hazard to reproduction or development. In this setting, the workers should be allowed to determine whether or not the potential for effect is sufficient for concern. If not, the worker may reasonably decide to continue on the job. If there is concern, the worker should be provided with a choice of alternative jobs, without professional disincentives, that carry a minimal reproductive or development risk.

provide a margin of safety for reproductive and developmental health, and because the basis for personal decisions must be made with adequate information, broad-based and unbiased education of all potentially exposed workers of both sexes is crucial.

4. *A flexible work-modification plan.* Despite the institution of controls to minimize risk in a gender neutral fashion, some workers are likely to choose a greater level of risk aversion when planning pregnancy, after conception, or while breast feeding. There are many excellent medical reasons and other understandable personal reasons for this choice. Ideally, these choices should be available to individual employees of either sex without undue company scrutiny, interference, or disincentives, such as loss of wage, job security, or career path. Although the experience in most companies is that few employees actually use these options, their availability is widely appreciated by employees as a benefit. More important, such flexibility facilitates the practice of the highest quality preventive medicine.¹⁴⁸

CONCLUSIONS

Physicians and other healthcare professionals are increasingly called on to counsel patients, unions, corporations, and public health agencies concerning the impact of occupational exposures on reproductive and developmental health. It is important to recognize certain fundamental principles in responding to these concerns: (1) the available data on human reproductive and developmental hazards are deficient; (2) because human data are lacking, it is essential to extrapolate information from animal data (this is also a central component of the protection of public reproductive and developmental health); (3) the criteria or stringency of data analysis for assigning causation are substantially different from those required for the protection of the public health; (4) our knowledge of reproductive and developmental toxicity is developing rapidly and is expected to change substantially in the future; and (5) finally, men and women must be treated equally so that reproductive and developmental health are protected.

Chapter 28

Neurologic and Psychiatric Disorders

28.1 Central Nervous System Diseases

Jordan A Firestone, William T Longstreth Jr

Chemical agents capable of damaging the central nervous system (CNS) are ubiquitous in the environment. Industrial processes are notorious sources for some of the most well known of these neurotoxins, which contaminate both the worksite and the surrounding environment. The United States Environmental Protection Agency lists over 65,000 chemicals currently used in the US for commercial purposes, adding 2000–3000 new ones each year.¹ Reflecting the growing public concern about chemical exposures, the Environmental Protection Agency² and the Food and Drug Administration³ have issued revised guidelines for risk assessment, including specific test batteries for neurotoxicity and developmental neurotoxicity. Unfortunately, only a few chemicals have been thoroughly tested, and the guidelines have been criticized for being ineffective at identifying potential neurotoxins.⁴ Although neurotoxicity is apparent when intense high-level exposures result in acute illness, there is increasing evidence linking chronic low-level exposures with neurodegenerative diseases.⁵ Given the frequency with which potentially neurotoxic exposures occur, clinicians may be missing these causal factors in many patients presenting with central neurologic symptoms.

The effects of toxins on the nervous system are protean. The nervous system is uniquely susceptible to intoxication for several reasons (Table 28.1.1). When the peripheral nervous system is affected, characteristic symptoms and signs develop (see Chapter 28.2). In these cases, much can be done to specify the degree and type of dysfunction, including a histologic examination of a peripheral nerve biopsy specimen. On the other hand, the effects of toxins on the CNS – the brain and spinal cord – are more complex than on the peripheral nervous system. Clinical disorders of the CNS are variable in their presentation and difficult to classify, often involving a host of non-specific symptoms. Typically, the brain and spinal cord cannot undergo biopsy for histologic examination. Thus, clinicians often focus on describing neurologic function and excluding other neurologic conditions, rather than on diagnosing a specific neurotoxic disease. This chapter will review the challenges in diagnosis, organize an approach to patients with CNS dysfunction as the result of a neurotoxic exposure, and present a scheme for classifying diseases related to neurotoxins.

CLINICAL EVALUATION

In order to facilitate an accurate diagnosis, a clinical evaluation must include a detailed account of the patient's

initial presentation. The most important elements of this evaluation are a comprehensive history and detailed neurologic examination, which together yield the most relevant diagnostic information. Because neurotoxic diseases may be evanescent, documentation of a thorough baseline neurologic examination is crucial, and close follow-up is important. The differential diagnosis can be further refined by review of relevant exposure documents, such as Material Safety Data Sheets (MSDS) and duty logs, as well as literature searches for reported associations. Consultation with a neurologist may be needed to define subtle features of the neurologic examination and help decide what ancillary testing is appropriate to clarify the disease process and exclude other causes for the patient's problems.

History

The first challenge facing the clinician is to determine if the patient's condition is related to a neurotoxic exposure; the cornerstone for this evaluation is a detailed history.

The manner in which a patient with a potential neurotoxic exposure presents for medical evaluation is related in part to the level of the exposure and potency of the toxin. The most straightforward presentation is when the patient is aware of a specific chemical exposure. The person may have learned that exposure to some substance is potentially hazardous and is worried about possible injury. The concern is augmented when the organ targeted for injury is the brain. In this situation, determining the level of exposure represents the challenge. At one extreme, the exposure may be extremely small, and the risk of detectable disease equally small; for example, the patient who is otherwise healthy and is concerned because of an exposure to aluminum while using aluminum cookware and soft-drink cans. For such cases, a history and physical examination are generally adequate to convince the clinician whether a serious problem exists. At the other extreme, a patient may present with obvious dysfunction of the CNS related to a massive neurotoxic exposure. Many times, such large exposures are accidental, but other times, they are intentional, as occurs with homicide, suicide, and substance abuse. Examples would include the accidental exposure of a worker to carbon monoxide, the use of cyanide for homicide, and the sniffing of glue in search of euphoria.

When the patient has symptoms but does not immediately associate them with some exposure, the clinician must question the patient about environmental exposures,

- Neurons and their processes have a high surface area, increasing their effective exposure to chemicals
- The high lipid content of neuronal structures results in accumulation and retention of lipophilic chemicals
- Metabolic demands are high, so neurons are strongly affected by energy or nutrient depletion
- High blood flow, for high metabolic demands, increases the effective exposure to circulating chemicals
- Chemical toxins interfere with normal neurotransmission by mimicking the structures of endogenous molecules
- Following chemical injury, recovery of the normal, complex interneuronal connections is imperfect
- Neurons cannot regenerate once killed by chemical exposures

Table 28.1.1 Factors contributing to the susceptibility of the nervous system to chemical injury

particularly those occurring at work. Questions to identify neurotoxic exposures should include a detailed occupational and environmental health history (see Chapter 3). An exposure may have resulted in a disease that has forced the patient to retire; in this case, the key will lie in questioning the patient or the patient's family about exposures that have occurred in the past. It may also be necessary to explore past exposures in cases of chronic neurodegenerative diseases, for which the clinician may not have a ready explanation and may therefore erroneously attribute to aging alone.

If a worker has neurologic symptoms that he or she believes are related to a particular neurotoxin, then the clinician needs to document the symptoms and determine whether they are consistent with the known effects of the neurotoxin at that level of exposure. For example, a worker spills an insecticide, such as malathion, and develops transient confusion, agitation, flushing, blurred vision, dry skin, and dry mouth. Here, the neurotoxic effects of an organophosphate resulting in cholinergic excess are readily apparent (see Chapter 48). Unfortunately, most clinical situations are not as straightforward. If after consulting with appropriate sources there is no apparent link between the symptoms and exposure, then the condition is either not related to the exposure or represents a newly recognized manifestation of a neurotoxin. In such cases, principles of causation must be applied (see Chapter 1).

The pattern of associated symptoms is useful in recognizing and identifying a particular neurotoxic syndrome, and certain neurologic complaints should alert a clinician to explore the occupational health history thoroughly (Table 28.1.2). Higher cortical functions can be extremely sensitive to various brain insults, including neurotoxins. Complaints of changes in cognition, behavior, and mood should always prompt questions about exposure to neurotoxins. In addition, many parts of the nervous system

- Demonstrable exposure
- Temporal connection
- Cognitive or behavioral changes
- Incoordination
- Non-focal dysfunction

Table 28.1.2 Pattern recognition for neurotoxicity

must be operating normally for coordination to be intact, so complaints about incoordination should also raise suspicion about neurotoxins. Such complaints can take many forms, including dizziness, unsteadiness of gait, or difficulty with fine finger movements. The patient is usually aware of problems with coordination, although they may be difficult to characterize. The patient may not necessarily be as aware of problems with cognition. These complaints may come from friends and family members instead of the patient.

A key element in recognizing a pattern consistent with neurotoxicity is the distinction between focal and more diffuse involvement of the CNS. Typically, evidence of focal involvement weighs against the problem being related to a neurotoxin. In this context, focal changes need to be distinguished from system-specific involvement. A focal lesion generally refers to a specific site of injury, such as a tumor or stroke, which is anatomically localized but has a broader functional impact. Thus, the patient with temporary hemiparesis and aphasia may have had an ischemic injury in the middle cerebral artery distribution due to vascular disease, rather than a neurotoxic cause. In contrast, system-specific injury often reflects that system's inherent metabolic or physiologic susceptibility to intoxication rather than its anatomic localization. A recent example that has revolutionized thinking about neurotoxins involves the effects of a meperidine derivative, 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), that selectively damages the dopaminergic motor system of the brain. The resulting clinical picture is indistinguishable from Parkinson's disease. This system-specific neurotoxin will be discussed in more detail later in this chapter.

Another element to be considered is the temporal sequence of events. Key distinctions include acute versus insidious onset, constant versus intermittent dysfunction, and progression versus stabilization or improvement. A consistent temporal association between symptoms and exposures is an important aspect in assessing a likely toxic etiology. Little doubt exists when acute symptoms are associated with accidental overexposures, as in organophosphate poisoning. Intermittent complaints may be associated with non-continuous exposures, such as with a rotating duty roster. Perhaps the most challenging time course is one of insidious onset with progressive deterioration. In this case, other clues may be useful, such as anatomic or functional localization. For example, a progressive hemiparesis may suggest a focal neoplasm, whereas progressive gait instability may reflect a system-specific cerebellar effect of chronic solvent toxicity.

By combining facts about the exposure scenario with the symptom complex and temporal sequence, a pattern of CNS dysfunction consistent with neurotoxicity may emerge. Recognition of this pattern is essential to diagnosis. The information gleaned from the initial history further guides the clinician in the subsequent physical examination and later selection of ancillary tests.

Test areas	Maximum score	Score
Orientation What is the (year) (season) (date) (day) (month)? Where are we: (state) (county) (town) (hospital) (floor)?	5 5	
Registration Name three objects: 1 second to say each. Then ask the patient all three after you have said them. Give 1 point for each correct answer. Then repeat them until he or she learns all three.	3	
Attention and calculation Serial 7s. 1 point for each correct. Stop after five answers. Alternatively spell 'world' backward.	5	
Recall Ask for the three objects repeated above. Give 1 point for each correct response.	5	
Language Name a pencil and watch. Repeat the following 'No ifs, ands, or buts.' Follow a three-stage command: 'Take a paper in your right hand, fold it in half, and put it on the floor.' Read and obey the following: Close your eyes. Score 1 point only if he or she actually closes his or her eyes. Write a sentence. Do not dictate a sentence; it is to be written spontaneously. It must contain a subject and verb and be sensible. Correct grammar and punctuation are not necessary. Copy design. On a clean piece of paper, draw intersecting pentagons, each side about 1 inch, and ask the patient to copy it exactly as it is. All 10 angles must be present and 2 must intersect to score 1 point. Tremor and rotation are ignored.	2 1 3 1 1 1

Age-specific norms for the Mini-Mental State Exam. Neurology 1988; 38:1565-8.</small>		

Table 28.1.3 Mini Mental State Examination*

Physical examination

By the time the history is completed, the clinician should have strong suspicions about what the neurologic examination will show. The examination thus provides an opportunity to test hypotheses generated from the history by either confirming expected findings or eliminating alternative explanations. Although the general medical examination may supply clues that the patient has been exposed to a neurotoxin – for instance, gingivitis can occur with chronic mercury poisoning and transverse white lines in the fingernails (Mees’ lines) can be seen with arsenic poisoning – such pathognomonic findings are often not present. Therefore, the neurologic examination is essential to document the localization, the type, and the degree of neurologic impairment. There are six broad areas that should be screened in a routine neurologic examination:

- mental status;
- cranial nerves;
- motor system;
- reflexes;
- sensation; and
- coordination and gait.

A structured approach to these six areas helps ensure completeness and reproducibility.⁶

Testing the mental status and higher cortical functions begins with an assessment of the form and content of communication with the patient during the clinical interview. More formal, structured neuropsychologic screens provide advantages of reproducibility and reliability.⁷ One

commonly used screen that can be easily performed in the clinic is the Mini Mental State Examination (MMSE; Table 28.1.3). Age-adjusted norms have been established, with 29 or 30 being a normal score for persons under age 65 years.⁸ Although a normal score cannot rule out subtle cognitive problems, an abnormal score is concerning. Bedside neuropsychologic testing is insensitive to subtle abnormalities that the patient, family members, or friends may readily recognize. In these situations, more detailed neuropsychologic testing is indicated. Certain abnormalities of higher brain function, such as aphasias or apraxias, may suggest focal cortical involvement. The finding of such focal signs on detailed testing makes it unlikely that neurotoxicity is the sole explanation for the patient’s complaints.

The 12 cranial nerves should be screened to search for evidence as much to refute as to support the hypothesis that a patient’s complaints are related to a neurotoxin. For instance, the finding of a bilateral intranuclear ophthalmoplegia would push the clinician strongly toward a diagnosis of multiple sclerosis. Multiple sclerosis is frequently a consideration in patients suspected of having a neurotoxin-related disease, given the various symptoms and signs with which multiple sclerosis can present and that it affects young men and women who may try to relate their symptoms to something in the workplace.

The first cranial nerve serves olfaction. While not easy to test in a reliable fashion, impairment of olfaction as an early finding is noteworthy. An area of controversy has been the hypothesis proposed by some investigators

that certain neurotoxins gain access to the brain via the olfactory system, thence spreading to the neighboring hippocampal systems, affecting memory, or the basal ganglia, affecting motor function. Olfactory impairment is a common finding in patients with neurodegenerative diseases,^{9,10} as well as chronic rhinosinusitis. Various substances can be used to test olfaction, and kits are available for formal assessment.¹¹

The second cranial nerve, serving vision, is susceptible to neurotoxic injury. Bilateral findings can suggest a diffuse neurotoxic process, and bilateral optic neuropathy has been described with exposures to heavy metals, solvents, and insecticides. However, unilateral dysfunction suggests other disease processes. Physical findings include diminished visual acuity, a relative afferent pupillary defect to a swinging light, and a pale optic disc. Testing of the visual field is an important screen for focal brain disease, and therefore most visual field defects suggest an alternative cause for the patient's complaints. Bilateral field defects can rarely result from toxins. Blindness with unreactive pupils points to a problem anterior to the optic chiasm, as can occur with methanol intoxication. On the other hand, preservation of the pupillary light response indicates that the problem is in the brain, not in the eyes, termed cortical blindness. Poisoning with organic mercury can produce this syndrome, with constricted visual fields and eventual loss of vision. Neuropathologic examination in such patients confirms damage to the cerebral cortex serving vision.

Several aspects of the second cranial nerve can be tested. Visual acuity, visual fields, pupillary light response, and fundoscopy should be checked (see Chapter 20.1). Tests of color vision can be easily administered in the clinical setting and serve as sensitive screens of optic nerve function. For this reason, they have also been advocated for inclusion as a standard element in epidemiologic field studies.¹²

Examination of extraocular movements – cranial nerves III, IV, and VI – can give evidence to support a neurotoxic exposure. Certain types of gaze-evoked nystagmus can be seen with acute intoxications affecting the cerebellar system. Diplopia resulting from extraocular muscle paresis can occur with a number of neurotoxins, but this typically reflects dysfunction of the peripheral, not the central nervous system. Many degenerative diseases of the brain, including those related to toxins, can be associated with slowing of the saccadic, or normally lightning-like, eye movements.

The remaining cranial nerves are less frequently affected by neurotoxins acting on the brain. The fifth and seventh cranial nerves serve facial sensation and strength. The eighth cranial nerve serves hearing and balance. The ninth and tenth cranial nerves serve the function of swallowing. These cranial nerves are more frequently affected in their peripheral portion by neurotoxins; CNS involvement typically suggests a vascular, neoplastic, inflammatory, or demyelinating etiology.

The cranial nerves serving motor function, including V, VII, XI, and XII, can be involved in processes such as

	Upper motor neuron	Lower motor neuron
Atrophy	Moderate	Marked
Tone	Increased	Decreased
Reflexes	Increased	Decreased
Plantar response	Extensor	Flexor
Fasciculations	Absent	Present

Table 28.1.4 Localizing weakness based on examination

amyotrophic lateral sclerosis, that affect alpha motor neurons in the anterior horn of the spinal cord. Some associations between motor neuron disease and environmental exposures, including exposures to specific solvents and heavy metals, have been observed.^{13,14} The tongue, served by cranial nerve XII, can be a good place to detect the resulting weakness and atrophy. Fasciculations can also be seen, though they can be difficult to distinguish from other movements. The task is made easier by examining the tongue while it is resting in the mouth, rather than protruded. For unclear reasons, muscles that serve eye movements are typically spared.

Examination of the motor system should include assessments of the strength, bulk, and tone of the muscles. All three elements must be considered, because although weakness suggests a problem in the motor system, it may reflect dysfunction of the muscle itself, the neuromuscular junction, the peripheral nerve, the anterior horn cell, or the so-called upper motor neuron. Localization within this pathway strongly influences diagnostic considerations and the ordering of ancillary tests.

Although the lower (alpha) motor neuron is influenced by many higher centers and descending systems, the simplified model distinguishing between upper and lower motor neuron lesions is useful clinically. Findings on the examination often suggest localization to the upper or lower motor neuron (Table 28.1.4). Both categories involve weakness. Diminished bulk, or atrophy, can also occur with either type of lesion, although it is usually more marked with a lower motor neuron lesion. In addition to reflex abnormalities (discussed later), the most useful feature in separating the two categories is a change in muscle tone. Tone is best assessed with passive movements of the limb, usually the upper extremity. It is important for the patient to be fully co-operative to avoid a superimposed component of volitional tone, which can confound interpretation. Lower motor neuron lesions, involving the motor system from the anterior horn cell to the muscle proper, produce decreased muscle tone, or hypotonia. Upper motor neuron lesions, involving higher centers and descending systems that modulate activity of the anterior horn cell, produce increased tone, or hypertonia. Two exceptions are those related to cerebellar dysfunction and to certain lesions of the basal ganglia, which can produce hypotonia.

The increased tone seen with involvement of the descending motor tracts is called spasticity. It is characterized by a resistance to passive movement, which is variable throughout the range of movement and depends on the speed of movement. Unlike spasticity, rigidity is

characterized by increased tone that does not vary throughout the range of movement or with the speed of movement. Rigidity usually results from basal ganglion dysfunction.

Spasticity may reflect a toxin-related dysfunction of the descending tracts that directly influences the lower motor neuron, producing a clinical myelopathy. These tracts contain some of the longest axons in the nervous system, and are thus vulnerable to some of the same agents that cause length-dependent peripheral axonopathy, such as tri-ortho-cresyl-phosphate.^{15,16} Nitrous oxide is another agent that can damage central tracts, giving a clinical picture similar to that seen with vitamin B₁₂ deficiency,¹⁷ though this typically occurs only after repeated exposures, such as with substance abuse. Early after an exposure to such toxins, the signs and symptoms related to the peripheral nervous system injury may predominate, while only later does the injury to the CNS become evident.

Rigidity, reflecting dysfunction in central motor systems that do not directly influence the lower motor neuron, can also be related to neurotoxins. Rigidity is one of the cardinal manifestations of parkinsonism, reflecting dysfunction of the basal ganglion. The other features of this syndrome are bradykinesia with a paucity and slowness of movements, resting tremor with a typical frequency of 3–7 Hz, and postural instability with the potential for frequent falls. The diagnosis of parkinsonism is based on clinical assessment; ancillary tests are not helpful. Several neurotoxins can damage the neural inputs or outputs of the basal ganglion and result in this syndrome. Such selective neurotoxins include carbon monoxide, carbon disulfide, manganese, rotenone, and MPTP. The marked similarities between toxin-induced movement disorders and idiopathic Parkinson's disease have raised concerns that the two conditions may be related,^{5,18} as discussed in more detail later.

Rather than manifesting with rigidity and bradykinesia, injury to certain regions of the basal ganglion can manifest with the opposite picture: reduced tone and hyperkinesias. The hyperkinesias can manifest as a variety of involuntary movements involving the face, trunk, and limbs. Careful observation during the history and physical examination is usually enough to suspect such a movement disorder. The causes of such disorders are numerous, including genetic diseases such as Huntington's or Wilson's disease. Neurotoxic exposures can also produce this picture; for example, as an acute effect of a drug such as cocaine, or as a delayed effect of a drug such as haloperidol.^{19–21}

Tendon reflexes provide a quick screen, reflecting balance between the function of the upper and lower motor neuron. Increased tendon reflexes, especially in the setting of other findings of upper motor neuron dysfunction, strongly suggest a problem in the CNS. Initially reduced or absent tendon reflexes cannot rule out CNS involvement, because the injury to the peripheral nervous system that produces hyporeflexia may initially mask the manifestations of the concomitant CNS injury, as in the case of tri-ortho-cresyl-phosphate poisoning. Examination of the tendon reflexes can also suggest an injury to the

cerebellum. In these situations, pendular reflexes are present: the limb keeps swinging longer than usual following elicitation of the reflex. A reflex that gives strong evidence in favor of an upper motor neuron lesion is the extensor plantar response or the so-called Babinski sign.

Examination of sensation can help localize dysfunction to the peripheral as opposed to the central nervous system. Screening involves checking the patient's sensitivity to several modalities in several locations, including vibration in the distal lower extremities. Most patients with a normal sensory system can appreciate vibration in the great toe from a vigorously thumped 128-Hz frequency tuning fork for more than 10 seconds. Typically, findings on the sensory examination that point to a problem in the CNS do not suggest a neurotoxic lesion. Thus, the dissociated sensory loss of a spinal cord syrinx or the crossed sensory changes of a brainstem stroke exclude an etiology related to a neurotoxin. In patients in whom the sensory examination shows a stocking-glove type of reduced sensation, a diffuse peripheral polyneuropathy should be suspected, which can be metabolic or toxin induced.

The presence of incoordination on the physical examination is non-specific. For coordination to be normal, many of the aspects of the motor and sensory function already discussed must be intact. Incoordination could indicate a problem in the CNS, the peripheral nervous system, or both. It could indicate a problem in the motor systems, sensory systems, or both. Incoordination can result from either acute or chronic intoxication. Despite its lack of specificity, incoordination is a sensitive screen for evidence of neurotoxic effects on the nervous system, because coordination testing reflects broadly the function of the nervous system.

Evaluation of coordination should include both the upper and lower extremities. Tasks should be carefully observed for speed, smoothness, and agility. For the upper extremities, the patient should move quickly from one target to another, e.g., finger to nose. For the lower extremities, the heel should be moved up and down the shin of the opposite leg. Rapid alternating movements, such as finger and toe tapping, or clapping first the front and then the back of one hand on another, should be evaluated. Gait should be observed first with the patient walking naturally and then with increasing difficulty by having the patient walk on heels and toes, tandem walk forward and in reverse, and in a semi-squat while holding a tandem position. Though computerized posturography has progressed as a tool for clinical assessment,^{22,23} incoordination is not easily quantified, and the decision about its presence or absence ultimately relies on clinical judgment.

Ancillary testing

Ancillary tests of CNS function can serve several purposes in the evaluation of patients suspected of having a neurotoxin-related disease. Most importantly, these tests can exclude other diseases. For example, imaging studies may

show focal abnormalities such as neoplasm or stroke that account for a patient's complaints. Tests can be used to help clarify uncertainties in the clinical presentation by demonstrating objective abnormalities underlying the patient's subjective descriptions. For example, a substantially elevated carboxyhemoglobin level may explain vague complaints of headache and decreased concentration resulting from occult carbon monoxide exposure. Ancillary tests can also be used as more sensitive screens for the effects of neurotoxins on the CNS than the routine history and physical examination. This benefit is particularly apparent in the evaluation of cognitive function, which can be rigorously assessed with neuropsychologic testing, to follow up screening findings on the MMSE. Finally, ancillary testing can be used to quantify neurologic deficits. Such measurements may be used to gauge the degree of impairment for compensation purposes, to assist with vocational counseling by providing a guide for what a patient may be able to accomplish with such deficits, and to provide a baseline from which to judge the clinical course of the illness or response to treatment. Ancillary tests will be considered in a few broad groups as follows:

- anatomic studies, such as computed tomographic (CT) scanning and magnetic resonance imaging (MRI) of the head;
- physiologic tests, such as elicitation and averaging of sensory-evoked potentials;
- functional assessments, such as neuropsychologic testing;
- bioassays, such as cholinesterase levels; and
- miscellaneous tests, such as positron emission tomography (PET).

Anatomic studies

Most neurotoxins do not produce injuries that can be detected by imaging studies that detail the anatomy of the brain and spinal cord. An exception is the group of toxins that can injure the basal ganglion and may result in bilateral abnormalities in the globus pallidus. In most circumstances, the clinician will use imaging studies to exclude other, non-neurotoxic diseases. CT scanning is an excellent screen for mass lesions, such as brain tumors, which will usually lead to symptoms or signs indicating a focal dysfunction of the brain. If the history and physical examination lack such findings, then the yield from CT scanning is low. As a screening test, MRI has proven to be more sensitive than CT scanning for most conditions.²⁴ MRI supplies more anatomic detail than does CT scanning; contrast agents can increase the sensitivity of both techniques. One situation in which MRI is particularly good is in detecting abnormalities of the white matter, so-called leukoencephalopathy.²⁵ Multiple sclerosis has many clinical presentations, and although most suggest focal or multifocal involvement of the brain or spinal cord, some could be confused with neurotoxin-related disease. Confusion is most apt to occur in distinguishing the chronic progressive forms of multiple sclerosis from a disease caused by a neurotoxin. In such cases, the presence of characteristic periventricular white matter hyperintensities may support

the diagnosis of multiple sclerosis. It is imperative that the medical history correlates with the imaging results, because in many cases the MRI may also be non-specific, showing abnormalities that are of uncertain significance. For instance, the finding of unidentified bright objects (UBOs) is common in otherwise normal people.

Toxins are often suspected in the differential diagnosis of cognitive decline or dementia. Imaging may be used to evaluate such patients, though it most commonly does not yield a specific diagnosis and cannot help distinguish whether or not dementia is related to a neurotoxin. Cerebral cortical atrophy, often demonstrated in such cases, does not correlate well with cognitive performance.²⁶ Atrophy is a non-specific finding that may look the same in Alzheimer's disease, Huntington's disease, or a solvent-related dementia.

One finding on imaging studies that suggests a neurotoxic etiology is bilateral and symmetric damage to the basal ganglion, most commonly involving the globus pallidus. These findings are of particular interest when the patient has clinical evidence of parkinsonism. Carbon monoxide, carbon disulfide, and manganese are examples of agents that can produce these lesions. The case of a 27-year-old man found unconscious in a parked recreational vehicle is illustrative. He had been using a small charcoal burner to keep warm and had suffered severe, acute carbon monoxide poisoning. The patient eventually regained consciousness but had parkinsonism, with bradykinesia, rigidity, and resting tremor. MRI showed bilateral symmetric hyperintensities in the globus pallidus, typical of what can be seen in such cases (Fig. 28.1.1).

Although CT scanning can demonstrate the bilateral abnormalities of the globus pallidus, MRI is the preferred method in these circumstances. However, there are some caveats to interpretation. First, the finding of bilateral basal ganglia abnormalities on imaging is not specific to a neurotoxic etiology: Wilson's disease and certain inherited mitochondrial disorders can have a similar appearance. Next, if the neurotoxin causes parkinsonism by selective damage to the substantia nigra, as occurs with MPTP, in contrast to widespread damage to the basal ganglia, such as with carbon monoxide, then the imaging may be unremarkable. Finally, although MRI abnormalities may be seen early in the course of disease, the findings may normalize over time, even when symptoms persist.

To summarize, the clinician suspecting that a patient whose history or physical examination findings suggest neurotoxic involvement of the brain or spinal cord should have low expectations about the imaging results. Nonetheless, given the broad differential diagnosis, which includes diseases like multiple sclerosis whose presentations can be non-specific, imaging is often necessary. Screening should be done with the most sensitive test, which is MRI. The clinician must be cautious not to overinterpret non-specific findings.

Physiologic tests

Physiologic dysfunction of the CNS may not be manifest by imaging tests. Tests that reflect physiologic rather than

Figure 28.1.1: Magnetic resonance imaging scan of a 27-year-old man with parkinsonism related to carbon monoxide poisoning. Axial (A) and coronal (B) spin density images of the brain, including basal ganglia, are shown. Hyperintensities are present in the lentiform, or lens-shaped, nucleus of the basal ganglion. The lentiform nucleus has two parts: (1) the more medial globus pallidus and (2) the more lateral putamen. Note involvement of the globus pallidus, with relative sparing of the putamen.

anatomic changes are useful in the evaluation of many diseases related to a neurotoxic exposure.

The electroencephalogram (EEG) is used to record the electrical activity of the brain. Many things can affect the EEG tracing, so changes rarely point to a specific cause. The EEG is also difficult to quantify, and subtle intoxication can lead to EEG changes that can be difficult to interpret. Spectral analysis techniques have been developed,²⁷ but although they have been used in epidemiologic studies, there remain considerable barriers to their effective application in most clinical situations.²⁸ Many toxins that affect brain function, such as organic solvents and heavy metals, will affect the appearance of the EEG diffusely. The changes that are most obvious on the EEG, such as diffuse slowing, are often associated with evidence of toxic encephalopathy on the neurologic examination, with alteration of cognition, coordination, or both. These diffuse findings can be contrasted with EEG evidence of focal brain dysfunction, which is typically not related to neurotoxins.

A common application of EEG testing is in the evaluation of seizures. Epilepsy can be diagnosed when the EEG tracing shows characteristic epileptiform discharges in the appropriate clinical setting. Generalized convulsions can be a manifestation of a neurotoxic exposure, such as to an organochlorine insecticide. However, the convulsions themselves do not necessarily indicate a diagnosis of epilepsy, which is defined by the recurrence of unprovoked

seizures. Unless the EEG is done around the time of a toxin-induced seizure, the tracing should be free of epileptiform activity.

Whereas quantitative information is difficult to obtain from a routine EEG, it is more readily obtained from evoked potentials. In these tests, a sensory stimulus is used to trigger a neural response. By averaging the response to many discrete stimuli, a time-linked sensory-evoked response can be detected. Although evoked potentials can provide quantitative information, many variables can confound interpretation and results are not specific. As always, the entire clinical scenario must be considered. Nonetheless, event-related potentials have shown great promise as sensitive indicators of brain dysfunction in population studies.²²

Functional information about the visual pathways can be obtained from visual-evoked potentials. Providing retinal function is normal, the results can provide an indication of dysfunction in the optic nerves. Although such optic nerve dysfunction could result from a neurotoxin, it may also result from a vitamin deficiency, a tumor, or a demyelinating disease. As in other parts of the nervous system, asymmetric involvement tends to favor etiologies other than those related to neurotoxins.

The brainstem auditory-evoked response (BAER) screens auditory pathways that are both peripheral and central, from the cochlea of the inner ear to the medial geniculate nucleus of the diencephalon. The most common

abnormalities related to toxic exposures involve injuries to the peripheral portions of this system.

Somatosensory-evoked potentials can be elicited by stimulation of peripheral nerves in the upper and lower extremities. Like the BAER, this test indicates the function of not only the peripheral, but also the centrally projecting sensory pathways. If the peripheral system is capable of carrying a signal, then the coexistence of central and peripheral involvement, as with tri-ortho-cresyl-phosphate poisoning, can be demonstrated with this test.

Functional assessments

The ultimate impact of neurologic disease is in terms of functional limitations. The neurologic examination itself is purposely organized into functional components. These basic maneuvers have been extended through a variety of functional assessments developed to recognize, characterize, and quantify functional deficits. In certain cases, tests of sensory threshold and posturography may be useful, though a detailed examination is generally adequate to detect clinically significant functional limitations. By far the most important for evaluating global cerebral changes within the CNS are assessments of neuropsychologic functioning.

Neuropsychologic testing is the best method to assess subtle abnormalities of cognitive function. The spectrum of neuropsychologic tests is great, and selection must be tailored to the particular situation. For instance, the tests administered to an individual with complaints of chronic memory problems may differ substantially from the tests used to screen a large number of workers in an epidemiologic study or from that used to monitor acutely exposed workers. When screening large numbers of persons, the test battery must be short. Some tests are hand administered, such as the Neurobehavioral Core Test Battery of the World Health Organization;²⁹ others are administered via a microcomputer, such as the Neurobehavioral Evaluation System.³⁰ These screens can typically be administered in 40 to 90 minutes. Although such screens may perform well for assessing and comparing groups of exposed persons, more extensive testing (typically lasting many hours) is performed for clinical evaluation of an individual patient.

Extensive neuropsychologic testing provides the most sensitive assessment of brain dysfunction. When dysfunction is identified, the testing can also indicate the degree of impairment, and where rehabilitation efforts should be focused. A baseline is also useful for comparison in subsequent testing: neurotoxic injury should stabilize following cessation of an exposure without further deterioration and with possible variable improvement, whereas problems related to neurodegenerative disorders, such as Alzheimer's disease, may be expected to worsen. Thus, repeated testing over time may be indicated depending on the disease course.

Many tests are available to evaluate the areas of memory, intelligence, executive function, personality, mood, and coordination. Two of the most widely used comprehensive sets of tests are the Halstead-Reitan Battery

and the Luria Nebraska Neuropsychological Battery. Although the latter has some advantages when dealing with patients who have minimal education or severe brain damage, the former may be a more sensitive screen for the subtle effects of a neurotoxin. Tests evaluating verbal memory, attention, visual tracking, and visual memory are particularly important for assessing neurotoxic injury. Many screens of personality and mood are available, but the most commonly used is the Minnesota Multiphasic Personality Inventory (MMPI). Several tests of coordination are available that assess motor speed, reaction time, dexterity, and balance. Some of the available tests are old and have well-established norms. Others, more recently developed, have the advantage of evaluating different functions in different ways, but are limited by a lack of established normative values.

Neuropsychologic testing should be performed by or under the supervision of a qualified neuropsychologist. The interpretation of the tests must be in the context of the patient's past education. Verbal performance is thought to be relatively resistant to the effect of neurotoxins on brain function, and it is often used as an estimate of pre-exposure function. Therefore, with an important neurotoxic exposure, evaluation of memory could elicit scores much lower than would be expected based on verbal performance. Psychologic factors can also affect test results, as can alcohol and drug abuse. Concurrent depression or anxiety can adversely affect test performance, and should be considered in the assessment of cognitive impairment. Such a situation could still be related to a workplace exposure as a secondary effect, if the exposure is the proximate cause of the psychologic condition.^{7,31}

Bioassays

Many clinical laboratory tests can be performed to evaluate the possibility that a patient has an illness related to a neurotoxin. The body's burden of some neurotoxins, such as lead or other metals, can be estimated based on levels in the blood or urine. For other neurotoxins, indirect measures are available, such as red blood cell cholinesterase activity in cases of organophosphate exposure or carboxyhemoglobin level in cases of active carbon monoxide exposure. For most neurotoxins, however, direct or indirect monitoring is not readily available. Most other tests of the blood, urine, or spinal fluid are aimed at evaluating other diagnostic possibilities. Multiple sclerosis and spirochetal diseases, such as syphilis and Lyme disease, can mimic almost any disease of the CNS, including those related to neurotoxins. Thus, developing and refining bioassays is an area of ongoing research interest.³²

Genetic screening represents the latest challenge in the application and interpretation of new bioassays. With the technologic innovations that have accompanied the human genome project have come an explosion of data regarding human genetic variability. Genetic polymorphisms are now thought to hold one of the keys to understanding differences between individuals in susceptibility to toxin-related diseases.³³ Candidate genes include the

enzyme systems responsible for bioactivation and detoxification of xenobiotics and the receptor and transporter systems involved in neurotransmission.⁵ The sheer quantity of data and its rapid rate of acquisition have produced significant pragmatic challenges for data storage and manipulation as well as statistical assessment, spurring development of the related field of bioinformatics. One early conclusion from this work is that the vast majority of diseases are multifactorial, involving the combined effects of several processes.

Miscellaneous tests

New technology is constantly evolving. Some applications, such as transcranial Doppler (TCD), will probably never be of much help in diagnosing neurotoxic diseases. Others, such as PET, single-photon emission computed tomography (SPECT), and functional magnetic resonance imaging (fMRI), may find a use in allowing direct assessment of the effects of specific neurotoxins on brain function. Still others, such as magnetic resonance spectroscopy³⁴ and magnetic resonance microscopy,³⁵ may help define the pharmacokinetic and pathologic effects of toxic exposures. Whether any of these new tests will have enough specificity to be useful for clinical diagnosis remains open to question.³⁶ Currently these tests are primarily useful as research tools.

CLASSIFICATION OF DISEASES OF THE CENTRAL NERVOUS SYSTEM RELATED TO NEUROTOXINS

Diffuse toxic encephalopathy

- Acute
- Chronic

Selective toxic encephalopathy

- Cell bodies
- Ion channels
- Neurotransmitter systems

The classification scheme presented here primarily emphasizes the clinical manifestations of toxic exposures to the CNS. While it would be most desirable to develop a concise scheme based entirely on each individual toxin's mechanism of action,³⁷ the multiplicity of known mechanisms for selected toxins, coupled with a limited database for most others, makes such an approach clinically impractical.³⁸ Although some selective toxins produce characteristic clinical syndromes, it remains more useful for diagnostic purposes to rely on a classification based on two features of the toxin's effects: anatomic distribution and time course.

The clinical manifestations of a toxin are related to which anatomic areas of the brain or spinal cord are compromised. Toxic encephalopathy is the phrase used to indicate a dysfunction of the brain caused by a toxic exposure. Toxic myelopathy is the phrase used to indicate toxin-related dysfunction of the spinal cord. For encephalopathies, the effects of toxins that are diffuse and

lead to non-specific clinical syndromes are distinguished from those that are selective and lead to specific clinical syndromes. The time course of neurotoxic injury often impacts on the reversibility of the effect. The nervous system is noted for its plasticity, or ability to compensate for subtle alterations of function. However, when tolerances are exceeded, more sustained or irreversible damage to the CNS may occur. This is very important, because under most circumstances, the brain and spinal cord lack the capacity to regenerate neurons.

While it would be possible to draw distinctions between the acute and chronic forms of both diffuse and selective encephalopathies, these distinctions will only be discussed in detail in the context of diffuse encephalopathy. The selective encephalopathies are instead categorized by toxic effects involving clearly established cellular mechanisms.

Diffuse toxic encephalopathy—acute

Acute diffuse toxic encephalopathy reflects a global cerebral dysfunction of rapid onset (typically days or weeks). It is a condition that many have experienced when they have felt the effects of an alcoholic beverage. There is nothing specific about these encephalopathies; virtually any organic solvent has the potential to produce such effects (see Chapter 40). The effects typically resolve completely, but if overwhelming can result in a non-specific chronic encephalopathy, as discussed in a later section.

Pathogenesis

Toxins producing an acute encephalopathy interfere with basic cell functions in the brain, although the exact mechanisms remain obscure for some agents. Typically, such toxins gain easy access to the brain, and thus have the ability to alter brain function rapidly. Although active transport systems exist to convey many compounds into the CNS, most of these agents gain entry because they are highly lipid soluble and can readily diffuse across membranes. Besides organic solvents, which can alter cellular membrane function, several gases can also affect brain function diffusely, including the gas anesthetics, carbon monoxide, hydrogen sulfide, and cyanide. Heavy metals can also cause acute encephalopathies, but this is more commonly associated with the organic metals (e.g., methyl mercury or tetraethyl lead) than with the inorganic ones (e.g., lead, arsenic, mercury, or thallium).

Clinical and diagnostic approach

The clinical manifestations of an acute diffuse toxic encephalopathy depend on the intensity of exposure. The symptoms and signs can range from mild euphoria with a normal examination, to stupor, coma, and death. The earliest manifestations are behavioral, with some alteration in mood typically reflecting disinhibition. Headache and seizures may also be relatively early manifestations. In general, the greater the exposure, the more severe the impairment of cerebral function, and suppression of level of consciousness. With moderate exposures, the physical examination shows evidence of the intoxication, such as

lateral gaze-evoked nystagmus and incoordination, with sloppy fine finger movements and gait ataxia. The cerebral cortex is more sensitive to these toxins than the brainstem; typically, even when consciousness is lost, brainstem function remains intact. Thus, the pupillary light responses, corneal reflexes, oculoccephalic reflex, gag reflex, and spontaneous respiration are preserved until late in the clinical course, unless some complication occurs. In the absence of asymmetric signs suggesting a focal brain injury, the combination of unconsciousness with intact brainstem function suggests a toxic or metabolic etiology. Aspiration with respiratory arrest or cardiotoxicity with hypotension may lead to further loss of function and death.

Diagnosis does not generally present a challenge for acute syndromes, because the exposure and clinical manifestations are closely linked in time. An accurate history, if it can be obtained, will usually indicate the diagnosis. However, because toxic and metabolic encephalopathies can be indistinguishable, blood should be sent for electrolyte and glucose levels, renal function tests, liver function tests, and, when appropriate, endocrinologic screens. Arterial blood gases may also be indicated, both to evaluate acid-base disturbances and to assess hypoxia or hypercarbia in order to guide decisions regarding ventilatory support.

If the patient presents at the time of maximal symptomatology, the toxin is most likely to be present systematically, with the greatest likelihood of detection. Because a detailed history is not always initially available, a high index of clinical suspicion should guide the selection of ancillary tests. Blood and urine toxicologic screens will detect most substances of abuse. Screens are more difficult for the types of exposures that would occur in the workplace. Most heavy metals can be detected, but most solvents cannot be detected using readily available tests. The presence of a solvent may be suggested by an elevated serum osmolality that is not explained by abnormal sodium, glucose, urea or ethanol levels, or by measuring metabolic levels. A carboxyhemoglobin level may be useful in detecting occult carbon monoxide, if the specimen is obtained at, or very soon following, the period of active exposure. Acute and convalescent cholinesterase activity levels are useful in documenting organophosphate exposure. While such confirmatory testing is desirable, a complete history is often adequate to establish a causal link between a toxic exposure and an acute clinical syndrome severe enough to require medical attention.

The postictal confusional state, following a generalized seizure or ongoing partial complex status epilepticus, can present with symptoms such as delirium that might be confused with toxic encephalopathy. In such situations, an EEG may be useful in establishing the proper diagnosis. The most difficult situation to interpret is when a neurotoxin lowers the seizure threshold in an individual with an underlying susceptibility for seizures. Thus, for some individuals, provoked seizures occur only in the setting of exposure to a neurotoxin, though the toxin may not be the only causal factor.

With a suggestive history and a physical examination that does not reveal focal brain dysfunction, further ancil-

lary testing is typically not needed. However, if questions exist about the history or physical examination, then imaging may be necessary. Other conditions can mimic a toxic-metabolic encephalopathy, including psychosis, meningitis, subarachnoid hemorrhage, head trauma, early central herniation syndrome, and multiple small cerebral emboli. For any of these conditions, brain imaging followed by sampling of the cerebrospinal fluid may be necessary.

Treatment and prognosis

As with most overdoses, treatment of an acute diffuse toxic encephalopathy is primarily supportive. The patient should be physically removed from the source of exposure, including removal of contaminated clothing and thorough cleansing of exposed skin. Vital functions, such as respiration and circulation, are supported until the toxin is cleared. Because most toxins causing these conditions act diffusely on the brain, specific antidotes are typically not available. Specific treatments are indicated for certain exposures, such as ethanol for methanol intoxication, induced methemoglobinemia for cyanide or hydrogen sulfide exposure, chelation for heavy-metal toxicity and high-dose oxygen (including possible hyperbaric therapy) for acute carbon monoxide poisoning.

For most of the toxins that act diffusely on the brain, recovery from a single or limited number of exposures is complete. The process of recovery is a reversal of the sequence described previously, with the level of consciousness gradually returning to normal. Withdrawal syndromes involving severe agitation and seizures are uncommon without repeated exposures. In severe cases the brain is damaged from a single exposure, when a chronic encephalopathy ensues. More often, the prognosis is a function of the cardiac and pulmonary decompensation that can complicate an acute diffuse toxic encephalopathy.

Specific agents

The syndrome of acute diffuse toxic encephalopathy is not specific. It may be caused by any neurotoxin that can gain ready access to the CNS. Such agents include solvents, metals, and gases (see Table 28.1.5). As the acute

Neurotoxin	Target	Clinical syndrome
Tetrodotoxin	Ion channel	Paralysis
Organochlorines	Ion channel	Paralysis
Organophosphate	Acetylcholinesterase	Cholinergic excess
MPTP*	Dopaminergic cells	Parkinsonism
Carbon monoxide	Globus pallidus	Parkinsonism
Carbon disulfide	Globus pallidus	Parkinsonism
Manganese	Globus pallidus	Parkinsonism
3-Nitropropionic acid	Basal ganglion	Dystonia
Domoic acid	Glutaminergic system	Amnesia
BOAA†	Glutaminergic system	Lathyrism
Organic mercury	Occipital cortex	Cortical blindness
Nitrous oxide	Spinal cord	Spastic paraparesis
Fluoroethyl acetate	Cerebellum	Ataxia
Rotenone	Mitochondrion	Parkinsonism

*1-Methyl-4-phenyl-1,2,3,6-tetrahydropyridine.

Table 28.1.5 Examples of selective neurotoxins

encephalopathy clears, evidence may emerge of a residual chronic encephalopathy, which is discussed in the next section.

Diffuse toxic encephalopathy—chronic

Chronic diffuse toxic encephalopathy represents persistent injury to the brain, as a result of cumulative or multiple repeated exposures (often over a period of months or years) or, rarely, a single massive exposure to a toxic that causes severe acute diffuse encephalopathy. Evidence exists to implicate numerous toxins causing acute toxin encephalopathy, such as solvents and metals, in producing a chronic diffuse toxic encephalopathy. With repeated episodes of acute encephalopathy, often over many months or years, persistent impairment can occur.

Pathogenesis

Although the mechanisms are not completely understood, continuous or repeated exposures can lead to an encephalopathic condition that can no longer be completely reversed, even though the toxin itself has cleared. This process is thought to reflect the fact that typical protective mechanisms have been damaged or overwhelmed. The resulting irreversible brain damage produces persistent neurologic dysfunction. It is likely that metabolic pathways for detoxifying and excreting exogenous toxins are involved.³⁹ These systems are known to be in a dynamic balance, responding to external factors through complex interactions that may result in relative excesses of toxic metabolites. Extensive evidence has accumulated regarding the mechanisms of oxidative stress and apoptosis in neurodegeneration.⁴⁰ These mechanisms may provide common final pathways for injury when activated by a variety of toxic exposures.

Clinical and diagnostic approach

The clinical manifestations of chronic diffuse toxic encephalopathy usually involve varying degrees of cognitive impairment. The earliest problems are often subtle, and include changes in behavior and mood. Alternatively, a toxin may produce cognitive dysfunction to which the patient responds emotionally. The clinician may recognize the emotional change, rather than cognitive difficulties, and consider psychiatric referral. In either case, the organic nature of the complaints must be recognized. Some agents have been considered to alter mood more commonly. For example, inorganic mercury (historically used in hat manufacture) has been associated with mania, typified by the Mad Hatter in *Alice in Wonderland*, while carbon disulfide has been associated with depression. Generalizations regarding mood effects are probably not justified; psychosocial factors unique to the exposed individual are likely more important in determining that individual's response.

With progressive dysfunction, cognitive impairment becomes more readily apparent in the history and physical examination. Complaints and examples of declining skills include trouble balancing a checkbook, difficulty

remembering appointments, and getting lost in conversations or while traveling. Unfortunately, the condition can remain unrecognized or attributed to other causes until it has advanced to the stage of frank dementia.

Much of the laboratory evaluation is devoted to excluding the rare, treatable causes of dementia. Exactly what constitutes an appropriate panel of screening tests has been debated.⁴¹ In the appropriate exposure scenario, a broader battery of testing is indicated. For example, evidence of exposure to heavy metals can be assessed directly by measuring levels in the blood or urine. Because these levels are more reflective of recent exposures, they may not adequately assess relevant past exposures or the body's accumulation of the metal (see Chapter 39). When the index of suspicion is high, a chelation challenge can be performed to exclude more completely the possibility of previous exposures, such as with lead. Unfortunately, such measurements are variable, making it crucial that clinical correlation guide appropriate treatment.⁴² The differential diagnosis of presenile or senile dementia of the Alzheimer's type should also be considered.

Treatment and prognosis

Specific therapies for chronic diffuse toxic encephalopathies are limited, as would be predicted with diffuse destruction of brain tissue that generally lacks the capacity to regenerate. The patient should be separated as soon as possible from the neurotoxic exposure, and, in the case of certain metals, chelation therapy can be considered in an attempt to reduce the body's accumulated burden of the toxin. Other agents that can further injure the brain should be strictly avoided, as it does not make sense to avoid one neurotoxin but to continue being exposed to others – e.g., alcohol use. Medications prescribed by physicians should be reviewed carefully to exclude those drugs whose effects might adversely impact cognitive function.

The prognosis for a return of cognitive function is poor. Even in the absence of further exposure, cognitive function may continue to decline with aging. On the other hand, changes in behavior and mood may be more amenable to treatment; consultation with a psychiatrist may be helpful, in this regard. Anxiety or depression can aggravate cognitive impairment, and treatment of psychologic factors may result in significant improvement. Cognitive therapy and strategies to improve organizational skills may be appropriate, and should be supervised by a trained neuropsychologist.

Specific agents

Similar to the acute diffuse toxic encephalopathy, clinical symptoms and signs of the chronic diffuse toxic encephalopathy are non-specific and are not associated exclusively with a particular exposure. Thus, the clinical appearance may be the same whether the exposure has been a solvent, such as toluene, or a metal, such as inorganic lead. Of note, such non-specific encephalopathies can also follow exposures to agents that have the potential to yield selective injuries with specific syndromes. For example, in some patients, exposure to carbon monoxide

results in a chronic diffuse toxic encephalopathy instead of the selective injury to the basal ganglia, discussed in the next section.

Selective toxic encephalopathy

Why some neurotoxins exert selective effects, injuring a particular part of the nervous system, remains uncertain in most cases. For instance, the globus pallidus is particularly sensitive to carbon monoxide, and the occipital cortex to mercury. For some of these toxins, selective effects reflect pathophysiologic actions through specific cellular mechanisms.³⁸ The resulting clinical syndromes can reflect either reduced function within the injured neurotransmitter system or a relative imbalance between the functions of remaining neurotransmitter systems. Although it is likely that selective encephalopathies reflect both nervous system-related and exposure-related factors, the reasons for selective vulnerability of specific brain regions are largely unknown.

One factor that may explain some of the variation in susceptibility is the timing of exposures relative to critical periods of nervous system development. The nervous system's many discrete neuronal populations and interacting systems continue to develop at variable rates throughout the first three decades of life. Toxic exposures may exert their most profound effects when the organism is in a particularly vulnerable stage, leading to problems that would not occur with exposures at other stages of life.⁴³ The most prominent example of this phenomenon is the susceptibility of infants to lead encephalopathy, which underscores the importance of thorough neurodevelopmental toxicology testing.⁴

Most of the toxins capable of producing an acute selective toxic encephalopathy act on neurons. While it is possible for any constituent of the CNS to be the target of a selective toxin, clinical examples of damage to the CNS's glial cells, myelin, or vasculature are uncommon and will not be discussed here. Rather, the discussion will concentrate on the toxins directed at the neuron itself, considering those acting on the neuron cell body, ion channels, neurotransmitter systems, or structural integrity. As opposed to the toxins leading to the non-specific encephalopathies described in the previous section, many of these toxins produce characteristic syndromes. Examples of some selective neurotoxins (Table 28.1.5) are discussed in the following section.

Cell bodies

Some neurologic diseases are characterized by pathologic findings involving loss of a particular population of neuronal cell bodies. For example, pigmented cells of the substantia nigra are lost in Parkinson's disease, anterior horn cells in amyotrophic lateral sclerosis, and pyramidal cells of the hippocampal formation in Alzheimer's disease. Although the initiating factors may not necessarily involve attack directly at the cell body, the loss of cell bodies is what distinguishes these diseases from others in which the pathophysiology primarily involves cellular dysfunction

rather than cellular death. The mechanisms of cell death activated in these diseases remain uncertain, but evidence implicating the related mechanisms of mitochondrial dysfunction, energy depletion, oxidative stress, and apoptosis continues to accumulate.^{40,44}

Perhaps the most prominent example of a selective neurotoxin is MPTP. Research on the effects of MPTP has revitalized interest in the basic mechanisms activated by selective neurotoxins in producing neurologic disease. These findings have raised substantial concerns regarding the contribution of toxins to degenerative diseases of the CNS. The distinct possibility exists that devastating illnesses such as Parkinson's disease, amyotrophic lateral sclerosis, Alzheimer's disease, and many others, whose causes have been considered idiopathic, are actually related to environmental toxins. The strength of these arguments is largely related to what has been learned from the MPTP model of Parkinson's disease.

MPTP became infamous as a meperidine derivative that some intravenous drug abusers mistakenly injected in the hope of achieving narcotic effects.⁴⁵ These individuals rapidly developed a condition virtually indistinguishable from idiopathic Parkinson's disease. MPTP was later shown to produce similar effects when given to certain animal species, and using those models, the mechanism of action of MPTP has been identified.⁴⁶ A key step involves its conversion by glial monoamine oxidase B to 1-methyl-4-phenylpyridinium ion (MPP⁺). Support for the concept of MPTP being a toxic precursor, or protoxin, is that inhibition of monoamine oxidase B can prevent the effects of MPTP. MPP⁺ has avid affinity for the dopamine transporter located at the terminal axons of dopaminergic neurons. It is thereby concentrated selectively in dopaminergic cells of the substantia nigra, activating a lethal biochemical cascade. Most intriguing from an occupational and environmental perspective is that MPP⁺ is a substance called cyperquat, used in the past as an herbicide and chemically related to paraquat, an herbicide that remains in common use. Even more compelling is a recent report describing the effects of rotenone, a common pesticide and mitochondrial complex I inhibitor.⁴⁷ With chronic, systemic exposures to rotenone, rats developed a neurodegenerative disease with pathologic findings comparable to human Parkinson's disease patients.⁴⁸

Elucidation of the mechanism for neurotoxic injury related to MPTP raises the possibility that other neurotoxins could affect selective neuronal populations, resulting in clinical manifestations of neurodegenerative diseases. An apparent inconsistency is that these diseases usually manifest as progressive disorders in later life, whereas the most intense chemical exposures proposed to cause them probably occur over a limited period, at an earlier age. This inconsistency may be explained through the combined effects of aging and exposure to a selective toxin (Fig. 28.1.2). Later in life, neurons begin to die, presumably as a part of natural aging. Normally, the excess of neurons in the brain protects against the development of symptoms. However, the loss of neurons may be more important if a proportion of the available cells have been eliminated by an earlier exposure. In

Figure 28.1.2: Hypothetical loss of neurons with exposure to a selective neurotoxin. The loss may be so great that the threshold for symptomatic disease is crossed at the time of an acute exposure (option 1). Alternatively, not enough neurons may be destroyed to produce symptomatic disease acutely. But with further loss due to increased vulnerability (option 2) or to aging alone (option 3), the threshold for symptomatic disease may be crossed. (Modified from Langston JW. Predicting Parkinson's disease. *Neurology* 1990; 40(Suppl 3):70-74.)

this case, the subsequent age-related loss of cells may lead to a point where a threshold is passed. Beyond this threshold, the loss of cells leads to clinically apparent disease that slowly progresses as the aging process continues. Alternatively, the toxin may have made the cells more vulnerable to the effects of aging, resulting in accelerated senescence. Such hypotheses have generated interest in many idiopathic degenerative diseases of the brain and spinal cord, as conditions that are potentially related to environmental toxins, and prompted a search for a multifactorial model to explain why some individuals are more susceptible to neurotoxic effects.

Ion channels

Normal nervous system function depends intimately on membrane-associated ion channels. Consequently, brain function can be severely disrupted when ion channels are affected by a neurotoxin. Some of the most potent biologic toxins have ion channels as their target.⁴⁹⁻⁵² Some of these channel blockers include tetrodotoxin from puffer fish and saxitoxin from shellfish contaminated by a red tide. Other toxins potentiate channel function by increasing either the frequency or duration of channel openings, thereby increasing ionic permeability. Examples include ciguatoxin from certain marine fish, and some insecticides, including organochlorines and pyrethrins.

Biologic toxins are typically found in specific geographic areas, and although the clinical syndrome may suggest the diagnosis, these conditions are so rare that a high index of suspicion and thorough history are the keys to diagnosis. A greater threat is probably associated with insecticides, because of their widespread use. With any toxin that affects membrane channels, sensory symptoms around the mouth and face can be the earliest manifestations. With higher exposures, sensory symptoms become more widespread and motor signs of intoxication develop.

Seizures can also occur, especially with organochlorine pesticides. With severe poisoning, paralysis and respiratory arrest may intervene, resulting in death. Treatment is usually supportive, and, assuming no complication such as cardiopulmonary arrest has occurred, recovery may be complete.

Neurotransmitter systems

The number and diversity of known neurotransmitter systems have steadily increased. These systems provide a direct means by which a toxin can produce selective dysfunction of the CNS. Regulation of synaptic neurotransmission is complex, and any aspect can become the target of a toxin. Thus, a toxin can act to block or stimulate a postsynaptic receptor, block or be taken up by a synaptic transport system, or block transmitter degradation enzymes. Many of these effects occur with pharmaceutical agents commonly used in clinical practice. More relevant to the current discussion are the effects of naturally occurring biologic toxins and synthetic chemicals encountered in occupational settings and as environmental contaminants.

Cholinergic system One of the most well-characterized neurotransmitter systems is the cholinergic system. Acute cholinergic dysfunction produces a set of distinct clinical syndromes, characterized by relative excess or deficiency of cholinergic activity. A number of toxins can produce excess activation of the cholinergic system. The hyperactivity can occur directly with toxins acting as receptor agonists, such as those found in certain species of mushrooms (e.g. *Amanita muscaria*, for which a whole class of cholinergic receptors is named). Alternatively, activation may occur indirectly with toxins that inhibit acetylcholinesterase and thereby increase the availability of acetylcholine at the synapse. This is the mechanism of the organophosphate pesticides and organophosphorus chemical warfare agents (see Chapter 48). Still other toxins can inhibit the cholinergic system by acting as receptor blockers, such as in the plant species used in mystical rituals (e.g. *Datura stramonium*). Regardless of whether the toxin gains access to the CNS, effects on the autonomic nervous system and neuromuscular junction are common and can be used to define the severity of the poisoning.

The syndrome of cholinergic excess variably includes nausea, vomiting, diaphoresis, sialorrhea, lacrimation, abdominal cramps, diarrhea, bradycardia, miosis, and muscle fasciculations with weakness. The specific constellation of symptoms can vary between individuals. If the toxin gains access to the CNS, symptoms may include confusion, agitation, ataxia, tremor, and seizures. In some cases, the relative preponderance of peripheral symptoms can mask injury to the CNS. For example, the early course of poisoning with tri-ortho-cresyl-phosphate may be dominated by signs of lower motor neuron hypotonic weakness, later replaced by signs of upper motor neuron spasticity and incoordination.

Given the characteristic symptoms and signs, the diagnosis of cholinergic excess should be suspected and

empiric treatment initiated even in the absence of a detailed history. Atropine will block the muscarinic effects of excess acetylcholine but not the nicotinic effects. Certain oxime compounds, such as pralidoxime, can facilitate acetylcholinesterase reactivation, and should be used for poisoning involving prominent nicotinic symptoms. Although these treatments may reverse the acute manifestations of cholinergic excess, with severe poisoning some cognitive and behavioral symptoms may persist and new problems may arise at the neuromuscular junction.

With toxins that produce cholinergic inhibition, hallucinatory effects are common, and for some agents are the motivation to consume the toxin. Many of the other CNS manifestations are similar to cholinergic excess, including confusion, agitation, and seizures. On the other hand, systemic symptoms are in many ways opposite to those described earlier, and include atropine-like symptoms of flushing, dry skin, tachycardia, and mydriasis. Cholinergic drugs can be administered, but usually the altered state will clear with supportive therapy alone.

Catecholaminergic systems and parkinsonism The catecholaminergic neurotransmitter systems are common targets for selective agents. This makes them some of the most important systems for pharmaceutical drug actions. The systems can become hypoactive, as with dopamine receptor blockade by antipsychotic agents, or hyperactive, as when release of endogenous stores of norepinephrine is potentiated by amphetamines. Catecholamine transporters may also be targeted, as with serotonin selective reuptake inhibitors, providing another mechanism for increasing synaptic transmission. Although many other examples exist relevant to clinical pharmaceuticals and drug dependence, or occupational diseases, the most pertinent effects relate to diminished dopaminergic activity in the basal ganglia resulting in a parkinsonian syndrome.

The best understood toxin that produces parkinsonism is MPTP. As described earlier, its metabolite, MPP⁺, accesses neurons through a selective dopamine transporter. However, its ultimate effect is to decrease dopaminergic activity by killing cells in the substantia nigra. Other toxins that can lead to parkinsonism are carbon monoxide, carbon disulfide, and manganese.⁵³ Although this occurs more commonly following chronic exposures, the syndrome has been reported following a single severe exposure. Often, a diffuse encephalopathy occurs initially, with the more selective injury to the basal ganglia recognized later. For example, this has been described in patients from China with acute poisoning from ingesting mildewed sugar cane, in which the toxic agent has been identified as 3-nitropropionic acid.⁵⁴ While the severe poisoning initially produced a diffuse toxic encephalopathy, a fourth of survivors later demonstrated persistent dystonia, and MRI of these patients revealed hypodensities in the basal ganglia. In contrast to MPTP, the mechanism by which these agents induce parkinsonism involves a selective insult to the output cells of the basal ganglia located in the globus pallidus. Despite mechanistic differences, the clinical syndrome of parkinsonism is similar.

Regardless of the cause, a trial of dopaminergic drugs for bradykinesia and rigidity, or anticholinergic drugs for tremors, may be efficacious.

Glutamatergic system Another neurotransmitter system that has been studied extensively in recent years is the excitatory glutamatergic system. Excessive activation of glutamate receptors results in toxic levels of calcium influx, thereby mediating so-called excitatory neurotoxicity.⁵⁵ The complex intracellular events leading to cell death are not yet entirely clear, but the process may be involved in a variety of toxic, ischemic, and traumatic injuries to the CNS. This has motivated extensive research in the hope that modulation of such processes could provide therapeutic benefit. So far, though, clinical applications remain elusive.

Several neurotoxins are now recognized to act through hyperactivity of the glutamatergic system. One clinical syndrome was first reported in a group of patients from Canada who became acutely ill following ingestion of contaminated mussels.⁵⁶ The acute illness was characterized by headaches, seizures, hemiparesis, ophthalmoplegia, and alterations in the level of consciousness. In patients who recovered from the acute illness, chronic memory problems and peripheral polyneuropathy persisted. Neuropathologic examination in four patients who died demonstrated necrosis in the hippocampus, similar to that demonstrated in experimental animals given excitatory amino acid neurotransmitters. The offending agent has been identified as domoic acid, a potent excitotoxin.

Lathyrism is another disease related to a neurotoxin acting through the glutamatergic system. In times of famine, excessive consumption of the grass pea, *Lathyrus sativus* and related species, has led to a neurologic condition characterized by spastic paraparesis. The offending agent in the pea is thought to be beta-N-oxalylamino-L-alanine (BOAA). Like domoic acid, BOAA is proposed to mimic an excitatory neurotransmitter,⁵⁷ producing damage to the brain and spinal cord.

Amyotrophic lateral sclerosis shares some clinical features of lathyrism, suggesting that it might result from exposure to a substance that could kill or injure anterior horn cells. The increased incidence of motor neuron disease that occurs on Guam has been a mystery for years, and consumption of the cycad nut has been proposed as a cause of the condition. The cycad nut has a BOAA-like constituent, beta-N-methylamino-L-alanine. Although many uncertainties remain, the idea that an environmental excitotoxin contributes to this and other neurodegenerative diseases has gained wide acceptance.⁵⁸

Other systems Many other neurotransmitter systems exist, including those served by small molecules, such as gamma-aminobutyric acid (GABA) and adenosine; peptides, such as the endogenous opiates; and the recently recognized atypical transmitters, such as nitric oxide and D-lysine.⁵⁹ The roles for these systems in normal neurologic function are incompletely understood. Thus, while tempting, it seems premature to speculate about the potential

role for these transmitters in disease processes. Nonetheless, many drugs and toxins are known to affect these systems, and many more undoubtedly exist that are not yet recognized. History suggests that as basic information about these systems continues to accumulate, evidence for their involvement in neurotoxic processes will be forthcoming.

SUMMARY

Diseases affecting the CNS are challenging to diagnose and to treat, and those related to neurotoxins are no exception. The history and physical examination should allow the clinician to form and test hypotheses about the existence of neurotoxin-related disease. Problems of cognition and coordination should always prompt the clinician to question the patient about exposure to potential neurotoxins. Diagnostic hypotheses can be refined with judicious use of ancillary tests; however, these are frequently limited by lack of either sensitivity or specificity. Consultation with a neurologist may be useful in ruling out specific diagnoses.

A classification scheme that may be useful to a clinician involves a distinction between diffuse and selective effects, characterized further by time course and specific mechanism of toxic effect, where known. This scheme will need to be revised as more is learned about the detailed mechanism of action of neurotoxins and the interactions of the toxin with host factors, including age and genetic susceptibility. As this knowledge increases, it is likely that more and more diseases will be linked to neurotoxic exposures. Some may be previously unrecognized diseases, but more promising are the well-recognized degenerative diseases for which the cause is currently unknown and for which environmental exposures may play a role. Identification of such exposures may allow the opportunity for prevention of these often disabling and sometimes fatal degenerative diseases.

28.2 Disorders of the Peripheral Nervous System

Michael Pulley, Alan R Berger

The peripheral nervous system (PNS) is vulnerable to toxic and occupational injuries that may result in generalized polyneuropathies, focal compressive mononeuropathies, impaired neuromuscular transmission, or myopathy. Neurologic dysfunction may occur in isolation or in concert with other organ system involvement. Occasionally, the latter type of dysfunction suggests a toxic etiology (e.g., gastrointestinal symptoms in acute lead poisoning or alopecia and hyperkeratosis with subacute thallium poisoning). Most often, nervous system dysfunction occurs in isolation, its clinical manifestations being indistinguishable from naturally occurring disorders.

A detailed social and occupational history, and determination of the disease's course relative to the toxin exposure, is vital in establishing a link between the nervous system damage and an occupational or toxic insult. For these reasons, it is imperative that physicians caring for patients with potential occupational and environmental diseases have extensive knowledge of the way in which naturally occurring PNS diseases present, progress, and differ from those of occupational and toxic origin.

The peripheral neuropathies are a heterogeneous group of disorders; although much is known about the frequency of the different varieties of diabetic and hereditary neuropathies, there is little data concerning the overall frequency of PNS disease in the general population. A Centers for Disease Control survey of 5000 veterans, utilizing electrodiagnostic and strict clinical criteria, observed a 5% incidence of peripheral nerve dysfunction. A recent survey of 200 workers in a petrochemical facility, utilizing similar criteria, discovered 18% to have evidence of clinical or subclinical neuropathy; the overwhelming majority were traumatic-compressive. Others represented diabetic, alcoholic, and hereditary neuropathy seen in the general population. While symptomatic occupationally induced toxic neuropathy is relatively rare in North America, incidence has not been well characterized; asymptomatic toxic neuropathy may be more common, especially among exposed groups, e.g., exterminators and grouters.

CLINICAL EVALUATION

History

A focused neurologic, toxicologic, and occupational history is the cornerstone of the clinical evaluation. Because the clinical signs are usually insufficient to establish the etiology, specific elements of the history may be the only clue that suggests toxic or occupational causes. The examiner should inquire about both positive and negative symptoms relevant to motor, sensory, and autonomic function. A complete list of medications and family illnesses should be obtained. Attention should be paid to the following symptoms: (1) motor symptoms and signs, e.g., cramps, fasciculations, myokymia (undulating muscle movements), weakness, easy fatigability, and muscle wast-

ing; (2) sensory symptoms and signs, e.g., paresthesias (tingling or burning), dysesthesias (distorted sensations elicited by tactile stimuli), pain, numbness, anesthesia, and ataxia; and (3) autonomic symptoms, e.g., gustatory sweating, postural hypotension, gastrointestinal and genitourinary dysfunction and anhidrosis.

In patients suspected of having a peripheral neuropathy, the medical history may suggest not only the presence of neuropathy but also a pre-existing medical condition that could predispose the patient to either focal nerve entrapments or a generalized peripheral neuropathy (e.g. diabetes mellitus), that may suggest the underlying physiologic nature of the neuropathy. The clinical history may also indicate whether the process is generalized (as might be caused by toxins) or focal (as seen with occupationally related nerve lesions). The history may also disclose specific items that definitively identify a specific toxin or occupational insult.

Myopathic and neuromuscular junction dysfunction are manifested by weakness without sensory loss. Weakness is most prominent in the shoulder and pelvic girdle muscles and may be reported as difficulty climbing stairs or arising from a low chair. Getting out of a car is often difficult for patients with proximal weakness. Fatigability may result from impaired neuromuscular transmission. The historian should specifically inquire about the distribution of weakness (e.g., proximal versus distal and pelvic girdle versus shoulder), the presence or absence of pain and tenderness, sensory loss, and involvement of the extraocular muscles (manifested as ptosis or diplopia). The temporal profile should be determined, specifically the acuteness of onset, chronicity, and rapidity of progression. Almost all toxic neuropathies have their onset temporally related to exposure. It is a general rule in neurotoxicology that nerve dysfunction should begin around the time of ongoing or recent exposure and should eventually stabilize after exposure is terminated.

In some cases, prolonged low-level exposure to toxins may damage the PNS so insidiously that the patient either does not recognize the dysfunction or is not able to establish a temporal relationship between exposure and disease. Therefore, the history must carefully explore all possible exposures or inciting conditions, both by the compound's formal and common name and source (e.g., mercury and its lay term, 'thermometer tubes', or nitrous oxide and its common reference, 'sniffing the blue tank').

The occupational history should focus on habits that potentially predispose the patient to occupationally related nervous system disease (e.g., does the patient wear protective devices and change clothing before coming home; whether there is eating in the workplace). The health of coworkers, family members, and household pets should be inquired about; a similar illness might indicate a common exposure. Improvement of symptoms during time away from potential exposure (e.g., weekends or holidays away from the job) and the condition of the workplace (ventilation and drainage) are important items to be determined. In

addition, a complete list of occupational exposures should be obtained because, occasionally, a combination of toxins may be responsible. In some instances, a visit to the workplace is crucial in identifying a specific toxic or responsible environmental condition. In suspected iatrogenic or domestic toxicants, family members and friends should be questioned. A visit to the home may also be helpful. Specific questions regarding hobbies, food and water sources and recent pesticide applications or other chemical often yield crucial information.

Physical examination

The scope and depth of the physical examination are shaped by the information and differential diagnosis generated by the history. As an example, a history of occupational trauma suggests that a focal compressive neuropathy is likely and focuses the examination on potentially vulnerable nerves. Alternatively, a history indicating generalized nerve dysfunction directs the clinician towards probable polyneuropathy. Motor symptoms, without sensory loss, suggest muscle or neuromuscular junction dysfunction and mandate specific attention to proximal muscle strength and examination of extraocular muscles.

The neurologic examination is performed in the conventional manner; a determination should be made regarding the predominant modalities affected (motor, sensory, autonomic, or mixed) and the overall pattern, distribution, and severity of the deficits. Specific topographic patterns of peripheral nerve dysfunction include focal or multifocal, bilaterally symmetric, proximal versus distal, and upper versus lower extremity.

A brief bedside examination of mental status usually suffices when assessing patients suspected of having PNS disease. Questions should be included that examine orientation, short- and long-term memory, abstract thinking, calculation, and attention. An overall sense of the patient's mental status can often be obtained by the manner and attentiveness with which the patient relates the neurologic history. More subtle cognitive abnormalities are best identified by formal neuropsychologic testing (see Chapter 28.1).

The cranial nerve examination should especially focus on facial sensation and the strength of facial musculature. Because most neuropathic toxins produce a length-dependent distal axonopathy, facial sensation and muscle strength are spared until late in the disease course. Although facial numbness is a feature of trichlorethylene (TCE) intoxication, its presence may be related to a naturally occurring condition, such as Sjogren's syndrome or scleroderma, rather than a toxic neuropathy.

The motor examination should determine the topographic distribution of the deficit (e.g., multiple distal nerve segments, radicular or segmental, or limited to a few specific nerves). Most toxic insults produce generalized distal axonopathies; as such, weakness initially involves the distal legs with subsequent progression to the proximal leg muscles and hands. Findings that substantially differ from this, such as early proximal muscle weakness or hand involvement occurring prior to distal leg weakness, are less

consistent with most toxic neuropathies and suggest another diagnosis.

Weakness and/or atrophy in a single nerve distribution usually indicates a focal peripheral nerve lesion. The examination should determine whether all muscles of that nerve are affected or only those distal to potential entrapment sites. Aside from lead and TCE, most toxins do not cause focal nerve damage; such findings most often result from focal compression, which may or may not be caused by occupationally related trauma. Muscle atrophy suggests a chronic problem. Fasciculations are clinically obvious muscle twitchings, which, aside from suggesting a lower motor neuron process, may occur with lesions anywhere from the anterior horn cell to the distal nerve terminal.

The sensory examination should attempt to identify the predominant modality (and fiber size) affected. Large-fiber dysfunction involves loss of joint position sense, vibration, touch-pressure sensitivity, areflexia, sensory ataxia, and pseudoathetosis. Small-fiber dysfunction is characterized by a loss of pain and temperature sense, retained reflexes, and occasionally, autonomic dysfunction. In general, sensory abnormalities are most reliable when they correspond to appropriate patient complaints. Unfortunately, the sensory examination findings may be inconsistent or variable. Too much diagnostic emphasis should not be placed on inconsistent or neurologically inappropriate sensory findings. The presence of hyperesthesia (exaggerated response to sensory stimuli) or dysesthesia (unpleasant response to a normal non-noxious stimulus) should be noted. Mild sensory deficits are best appreciated when sensory stimuli are initially applied to areas of lesser sensitivity, and then the results are compared with those in corresponding normal areas.

Patterns of sensory deficits include a distal stocking-glove distribution (which would be most common in generalized neuropathies), segmental or dermatomal sensory loss (as occurs with radicular disease), or sensory loss in the distribution of one or more peripheral nerves. Most toxic polyneuropathies are of a mixed nature with all sensory modalities affected. The sensory examination should be correlated with the motor findings to determine whether a generalized or focal problem exists and to localize it topographically (e.g., anterior horn cell, ventral root, dorsal root ganglia, or peripheral nerve).

Tendon reflex testing should include the biceps (C5 and C6), brachioradialis (C5 and C6), triceps (C7), patella (L3 and L4), and Achilles (S1) reflexes. Reflex loss usually localizes the process to the PNS; in contrast, hyper-reflexia usually results from upper motor neuron lesions. In generalized axonal neuropathies, the initial tendon reflex to be diminished is the Achilles, followed by the patella and upper limb reflexes. Focal or asymmetric reflex loss suggests radicular or focal peripheral nerve disease. The presence or absence of a reflex, and its intensity, are poor indicators of disease severity, progression, or recovery. Patients often substantially recover sensory and motor function, yet have a poor return of tendon reflexes.

Examination of gait and stance is of critical importance in neurologic diagnosis. Patients with weakness of distal leg muscles may walk with a steppage gait as a result of bilateral

weakness of the ankle dorsiflexors. A waddling gait occurs in patients with proximal weakness. Severe large-fiber sensory loss may be initially manifested as gait instability, resulting in a wide-based stance and instability on standing with the eyes closed but not with eyes open (positive Romberg's test). Painful neuropathies may preclude the patient from walking; such individuals often walk on their toes to avoid tactile stimulation to their soles or have a slow, hesitant gait because of painful movements (antalgic gait). Tests of coordination are generally normal in patients with peripheral nerve disease. Severe sensory loss resulting in limb and gait ataxia should not be confused with cerebellar disease.

LABORATORY EVALUATION

Electrodiagnostic studies

The most critical laboratory investigation in evaluating peripheral neuropathies is the electrodiagnostic examination. Commonly referred to as nerve conduction velocity (NCV) and electromyography (EMG), the study consists of a nerve conduction portion, in which electrical stimulation is externally applied to the nerves to determine their conductive properties, and a needle EMG portion, which utilizes a sterile needle electrode, inserted directly into the muscle. Needle EMG assesses the electrical activity of a muscle and provides information regarding muscle function and motor unit integrity. Taken in concert, nerve conduction and needle EMG studies provide objective measurements of muscle, neuromuscular junction, and peripheral nerve function and are invaluable in diagnosing diseases of the PNS.

Techniques employed

Sensory conduction studies. The most sensitive electrophysiologic technique in evaluating peripheral neuropathies is the determination of sensory and mixed nerve conduction velocities and sensory potential amplitudes. Sensory conduction studies are performed by electrically stimulating either the pure sensory nerve or the mixed sensorimotor nerve. The recordings are made over the respective nerves, either distal (antidromic recording) or proximal (orthodromic recording) to the site of stimulation. Stimulation must always be supramaximal to ensure activation of all available sensory axons, and strict attention must be paid to limb temperature and proper positioning of recording and stimulating electrodes.

Sensory potentials may be difficult to obtain in elderly patients or those with peripheral nerve disease and usually require computer averaging to increase the signal-to-noise ratio. Information obtained from conventional nerve conduction studies predominantly reflects conduction within large-diameter sensory fibers. Degeneration of sensory axons is directly reflected by a diminution of sensory potential amplitudes. As such, amplitude abnormalities, rather than conduction velocities, tend to be the most sensitive indicator of an axonal peripheral neuropathy.

Segmental demyelination results in prolongation of distal latencies and slowed conduction velocity. Sensory

potentials are often temporally dispersed, resulting in complex polyphasic (serrated) potentials. Unlike neuropathies, preganglionic lesions (at or proximal to the root level) do not affect the distal sensory potential. Sensory conduction studies are therefore useful in distinguishing radicular disease from peripheral neuropathy.

Motor conduction studies. Motor conduction studies are performed by supramaximally stimulating mixed or motor nerves and recording the compound muscle action potential (CMAP) over the muscle's endplate region. Stimulation is at a proximal and distal site, and conduction velocity is determined for the intervening nerve segment. The amplitude of the CMAP represents the surface-recorded summation of multiple muscle fiber potentials, and as such, it parallels but does not directly correlate with the number of available motor axons. Because CMAPs are in the millivolt rather than the microvolt range (like sensory potentials), they are usually easier to obtain and do not require averaging techniques. Motor conduction velocities can be determined for any accessible nerve by varying the site of stimulation. Similar to sensory conduction, motor conduction studies generally reflect large-fiber function; the distal latency and conduction velocity reflect conduction in the fastest fibers.

All neuropathic lesions, including peripheral neuropathies, which result in axonal degeneration, will diminish CMAP amplitude. In most axonal sensorimotor neuropathies, changes in motor potential amplitudes lag behind those of sensory potentials. In axonal neuropathies, distal latencies and motor conduction velocities tend to remain unchanged until the loss of large-diameter, fast-conducting fibers necessitates conduction through only small-diameter fibers. In contrast, demyelinating neuropathies result in distal motor latency prolongation, slowed motor conduction velocities, and CMAP temporal dispersion; this is especially evident with proximal stimulation. Low-amplitude CMAPs with intact corresponding sensory potentials strongly suggest pathologic changes at or proximal to the root level. When motor or sensory conduction is focally slowed across a potential entrapment site, a compressive lesion should be suspected.

Needle EMG. Needle electrode recordings from normal and injured muscle provides crucial information regarding motor unit function. Resting normal muscle has little or no electrical activity aside from brief insertional discharges. Separation of the muscle fiber from its innervating nerve fiber (denervation) results in abnormal electrical activity, termed spontaneous activity (fibrillation or positive sharp wave potentials that occur with the needle at rest). The degree of spontaneous activity is only a rough guide to the extent of motor unit degeneration. Spontaneous activity is usually indicative of a neuropathic process, although it can also be seen in certain myopathies and, occasionally, in normal muscles.

Fasciculation potentials may be evident clinically and by needle EMG. They represent the involuntary and random firing of single motor units. They have little localizing value because they may occur with anterior horn cell

disease, radiculopathies, peripheral neuropathies, and a number of benign conditions.

Quantitative analysis of voluntary motor units (amplitude, duration, and degree of polyphasia) provides information regarding the chronicity of the neuropathic lesion or may suggest the presence of a myopathic process. Chronic motor unit reinnervation results in motor unit potentials (MUPs) that are increased in amplitude and prolonged in duration and may be polyphasic compared with those of normal units. This is in contrast to the small-amplitude, short-duration MUPs evident in many myopathies. Needle EMG also provides information regarding voluntary motor unit recruitment. Reduced recruitment is characteristic of most neuropathic conditions; myopathies tend to have normal motor unit recruitment despite clinical weakness. Because needle EMG analysis can be performed on multiple proximal and distal muscles, it is useful in determining the distribution and severity of a neuropathic process.

Quantitative sensory testing. Quantitative sensory testing (QST) is a non-invasive, painless technique to quantify vibration, temperature, and pain appreciation. It uses precisely measured and repeatable sensory stimuli to determine the absolute threshold of sensory appreciation. Several commercially available QST devices exist for each sensory modality to be quantified. QST is simple and can be administered by technicians. Accurate, age-controlled mean and standard deviation values are available. QST is especially recommended for rapid screening of large populations (e.g., workers at risk for toxic neuropathy) and/or longitudinal evaluations of patients at risk for subtle sensory dysfunction (e.g., cumulative trauma disorders). QST abnormalities may predate nerve conduction abnormalities in generalized peripheral neuropathies.

Nerve biopsy. The utility of nerve biopsy has been exaggerated. It has limited use in patients with generalized axonal toxic neuropathies and should be reserved for centers that have the expertise to examine and quantify the specimen fully. Nerve biopsy is usually performed on the sural nerve at the ankle and calf level. It is most helpful in identifying the etiology of multifocal neuropathies, such as amyloidosis, sarcoidosis, leprosy, and vasculitis. In general, nerve biopsy has little or no role in the evaluation of the patient with suspected toxic neuropathy because most of these entities result in axonal degeneration without specific diagnostic findings distinct from endocrine, metabolic, or nutritional neuropathies. Specific exceptions, such as suspected exposures resulting in giant axonal neuropathy, are discussed in the section on specific toxic neuropathy below.

PATHOPHYSIOLOGY OF PNS DISORDERS

Neurotoxic and occupational insults to the PNS usually produce syndromes that clinically mimic naturally occurring disorders. The PNS is relatively limited in the ways it

manifests injury. Certain insults tend to produce stereotypical disease manifestations; their recognition helps establish the nature of the neuropathic lesion.

Classification involves identifying the main site of neuropathic dysfunction (e.g., muscle, neuromuscular junction, or peripheral nerve, with differentiation between cell body, axon, and myelin) and the distribution of such lesions (e.g., proximal, distal symmetric, focal, multifocal, or segmental). The following is a brief summary of the generic types of peripheral nerve dysfunction, each of which may be caused by a number of metabolic, nutritional, infectious, and ischemic causes, as well as by toxins and trauma.

Symmetric generalized neuropathies

Distal axonopathies (central-peripheral axonopathy and dying back neuropathy)

The most common peripheral neuropathy that results from PNS insults, particularly toxin-induced injuries, is a symmetric distal axonopathy (Fig. 28.2.1). In many cases, the biochemical and pathophysiologic mechanisms are poorly understood. These neuropathies probably reflect failure of axonal transport, with resultant degeneration of vulnerable distal nerve segments, predominantly affecting large-diameter axons. Degeneration subsequently proceeds proximally toward the nerve cell body, both in the PNS and in central projections within the spinal cord.

Most distal symmetric axonopathies have a subacute onset with gradual progression. Neuropathies resulting from low-level toxin exposure may be relatively asymptomatic, with deficits apparent only to the physician on careful neurologic examination. Because the longest, largest diameter fibers are usually the most clinically affected, motor and sensory findings initially appear in the feet, only later moving proximally (length-dependent relationship). Sensory loss is initially in a stocking, and later glove, distribution. As the neuropathy worsens, the distal ends of intercostal nerves are affected, producing a cuirass, or shield, over the midthorax and abdomen. With extreme progression, the vertex of the head is affected. There is usually an early and symmetric loss of ankle reflexes; the more proximal reflexes may be spared until late in the disease. In most toxic neuropathies, sensory symptoms and signs initially predominate over motor deficits. Muscle wasting may occur in chronic cases, and trophic changes may be present, including loss of hair over the distal leg, skin ulceration, and loss of sweating in the feet.

Because recovery depends on axonal regrowth, complete recovery is often prolonged and slow. Axonal regeneration occurs at a rate of, on average, 2–3 mm/day. Even after removal from exposure, recovery may take months to years as the recovering nerves regenerate to their muscle end-organs through intact Schwann cell tubes, or uninjured motor axons supply collateral sprouts that innervate denervated muscle fibers. Function is restored in the reverse order to that lost; proximal muscles recover before distal muscles, and sensory loss recedes from proximal to distal levels. The clinical manifestations of concur-

Figure 28.2.1: The cardinal pathologic features of toxic distal axonopathy. The jagged lines (lightning bolts) indicate that the toxin is acting at multiple sites along motor and sensory axons in the peripheral nervous system (PNS) and central nervous system (CNS). Axon degeneration has moved proximally (dying-back) by the late stage. Recovery in the CNS is impeded by astroglial proliferation. (Adapted from Schaumburg HH, Spencer PS, Thomas PK, eds. *Disorders of peripheral nerves*. Philadelphia: FA Davis, 1983.)

rent degeneration of central axons may be initially masked by the lower motor neuron dysfunction but become clinically evident as peripheral nerve function recovers. The sequential manifestation of early PNS dysfunction, followed by central nervous system (CNS) symptoms as PNS function improves, is especially characteristic of some toxic neuropathies (e.g., organophosphates). Symptoms of CNS dysfunction include hyper-reflexia, Babinski's signs, and spastic tone.

Demyelinating neuropathies

Acquired demyelinating neuropathies (myelinopathies) are conditions in which the predominant lesions occur in the myelin sheath or Schwann cells (Fig. 28.2.2). Various degrees of associated axonal degeneration may accompany them. The most common example of an acquired demyelinating neuropathy is the Guillain-Barré syndrome (acute inflammatory demyelinating neuropathy, AIDP). Almost all toxins result in axonal rather than demyelinating neuropathies, with the notable exceptions of buckthorn toxin, diphtheria toxin, and perhexiline (Pexid).

Acquired demyelinating neuropathies usually have a subacute onset. Although initial clinical deficits usually involve the distal limbs, similar to axonopathies, the demyelinating neuropathies may be patchy, resulting in early proximal weakness, arm involvement before legs, and facial numbness. Early and diffuse areflexia is charac-

teristic. Unlike axonopathies, in which sensory symptoms predominate, myelinopathies may be predominantly motor. Sensory symptoms may be transient, mild, or inapparent. Large- rather than small-fiber modalities tend to be most severely affected. Occasionally, this large-fiber sensory loss results in limb and gait ataxia. Muscle wasting is usually minimal unless substantial axonal degeneration has occurred. Recovery not only begins earlier than with axonopathies but is usually more complete, owing to the greater number of intact axons. Signs of CNS dysfunction are only rarely present, resulting from concurrent demyelination within the CNS.

Neuronopathies

Injury to the cell body is termed neuronopathy; the clinical manifestations reflect dysfunction restricted to the segments innervated by the affected cell bodies. Neuronopathies are rarely caused by toxic insults. Motor, sensory, and autonomic neurons may be affected. Toxic neuronopathies, such as those from mercury, may affect the CNS or PNS, and neurons (Fig. 28.2.3); other causes of toxic neuronopathies include pyridoxine, megavitaminosis and doxorubicin (Adriamycin).

The pathologic basis is heterogeneous and, in most cases, poorly understood. Toxic neuronopathies, such as that from doxorubicin, probably result from disruption of sensory neuron nucleic acid metabolism with subsequent

Figure 28.2.2: The cardinal pathologic features of an inflammatory PNS myelinopathy. Axons are spared, as is CNS myelin. (Adapted from Schaumburg HH, Spencer PS, Thomas PK, eds. *Disorders of peripheral nerves*. Philadelphia: FA Davis, 1983.)

sensory axon degeneration. Dorsal root ganglia may be vulnerable to high molecular weight toxins because of a poorly formed blood–nerve barrier. The presence of fenestrated blood vessels in dorsal root ganglia increases vascular permeability and therefore toxin exposure.

Most neuronopathies are characterized by rapid or subacute onset of motor or sensory deficits that do not obey the length-dependent relationships seen with distal axonopathies. Initial sensory loss can occur anywhere; facial numbness occurring concurrently with sensory loss in the limbs is characteristic and reflects simultaneous involvement of cranial nerve and spinal dorsal root ganglia. Sensory loss is usually widespread, but strength is preserved. Although all sensory modalities are affected, vibration and position sense are the most severely impaired. Generalized areflexia is common and reflects loss of large-fiber function. Recovery is variable and often incomplete because of sensory neuron degeneration. Ganglion cells that are damaged but not killed may recover. Clinical recovery depends on the return of function within surviving neurons and collateral sprouting from intact sensory axons. Although CNS signs are not invariable, they may be present.

Focal (mononeuropathy) and multifocal neuropathies

Focal neuropathies may be caused by traumatic compression, chronic entrapment in fibro-osseous tunnels, traction

injuries, or ischemic injury, usually caused by small-vessel angiopathy (such as diabetes or necrotizing arteritis). Focal neuropathies are rare in toxic disease (exceptions are lead-related neuropathy, initially producing wrist drop, and TCE, producing trigeminal neuropathy). The most common focal neuropathies include:

1. Median nerve entrapment at the wrist or elbow.
2. Ulnar nerve entrapment at the elbow or wrist.
3. Radial nerve compression in the upper arm or forearm.

Focal nerve lesions can be classified by the degree of myelin and axonal injury. Various nomenclature systems have been proposed; regardless of which is used, each specifies the nature of the nerve injury as follows.

1. Mild injury in which myelin is damaged but the axon cylinders remain unaffected (Class I, neurapraxia).
2. More severe injury in which axonal continuity is lost but the nerve's connective tissue framework is maintained (Class II, axonotmesis).
3. Injury in which both nerve fibers and the connective tissue framework with varying degrees of damage (Class III, neurotmesis).

Aside from severe industrial accidents with open wounds, most occupationally related focal neuropathies are Class I and II. Some entrapments may be predisposed by an underlying, baseline condition. As an example, some patients with carpal tunnel syndrome (CTS) have congenitally small diameters of the carpal tunnel, a condition predisposing to median nerve entrapment. Focal neuropathies are charac-

Figure 28.2.3: The cardinal features of a rapidly involving toxic sensory neuronopathy. The jagged lines (lightning bolts) indicate that the toxin is directed at neurons in the dorsal root ganglion (DRG). Degeneration of these cells is accompanied by fragmentation and phagocytosis of their peripheral-central processes. The Schwann cells remain; there is no axonal regeneration. (Adapted from Schaumburg HH, Spencer PS, Thomas PK, eds. Disorders of peripheral nerves. Philadelphia: FA Davis, 1983.)

terized by sensory and motor deficits within the distribution of the involved nerve or nerves. Many entrapments, such as CTS, are associated with pain, which may bring the patient to medical attention. In some instances, the mononeuropathy may be symptomatic only during, or after, repeated movement or work-related activities.

Other entrapments, such as ulnar nerve lesions at the elbow or wrist, may be painless and present with weakness more than with sensory loss. Such cases may initially display advanced degrees of muscle atrophy because of the long delay in seeking medical attention. In focal neuropathies, only the segmental reflexes subserved by the involved nerve are affected. The degree of recovery generally depends on the underlying etiology (overuse, ganglion, fibrous band, hypertrophied muscle, or inflammation), the ability to avoid aggravating activities, and the degree of motor axon degeneration.

TOXIC AND OCCUPATIONAL PNS DISORDERS

Toxic peripheral neuropathies

Toxic polyneuropathies (TxPN) are relatively infrequent in North America. Most toxic polyneuropathies encountered in routine clinical practice are due to iatrogenic pharmaceutical intoxications, with occupational exposures less

common. The majority, and unfortunately the most difficult, cases of TxPN are individual intoxications due to small-scale occupational exposures, or intentional and homicidal ingestions.

The identification that a sporadic peripheral neuropathy results from toxin exposure in the occupational setting is often made difficult by an unclear exposure history. TxPN are usually distal axonopathies and thus clinically and electrophysiologically resemble neuropathies from metabolic abnormalities, nutritional deficiencies, or systemic illness. Clinically relevant and reliable toxicologic tests are often unavailable or unhelpful, either because the necessary laboratory tests are not available, or the substance is undetectable because of the delay between exposure and examination. When a naturally occurring medical cause is not readily apparent, diagnosis of a TxPN must be made with caution based on the principles discussed below (see following section).

The underlying pathology of many TxPN is a central-peripheral axonopathy.^{1,2} Our limited knowledge of the biochemical and pathophysiologic mechanisms of most neurotoxins has led to an overly simplified classification system according to compound class (e.g., solvents, metals). Such a classification is of limited clinical utility. A compound should not be presumed to be neurotoxic because of a superficial resemblance to a related known toxin of similar class; all compounds within the same class

are not necessarily neurotoxic (e.g., acrylamide monomer is capable of producing a devastating peripheral neuropathy, while the polymer does not). Structure–toxicity relationships are clear for some classes of substances, such as organophosphates and hydrocarbons.

Cardinal tenets of neurotoxic illness affecting the peripheral nervous system

The identification of a neurotoxic illness should satisfy, or at least not be inconsistent with, the following basic principles of neurotoxic disease.³ The key to correctly recognizing the presence of a TxPN does not depend on remembering the specific characteristics of the many potential neurotoxins, as much as understanding and applying these basic tenets.

Strong dose–response relationship. Most neurotoxins produce a consistent pattern of disease, commensurate with the dose and duration of exposure. Neurotoxins rarely cause focal or asymmetric deficits. Since most neurotoxins cause diffuse myelin and/or neuronal dysfunction, their related symptoms and signs are usually widespread and symmetric. In the case of TxPN, this usually means a relatively symmetric distal axonopathy with initial symptoms in the feet and proximal progression, with continued exposure. Less frequently does an occasional toxin cause strikingly asymmetric or focal dysfunction (e.g., lead and trichloroethylene).

Consistency of response. Although the same toxin may produce strikingly different clinical syndromes if the exposure dose or duration is different, a similar and consistent illness typically results in patients with similar exposures (though individual variation may occur). Neurotoxicity should be suspected when similar clinical manifestations occur in a group of individuals with a common chemical exposure.

Proximity of symptoms to exposure. Neurotoxic illness usually occurs concurrent with exposure or following a short latency. Neurologic symptoms do not generally begin months to years after exposure. The two most common exceptions are the 2–6-week delay following exposure to organophosphates and the occasional 2-month latency between cisplatin intoxication and onset of neuropathic symptoms.

In addition, the extent and severity of neuropathy are usually commensurate with the degree of toxin exposure. Thus, it is unlikely that a single, brief, low-level exposure will result in a devastating peripheral neuropathy.

Some lipid stored agents (e.g., chlorinated hydrocarbons) are detectable in fat biopsies years following exposure. Although this provides a valuable marker of previous exposure, there is no evidence that this state is associated with risk for future neurotoxicity, and attempts at removal or mobilizing the body burden are unnecessary.

Improvement usually follows cessation of exposure. Toxic polyneuropathies generally plateau and then gradually improve after removal of the neurotoxic agent. Some

degree of recovery is the rule, except in the most severely affected cases. A neuropathy that shows no improvement or continues to deteriorate, despite the cessation of exposure to a suspected neurotoxin, is less likely to be neurotoxic in nature. The clinical picture may become somewhat murky, however, in certain toxic axonopathies in which cessation of exposure may be followed by worsening of symptoms (coasting) for several weeks before recovery commences.

Confusing aspects of neurotoxic illness

Multiple clinical syndromes may result from different levels of exposure to a single toxin. Different exposure levels to the same substance may produce dramatically different syndromes. Most confusing is the bizarre constellation of symptoms that may arise from intoxication with intermediate levels of a neurotoxin. Examples include the different clinical syndromes produced by acute high-level and intermediate-level exposure, and prolonged low-level acrylamide intoxication. Exposures to high-level acrylamide causes early CNS dysfunction with drowsiness, disorientation, hallucinations, seizures, and severe truncal ataxia, followed by neuropathy of variable severity. In contrast, prolonged, lower-level exposure causes minimal CNS dysfunction but a marked peripheral neuropathy. Exposure to intermediate levels of acrylamide causes hallucinations, mental confusion and cognitive dysfunction, followed by sensory complaints affecting the distal limbs.

Another example is organophosphate poisoning in which there may be early, severe cholinergic symptoms resulting from excessive muscarinic receptor stimulation. Within 2 weeks generalized paralysis may occur with respiratory distress owing to nicotinic receptor blockade. After a few weeks, a distal axonopathy may be evident.

In some instances, a single compound may produce similar clinical symptoms at both high-level and low-level exposure, although different anatomic structures are affected. High-dose pyridoxine intoxication produces widespread sensory loss due to dorsal root ganglion dysfunction; low-level exposure produces similar symptoms but due to a distal axonopathy.

Asymptomatic disease. Prolonged, low-level exposure may occasionally produce widespread subclinical dysfunction. Clinical deficits may go unnoticed by the patient unless they perform a skilled job that requires fine-motor control or intact sensibility. Insidiously developing subclinical TxPN may occur in individuals who deny any disability.

Enhancement by chemical interaction. An agent without known neurotoxic activity may enhance the toxicity of a known neurotoxin that is present at a generally subtoxic level, a phenomenon sometimes termed the ‘bystander effect’. This phenomenon has raised the general public’s concern that the combined effects of multiple chemicals in hazardous waste disposal sites may be more toxic than their separate effects. Such sites may contain low, levels of

neurotoxic solvents, metals or pesticides, whose neurotoxicity may be potentiated by one or other of the chemicals present. Neurotoxic potentiation is illustrated by the epidemic of peripheral neuropathy which occurred in German youths who abused paint thinner containing n-hexane. Initially there were no instances of neuropathy, but when the paint thinner was reformulated by lowering the concentration of n-hexane and adding methyl ethyl ketone (MEK), there resulted an epidemic of severe distal axonopathy. Experimental evidence subsequently showed that while MEK by itself was not a significant neurotoxin, the compound dramatically potentiated the neurotoxic effects of n-hexane.

Chemical formula may not predict toxicity. The neurotoxic potential of a compound cannot be accurately predicted by its chemical formula. This is especially important to consider when evaluating cases of potential occupational exposure to chemicals that superficially resemble a known neurotoxin. An example is workers exposed to acrylamide polymer, a substance without associated neurotoxicity, who have been alarmed by healthcare providers familiar only with the effects of acrylamide monomer, a potent neurotoxin. Unpredictability exists because the underlying biochemical mechanisms and active metabolites of most neurotoxins are unknown.

Identification of toxic peripheral neuropathy

The presence of a toxic peripheral neuropathy is suggested by the following:

1. clinical suspicion raised by history and reinforced by compatible findings on physical exam;
2. lack of naturally occurring alternative explanations;
3. consistency with basic principles of neurotoxic disease (see above);
4. compatible laboratory findings (e.g., electrodiagnostic studies);
5. demonstration of elevated body burdens for a neurotoxic agent, (usually available only for active or recent exposures) or resolution of condition with removal from exposure.

The initial step is a suspicion raised by a thorough occupational history. Unfortunately, most toxic polyneuropathies are insidious in onset, and many patients are unable to discern a relationship between their symptoms and chronic, low-level, toxin exposure. Inquiry should focus on potential occupational, environmental, and iatrogenic exposures. The nature of the suspected toxin should focus the physical examination towards relevant deficits. Thus a suspicion of mercury poisoning should prompt a careful examination for tremor and mild cerebellar dysfunction. The role of the neurologic exam is to demonstrate that neurologic deficits are in a pattern and of a severity that is consistent with neurotoxic illness. Since the clinical deficits resulting from a TxPN are generally symmetric in distribution, the presence of multifocal deficits should suggest a diagnosis other than neurotoxic disease. In addition, since most TxPN affect mixed nerve function, finding a purely small-fiber neuropathy makes neurotoxic disease less likely.

Determination of body burdens

Several factors potentially limit the interpretation of screening levels for heavy metals. The toxin exposure may be too remote, allowing time for the offending agent to be cleared from the blood or other biologic specimen. In cases of prolonged exposure, the neurotoxin may be sequestered in various tissues and therefore not available to laboratory identification. With some chemicals, reliable reference ranges have not been established. In some cases, identification of the toxic form of a metal is required. Caution must thus be exercised when interpreting body burden results. An example is arsenic levels, which may be raised by recent shell food ingestion due to non-toxic organic forms. In such cases special testing may be required to assess the level of toxic inorganic arsenic. In some cases prolonged exposure (e.g., lead), or elevated levels in urine or serum after chelation, may increase the sensitivity of testing.

Electrodiagnostic assessment

Electrophysiologic findings should be consistent with a distal axonopathy or mixed axonal, demyelinating neuropathy. Only a few rare neuropathies, such as n-hexane, perihexiline, amiodarone, and early arsenic poisoning, have predominant slowing of conduction velocities.

Quantitative sensory testing

Quantitative thresholds for thermal and vibration appreciation have proven useful in documenting objective evidence of sensory impairment and monitoring the course of recovery or deterioration. These procedures are non-invasive and reproducible, and can be performed by a trained technician.

Systemic features suggestive of neurotoxic disease

The neuropathies resulting from most neurotoxins are remarkably similar in both their clinical and electrophysiologic characteristics. Occasionally, there may be systemic complaints or signs which suggest the nature of the neurotoxic insult. Usually these symptoms/signs are apparent with either acute high-level, or chronic low-level intoxication. The following clinical characteristics may be the identifying feature that suggests a TxPN.

- *Acrylamide*: dermal contact associated with contact dermatitis and/or excessive sweating of hands and feet.
- *Carbon disulfide*: chronic low-level exposure associated with a variety of behavioral and psychiatric abnormalities, along with peripheral neuropathy.
- *Ethylene oxide*: cognitive impairment and neuropathy with prolonged low-level exposure.
- *Hexacarbons*: acute, high-level exposure may mimic AIDP with prominent autonomic dysfunction.
- *Lead*: Mee's lines, blood abnormalities (basophilic stippling, anemia), gastrointestinal abnormalities, and predominantly a motor neuropathy.
- *Mercury*: tremor and ataxia with a predominantly sensory neuropathy.
- *Ethyl bromide*: corticospinal and cerebellar dysfunction along with an axonal neuropathy.

- *Organophosphate intoxication*: early cholinergic symptoms, with possible intermediate syndrome preceding neuropathy and late emergence of corticospinal tract dysfunction as the peripheral neuropathy resolves.
- *Polychlorinated biphenyls*: symmetric sensory neuropathy associated with brown acneiform skin eruptions (chloracne) and brown pigmented nails.
- *Thallium*: prominent GI distress with high-level exposure, alopecia, Mee's lines, hyperkeratosis with prolonged exposure, and sensory greater than motor neuropathy.

Specific toxic neuropathies

Metals

Excessive exposure to specific inorganic and organic metal compounds may cause peripheral nerve disease. Heavy metals are commonplace in industrial and agricultural settings. Exposure may be through inadvertent contamination or through voluntary ingestion, e.g., suicide attempts with arsenic or thallium. Two properties of metals are important in regard to the peripheral neuropathies they produce. The first is that metal compounds tend to be stored in a number of body organs (e.g., lead in bones). Delayed and gradual release of the toxin back into the circulation from these tissues even after cessation of exposure, may delay the time to recovery. The second property of metals is that, when present in sufficient quantity, they rarely affect the PNS in isolation. As such, systemic symptoms and signs related to hematopoietic, renal, and gastrointestinal dysfunction may accompany the peripheral neuropathy.

Arsenic

Acute arsenic poisoning classically occurred as a homicide or suicide, where a massive exposure was the usual case. However, chronic low-grade exposure, as well as occasional acute exposures, in the occupational setting also occur. Arsenic toxicity has been described in the smelting of lead and copper ore, mining, and the manufacture of integrated circuits or microchips. Non-occupational exposure may occur through contaminated well water, tainted illicit drugs, and the use of treated lumber (e.g., CCA). Arsenic gains entry to the body by inhalation, GI absorption and via dermal contact. The toxicity of arsenic may be related to its affinity for thiol groups. This affinity leads to binding with lipoic acid, which interferes with the conversion of pyruvate to acetyl CoA, and thus energy metabolism.⁴

Clinical considerations. The manifestations of arsenic toxicity depend on the level of exposure. Acute high-level exposure results in rapid onset of severe abdominal pain, vomiting and diarrhea. Cardiovascular effects include tachycardia, hypotension and vasomotor collapse with possible death. Poisoning may also cause CNS dysfunction that may be transient (psychosis, somnolence or stupor) or prolonged (behavioral and cognitive problems).⁵ If an individual survives acute high-level exposure, a neuropathy

manifests within about a week. Painful paresthesias and numbness are the predominant early symptoms beginning in the feet and then affecting the hands. Weakness soon follows and is also expressed in a length-dependent pattern, starting with the feet and later involving the hands.⁶ With high-dose exposure or inadequate treatment, the weakness may become severe and involve the respiratory muscles, mimicking Guillain-Barré syndrome. The deep tendon reflexes are depressed or absent early in the process.

Chronic low-level arsenic exposure results in dermatologic manifestations prior to overt clinical neuropathy. Patients may complain of non-specific symptoms such as anorexia, malaise, generalized weakness and vomiting. The dermatologic changes that follow include white transverse lines in the nails (Mee's lines), hyperkeratosis, hyperpigmentation of the skin, and irritation of the mucous membranes. Although the neuropathy is asymptomatic at this point, careful examination or electrophysiologic testing may reveal its presence. Continued exposure leads to development of symptomatic neuropathy. As with that caused by acute exposure, this is characterized by prominent sensory burning and numbness of the feet and later the hands.

Small and large sensory fibers are affected with resultant difficulties with proprioception in addition to the dysesthesias. Weakness tends to be mild and limited to the most distal muscles. Hematologic disturbances including symptoms of anemia and pancytopenia may also result from chronic arsenic exposure. Recovery is variable, often with mild persistent neuropathy. The neuropathy may continue to worsen for a period of weeks after removal from exposure (coasting) in both the acute and chronic neuropathies, and may result in significant residua.

Diagnostic considerations. Arsenic levels may be measured in the urine, and less effectively in the hair and nails. Urine arsenic levels may remain elevated for weeks after exposure. Levels greater than 25 µg per 24 hour urine specimen are abnormal unless there was recent seafood ingestion (a source of organic arsenic). Low-level long-term exposure, or exposure that has since ceased, may only be detected by measuring levels in the hair and nails, with limited reliability. Arsenic accumulates in these tissues due to binding with keratin. Blood arsenic levels are usually not helpful unless there is active exposure.

Nerve conduction studies reveal low amplitude or absent sensory responses. There is mild slowing of motor conduction velocities indicating loss of large, fast-conducting myelinated axons. EMG reveals active and chronic denervation in distal muscles.⁷

Treatment. Acute arsenic toxicity may be life threatening and treatment in an intensive care setting with aggressive fluid and electrolyte resuscitation is indicated with cardiovascular compromise. The primary consideration in chronic arsenic toxicity is terminating exposure. Removal of arsenic from the body is facilitated by chelation therapy. The agents used are British antilewisite (BAL or dimer-caprol) and dimercaptosuccinic acid (DMSA). BAL is a dithiol and allows excretion of arsenic by formation of a

non-toxic ring. The treatment should be started as soon as possible after poisoning and continued for several months. Unfortunately, the fully developed neuropathy is unlikely to respond to therapy.⁸

Lead

Lead toxicity has been a common problem in the past. Although elimination of lead-based paints and other environmental sources of contamination has reduced the frequency of lead intoxication, exposure may still occur, especially in the industrial setting. Occupational exposure has been reported in battery manufacturing, smelting plants, demolition, automobile radiator repair and working in indoor gun firing ranges. Paint ingestion is still a source of lead toxicity as is drinking 'moonshine' whiskey and burning batteries for heat. Both organic and inorganic lead causes toxicity. Lead gains access to the tissues via ingestion, inhalation or dermal contact. Lead interacts with carboxyl, sulfhydryl, amino and phosphate groups.⁹ This leads to disruption of the heme biosynthetic pathway and deficient activity of cytochromes, which are important for detoxification of harmful free radicals. Inorganic lead displaces calcium ions, disrupts ion transport through calcium channels, inhibits calcium adenosine triphosphatase activity, and results in accumulation of intracellular calcium. These factors likely play a role in the neurologic toxicity of lead.

Clinical considerations. Children most commonly display CNS dysfunction from lead intoxication. This may present as chronic cognitive dysfunction (developmental delay or loss of milestones) or an acute encephalopathy (see Chapter 28.1). Encephalopathy is also seen with acute, high-level exposure in adults; in both age groups dysfunction can progress to seizures, coma, or death.¹⁰ Although there may be some cognitive and behavioral dysfunction in adults with chronic, low-level, lead exposure, this is uncommon.

Peripheral neuropathy resulting from chronic lead exposure is most commonly seen in adults and rarely occurs in children. Lead neuropathy develops insidiously with chronic exposure. The manifestations are unusual in that motor dysfunction predominates and there may be few, if any, sensory symptoms or signs. The pattern is distal, symmetric weakness with atrophy and loss of deep tendon reflexes and occasionally fasciculations. The arms are involved preferentially in many cases and in generalized cases become affected relatively early. Although the older literature contained reports of focal neurologic deficits such as wrist drop, manifestations such as these are less common. It is thought that these may be due to secondary compression neuropathies. Although lower motor neuron damage is associated with lead exposure, no causal relationship has been demonstrated between lead exposure and development of idiopathic motor neuron syndromes such as amyotrophic lateral sclerosis.¹¹ Chronic lead exposure causes systemic toxicity in addition to neuropathy. Microcytic, hypochromic anemia is often seen, as are GI disturbances including constipation and abdominal pain. Other less common manifestations include renal dysfunction, fatigue, weight loss, and occasionally gout.

Diagnostic considerations. The electrophysiologic findings in lead neuropathy are controversial. In animal models, demyelination has been demonstrated, while in humans the physiology is generally axonal. Electromyographic evidence of active denervation and chronic motor unit reinnervation in distal muscles reflect the presence of axonal degeneration. Nerve conduction studies show evidence of sensory axon loss, even though sensory symptoms are minimal or absent. Compound motor action potential amplitudes are reduced in more severe cases. Nerve conduction studies may be abnormal before the appearance of symptoms.¹² The degree of abnormality correlates with the lead burden in the body.¹³ Somatosensory evoked potential (SSEP) amplitudes are correlated with blood lead levels. SSEP latencies have been reported to be prolonged in both central and peripheral nerve segments. Neuropsychologic testing reveals abnormalities in memory, attention and visuospatial functioning. Confirmation of current or past lead exposure is usually possible.

Laboratory evaluation reveals a microcytic, hypochromic anemia with basophilic stippling of erythrocytes. Urinary lead levels can be measured. Chelating agents that draw lead from soft tissues and allow for its excretion may increase the diagnostic sensitivity; however, they are not usually necessary for diagnosis. The ratio of the micrograms of lead excreted to milligrams of calcium ethylenediamine tetra-acetic acid (CaEDTA) administered should not exceed 0.6 and the 24-hour urinary lead level after chelation therapy (usually with CaEDTA) should not be greater than 1 mg.¹⁴

Treatment. The initial step is removal of the affected individual from further exposure. Treatment of lead intoxication is based on chelation. The goal is the mobilization of lead from the bone to allow elimination. Penicillamine, succimer, CaEDTA and BAL administered in short course are all effective chelating agents and improvement usually begins within 2 weeks (see Chapter 39.8). Oral agents (e.g., succimer) are usually adequate for milder cases, while combination therapy with EDTA and sometimes in combination with BAL is recommended for more severe intoxication that includes encephalopathy. Diazepam should be provided for treatment of seizures associated with lead toxicity although they are often refractory. In those cases that involve brain edema, mannitol, hyperventilation and fluid restriction should all be utilized to lower intracranial pressure. The mortality rate is high in those presenting with seizures and encephalopathy. Complete recovery from neuropathy is usual except in severe cases. The improvement typically begins 2 weeks after initiation of chelation therapy.

Mercury

Elemental mercury is used in thermometers, barometers and other gauges. Organic mercurial compounds have been used as a preservative in latex paints, in various disinfectants and are also used as industrial catalysts. Inorganic mercurial salts and elemental mercury are present in the

manufacture of chlorine, in dental amalgams, and in the natural gas industry. Outbreaks of mercury toxicity have been reported due to contaminated fish in Minamata Bay, Japan¹⁵ and in Iraq related to application of an organic mercury-containing fungicide to grain.¹⁶ Elemental mercury vapor is absorbed by inhalation. Mercury salts are absorbed through the skin and GI tract, and organic mercury is usually absorbed through the GI tract. While there is evidence that inhalation of low levels of mercury vapor occurs with mercury amalgam dental fillings, raising health concerns, no causal relationship between the presence of mercury amalgam dental fillings and clinical toxicity has been established to date.¹⁷

Clinical considerations. The form of mercury that one is exposed to determines the pattern of nervous system involvement and whether there are associated systemic symptoms. Although CNS dysfunction dominates, there are some reports of PNS effects. Elemental mercury is very lipid soluble and tends to cause more CNS involvement with little or no systemic signs. Low-level toxicity due to elemental mercury, known as micromercurialism, causes tremor, fatigue, GI dysfunction, anorexia and weight loss. Continued exposure leads to more prominent tremor that may involve the head, face and even the eyelids. Personality change, hyperexcitability and insomnia are other possible effects of chronic elemental mercury exposure. Mercury salts also cause systemic toxicity including GI symptoms and nephrotic syndrome. PNS involvement has been reported with exposure to all forms of mercury.

The relationship of mercury exposure to neuropathy is better established with mercury vapor than with organic mercury compounds. Mercury vapor exposure is associated with a subacute, motor neuropathy that may be confused with Guillain-Barré syndrome. However, electrophysiology reveals damage to motor axons rather than demyelination. There is usually a preceding irritation of the upper respiratory tract that may be mistaken for an infection. As with other forms of mercury exposure, mercury vapor may also cause neuropsychologic dysfunction. Organic mercury compounds such as methyl mercury cause tremor, hearing loss, constriction of visual fields, mental impairment and dysarthria with prolonged exposure. The other prominent symptom seen more often with organic mercury toxicity is sensory ataxia. This is thought to be due to damage of dorsal root ganglion neurons. Sensory neuron damage may be heralded by distal paresthesias, which progress more proximally and may involve the tongue.¹⁸ Complex organic mercurials are also associated with nephrotoxicity.

Diagnostic considerations. Diagnosis of mercury intoxication is based on eliciting the appropriate exposure history in the setting of a neurologic syndrome as described above. Mercury levels can be measured in urine, blood and hair with limited reliability in the latter. Blood mercury level is a good indicator of recent exposure while urine measurements including serial measurements (after administering penicillamine) are better for chronic exposure.¹⁹ Electrodiagnostic testing in cases of mercury intox-

ication has been reported to show a motor greater than sensory axonal neuropathy.²⁰ Nerve conduction studies may reveal evidence of a developing neuropathy in exposed workers prior to symptom onset.¹⁹

Treatment. Mercury intoxication is primarily treated by removal from exposure. Although excretion of mercury in the urine is increased by chelation with agents such as penicillamine or dimercaprol,²¹ it is not clear that this speeds recovery from the toxic effects. The prognosis is good for complete recovery in most cases, depending on severity of illness.

Thallium

Thallos salts were commonly used as pesticides and rodenticides in the past. Although rarely used now, accidental (mostly children) or homicidal poisoning continues to occur. Occupational thallium exposure is usually low-level and chronic, rather than acute and high level. Occupations that pose some risk include smelting plants, mines and cement factories. Consumption of contaminated food and water may also be a source of intoxication. Thallium is absorbed through the GI tract, by dermal contact or by inhalation. Thallium is distributed throughout the body as potassium would be and substitutes for it in reactions.^{22,23} However, the mechanism of toxicity has not been clearly elicited.

Clinical considerations. Thallium intoxication causes a distal, symmetric sensory greater than motor peripheral neuropathy. Pain is a prominent feature. Degeneration affects the distal portion of the longest axons initially and the large diameter sensory fibers are most susceptible. Involvement of small unmyelinated fibers may lead to a delayed autonomic neuropathy.²⁴

The manifestation of thallium neuropathy depends on the temporal course and intensity of exposure. The most common scenario is a massive, acute ingestion. Vomiting, abdominal pain and diarrhea occur within hours but may be delayed up to a day. Severe, burning distal paresthesias in the legs develop within 2–5 days and are accompanied by intense joint pains. Large and small fiber sensory modalities are affected and the sensory abnormalities include the hands and trunk relatively early. Although weakness is not usually a prominent complaint, it is frequently present on examination. Surprisingly, deep tendon reflexes tend to be preserved early in the disease process in spite of large fiber sensory loss. Cardiac and respiratory failure leading to death may also occur with massive ingestion. The mental status may decline to lethargy or coma. Although alopecia is the classic sign of thallium intoxication, it does not appear until approximately 15–39 days after ingestion and is not helpful in the acute setting. Alopecia is not specific for thallium poisoning and does not always occur. Renal insufficiency and paralytic ileus are other systemic manifestations sometimes seen with acute thallium poisoning. The presentation of an acute neuropathy with abdominal pain needs to be distinguished from acute intermittent porphyria and other metal poisonings (e.g., arsenic and lead). The recovery in acute thallium poisoning tends to be

incomplete. There is often residual CNS dysfunction. The recovery of the peripheral nerves is slow and there is often persistent sensory loss. In those with severe motor axon damage, weakness may also persist.

With a smaller initial ingestion, thallium neuropathy may present subacutely. Subacute thallium neuropathy evolves more slowly, beginning more than a week after exposure. Alopecia, hyperkeratosis and Mee's lines are more common. Other neurologic features reported with subacute thallium intoxication include cranial neuropathies, chorea and ataxia.²² The neuropathy is characterized by defects in all sensory modalities. Walking may be affected early on because of painful paresthesias in the feet. Although distal weakness is usually detected, the patient does not often complain of it and it is usually not severe. The deep tendon reflexes are slightly reduced or normal. Autonomic dysfunction may lead to hypertension and tachycardia. Subacute neuropathy tends to have a much better prognosis. With termination of exposure, most patients recover within 6 months. Hair regrowth begins earlier at about 10 weeks after withdrawal.

Diagnostic considerations. Thallium levels can be measured in urine, blood or body tissues. Sensitive methods capable of detecting microgram quantities are available. Although established blood levels that indicate toxicity are available, they do not reflect the total body burden, as thallium is sequestered in tissue. In cases without alopecia, a potassium chloride challenge will cause the urinary excretion of thallium to rise even when the baseline level in blood and urine is normal. Cerebrospinal fluid protein is normal in cases of thallium neuropathy. Nerve conduction studies demonstrate reduced sensory potential amplitudes with conduction velocity slowing. EMG shows evidence of acute and chronic motor axon degeneration. The electrophysiologic abnormalities can be used to follow the degree of peripheral nerve damage.²⁵

Treatment. GI elimination is enhanced by administration of Prussian blue or activated charcoal, which bind thallium in the gut.^{26,27} Laxatives are also helpful since constipation and paralytic ileus are frequently present. Forced diuresis or administration of potassium chloride enhances urinary excretion. Thallium has a half-life of 30 days in the body if no measures are taken to promote excretion.

Pesticides, herbicides and rodenticides

Organophosphates

Organophosphorous (OP) compounds are used as insecticides, antioxidants, petroleum additives, flame retardants, lubricants and plastic modifiers. The best characterized peripheral neuropathy caused by these compounds in humans is that due to triorthocresylphosphate (TOCP), although exposure to other OP such as parathion, chlorpyrifos, mipafox, trichlorfon and leptophos may cause a similar neuropathy. Intoxication is usually due to acci-

dental exposure from agricultural pesticide spraying. Individuals affected may be those mixing or applying the pesticide or those working in the fields shortly after spraying. OPs are absorbed through the respiratory and GI tracts as well as through the skin.²⁸ The action of OP is to irreversibly inhibit acetyl cholinesterase (AChE) in erythrocytes and nervous tissue by phosphorylation. Acetylcholine accumulates due to lack of degradation, leading to excessive stimulation of both muscarinic and nicotinic receptors. Most OP esters are quickly degraded in the environment. Pesticides containing OP are also intentionally ingested in suicide attempts.

Clinical considerations. The acute or type I OP syndrome is primarily due to excessive muscarinic cholinergic stimulation.²⁹ The effects are frequently seen within hours of exposure and are always present within one day. The specific OP and the degree of exposure determine the intensity of the acute syndrome. Characteristic symptoms include nausea, vomiting, diarrhea, bronchospasm, bradycardia, sweating, salivation, and micturition (see Chapter 48). Extreme intoxication leads to CNS involvement with fatigue, nervousness, emotional lability, decreased alertness, cognitive impairment, convulsions and coma (see Chapter 28.1). Prior OP exposure may increase susceptibility to developing the acute syndrome on subsequent exposure because of a decrease in functional AChE. The acute syndrome may have prominent mental status changes and other drug or toxin ingestion needs to be considered.

The type II or intermediate OP syndrome is the result of overstimulation of nicotinic ACh receptors in skeletal muscle.³⁰ The onset occurs within 12–96 hours of exposure. There may be a symptom-free interval of 1–4 days between the acute and intermediate syndromes. The initial feature is usually respiratory insufficiency. Proximal muscle and neck flexor weakness follow and distal extremity strength is usually preserved. Cranial muscles, including extraocular muscles, may be involved. Sensory function is unaffected. Dystonic posturing is occasionally seen. Recovery begins in the cranial muscles 5–15 days after exposure. It then proceeds from the respiratory muscles to the proximal muscles and lastly the neck flexors. Since atropine is specific for muscarinic receptors, it does not prevent or treat the intermediate syndrome. The differential diagnosis of the intermediate syndrome includes Guillain-Barré syndrome, periodic paralysis or a severe attack of myasthenia gravis.

Regardless of whether exposure has caused the type I or type II syndromes, a central-peripheral axonopathy may develop with exposure to some OPs. Central-peripheral axonopathy refers to a process that affects the distal portions of peripheral axons initially, but, with continued exposure, leads to damage of the distal portions of central axons. The delayed appearance of this neuropathy, 7–21 days after exposure, led to the phrase organophosphate-induced delayed polyneuropathy (OPIDP). This neuropathy is not related to the inhibition of AChE but rather to a distinct esterase localized to nervous tissue, termed neuropathy target esterase. Although the OPIDP is less frequent than

the cholinergic syndromes, it causes significant morbidity. Most agricultural OPs do not cause the OPIDP and those that cause subtle cholinergic symptoms seem more likely to cause delayed neuropathy. OPIDP frequently occurs in the setting of low-level, chronic exposure.

Although most toxic central-peripheral axonopathies are chronic, OPIDP is subacute. Symptoms are usually maximal within two weeks after onset. Initial manifestations include painful paresthesias in the feet and cramping pain in the calf muscles. Motor symptoms and signs are prominent and there is early weakness of the leg muscles including foot drop. The intrinsic hand muscles become involved next and the proximal muscles are spared until later in the course. Sensory loss can usually be detected with careful examination. Ataxia may be present, that is more severe than expected based on the degree of sensory loss and weakness. Although the ankle reflex is typically absent, the activity of the other reflexes is variable. The OPIDP needs to be distinguished from other toxic causes of a central-peripheral distal axonopathy.

Diagnostic considerations. Electrophysiologic testing is a very sensitive indicator of OP peripheral neurologic effects.³¹ Shortly after OP exposure, a single stimulus produces spontaneous repetitive motor action potentials (SRMAPs) following the initial compound motor action potential.³² While the ability to elicit SRMAPs is a sensitive marker of OP exposure, there is no correlation with the degree of intoxication. Once muscle weakness becomes evident, repetitive nerve stimulation produces decremental responses. In contrast to myasthenia gravis where the decrement is usually maximal by the fourth response, here it is most prominent by the second. With mild OP intoxication, rapid rates of stimulation may be necessary to demonstrate decrement, and there may be a subsequent incremental response. With high-level exposure, decrement is evident with slow rates of stimulation and SRMAPs may be absent.³¹

OPIDP is characterized electrophysiologically as a sensorimotor axonal neuropathy. Sensory nerve conduction abnormalities appear earlier and more prominently than motor nerve abnormalities, despite clinical motor symptoms. Sensory nerve action potentials are reduced in amplitude or absent, while motor conduction studies are normal or reveal minimal slowing of conduction velocity.³³ Needle EMG reveals evidence for acute and chronic denervation in the distal limb muscles. In the intermediate syndrome, EMG is normal, despite prominent muscle weakness.

Routine clinical laboratory findings are usually normal. Recent exposure to OP causes reduction in erythrocyte AChE levels. AChE levels less than 20% of baseline values are frequently associated with severe weakness. The wide range of normal erythrocyte AChE levels makes a single determination difficult to interpret. Serial measurements showing progressive decline in activity are more useful. The CSF protein level in OPIDP is normal or only mildly elevated.

Treatment. The acute and intermediate OP syndromes have a good prognosis as long as there is adequate supportive care. Although only 40–60% of AChE content is regen-

erated by 1 week after exposure, this is usually sufficient for functional recovery. Cognitive and behavioral abnormalities may persist after recovery from the acute syndrome.

Patients with mild OPIDP usually have excellent recovery. With more severe initial deficits, residual deficits such as claw hand deformity, foot drop or atrophy may persist. Damage of central axons may only become apparent after recovery from the peripheral neuropathy. Injury of distal portions of the corticospinal and spinocerebellar tracts may lead to spasticity or ataxia.

Vacor

N-3-pyridylmethyl-N-p-nitrophenyl urea (PNU) or vacor is a rodenticide that is structurally related to nicotinamide. Accidental or intentional ingestion is the most common form of exposure. This leads to a severe acute distal axonopathy with significant autonomic involvement. Vacor also damages the beta cells of the pancreas leading to acute diabetes mellitus. Massive ingestion leads to limb weakness and impairment of postural reflexes within the first hour. This rapidly progresses to severe generalized weakness including the cranial nerve innervated muscles, urinary retention and diabetic ketoacidosis. Those that survive the acute ingestion frequently continue to have endocrine and autonomic dysfunction. Motor weakness improves gradually over the course of months. The few autopsy studies reported have demonstrated wallerian-like degeneration in the peripheral nerves, roots and dorsal root ganglia.³⁴ Animal studies of vacor-induced neuropathy indicate defects of fast axonal transport in distal nerves.³⁵ There is also abnormal morphology of the neuromuscular junction. This impairment may explain the rapid onset of weakness. Although the precise biologic mechanism of vacor neuropathy is unclear, it can be prevented experimentally by administering nicotinamide.

Solvents

Carbon disulfide

Carbon disulfide is a clear liquid, which is a vapor at room temperature. Carbon disulfide is absorbed by inhalation, dermal contact and, although less common, can also be absorbed through the GI tract. It is used in the production of cellophane films and viscose rayon fibers (see Chapter 40). It is also a major metabolite in the breakdown of the drug disulfiram (antabuse), which is used as a deterrent for alcohol abuse. The toxicity of this compound is most likely related to its reactivity with amine, sulfhydryl and hydroxyl groups, which results in the formation of reactive sulfur atoms. Isothiocyanates are produced, which can covalently bind to and cross-link cytoskeletal proteins such as neurofilaments. This may be related to the formation of giant axonal swellings seen in experimental studies performed in rats. These are similar morphologically to those seen in hexacarbon and acrylamide neuropathies.

Clinical considerations. Acute or subacute high-level exposure results primarily in CNS dysfunction including

confusion, hallucinations, memory impairment, and emotional lability (see Chapter 28.1).³⁶ Chronic, low-level exposure causes a combination of peripheral neuropathy and CNS abnormalities. The neuropathy may be asymptomatic and only detected by electrophysiologic testing when exposure is low but, as the concentration increases, a progressive sensorimotor distal polyneuropathy emerges. This neuropathy produces distal numbness and weakness along with painful cramping in the legs. The knee and ankle reflexes are often absent. Continued exposure leads to involvement of the arms. CNS manifestations of prolonged exposure include headache, dizziness, depression, memory impairment and impaired sexual arousal. Exposed persons may also have extrapyramidal signs of tremor, bradykinesia, and cogwheel rigidity, as well as hemiparesis or spasticity.

Diagnostic considerations. Although CS₂ is difficult to measure, urinary levels of its metabolite, 2-triothiazolidine-4-carboxylic acid, have proved to be a sensitive measure of exposure. Nerve conduction studies reveal slowing of conduction velocities and prolongation of motor and sensory latencies. Needle electromyography reveals active and chronic denervation in distal leg muscles, reflecting axonal degeneration and chronic motor unit reinnervation.^{37,38} The spinal fluid profile is unremarkable.

Treatment. Early cessation of exposure is the key to prevent further decline. There may be a role for the use of pyridoxine to treat the neuropathy. The effects may be related to the reactivity of CS₂ with pyridoxine. The degree of recovery depends on the severity of dysfunction at the time of removal from exposure. In mild cases almost complete recovery from neuropathy and most of the CNS abnormalities can be expected. Occasionally, CNS recovery is incomplete, probably due to residual spinal cord damage. Severe neuropathy may not completely recover, and as many as a third may have symptoms and signs of neuropathy 10 years later.³⁸

***n*-Hexane and methyl-*n*-butyl ketone**

These compounds are clear, colorless, volatile liquids used as solvents (see Chapter 40). They are metabolized to the toxic compound 2,5 hexanedione.³⁹ Hexacarbons gain entry to the body via inhalation, dermal contact and, rarely, ingestion. Exposure occurs in the petroleum production and refining industries. They are also components of lacquers and glues, which are widely used in the shoe and cabinet making industries. Methyl-*n*-butyl ketone (MnBK) use in the manufacturing of plastic-coated and color-coated fabrics prompted an epidemic of peripheral neuropathy.⁴⁰ Intentional inhalation (glue sniffing) is also a cause of high-level hexacarbon exposure. Methyl ethyl ketone (MEK) is not significantly neurotoxic by itself, but is present in many solvent mixtures with *n*-hexane and MnBK, and may potentiate their neurotoxicity.

Clinical considerations. Isolated high-level acute exposure causes CNS depression and narcosis. However, repeated

massive exposure such as glue sniffing leads to a subacute, predominantly motor neuropathy with cranial nerve dysfunction.⁴¹ This neuropathy may be associated with autonomic dysfunction including impotence, hyper- or anhidrosis, and vasomotor instability. Chronic exposure to lower levels results in a slowly developing central-peripheral axonopathy that affects the sensory and motor systems in a length dependent fashion.⁴² Nerve fiber degeneration affects the distal portions of peripheral axons first, but with continued exposure leads to damage of distal corticospinal, dorsal column, and other central pathways. All sensory modalities are affected, beginning in the feet with dysfunction gradually progressing proximally with continued exposure. Numbness rarely progresses higher than the knee in spite of the eventual involvement of the hands, and pain is not a complaint. Although ankle reflexes are lost early in the course, the other reflexes are usually spared. Distal leg and arm weakness and atrophy occur with continued exposure. In severe cases, the neuropathy is complicated by malaise, weight loss, abdominal pain, and leg cramps. Worsening of symptoms after removal from exposure, a phenomenon described as 'coasting,' is common.

Diagnostic considerations. Electrophysiologic testing demonstrates a sensorimotor axonal neuropathy.⁴³ Active denervation is detected in distal muscles often before nerve conduction studies become abnormal. In severe cases, nerve conduction studies reveal marked slowing of distal motor conduction velocities, which is an unusual finding in other toxic neuropathies. Asymptomatic workers employed in factories where cases of solvent polyneuropathy have occurred have been demonstrated to have slowing of conduction velocities. The nerve biopsy reveals a very characteristic morphologic abnormality known as giant axonal swelling. This arises as a result of the accumulation of neurofilaments.⁴⁴ Giant axonal swellings are also seen with acrylamide and carbon disulfide exposure, and in the genetic giant axonal neuropathy.

The accumulation of neurofilamentous material is most prominent at the paranodal region, and is likely related to cross-linking and disruption of axonal transport. Spinal fluid protein is usually normal unless the nerve roots become involved, in which case CSF protein may be elevated. Because of the subacute presentation and the presence of conduction slowing, the neuropathy associated with repeated high-level hexacarbon exposure needs to be differentiated from Guillain-Barré syndrome.

Treatment. The only treatment is cessation of exposure to allow recovery. As mentioned above, symptoms frequently continue to worsen for 1–4 months after cessation of exposure. The 'coasting' phenomenon is possibly due to the lipid solubility of hexacarbons, which delays their elimination from the body. Measurement of 2,5-hexanedione in the urine can help detect exposure before significant toxicity occurs. Recovery depends on the severity of neuropathy. Patients with mild neuropathy usually make a complete recovery in less than a year. Residual

distal atrophy, weakness and sensory loss are not uncommon with severe neuropathies. The effects of central damage (spasticity, long-tract weakness) may only become evident after resolution of the neuropathy.

Trichloroethylene

The solvent trichloroethylene (TCE) is used as a degreasing agent, a cleaner for photographic equipment and lenses, and in the extraction of fats and oils from vegetables (see Chapter 40). It is also used in the dry cleaning and rubber production industries, and previously was used as an anesthetic agent. Toxicity may be related to a breakdown product, dichloroacetylene (DCA), rather than TCE itself. TCE is usually absorbed by inhalation and is very lipid soluble.

Clinical considerations. Acute exposure is the most common scenario and trigeminal nerve dysfunction is a frequent manifestation. The sensory loss is usually in the distribution of all three trigeminal divisions and there may be weakness of mastication. Other cranial neuropathies affecting the facial, optic, oculomotor and glossopharyngeal nerves have been reported. There is a questionable relationship to a distal sensorimotor peripheral neuropathy. Acute exposure to TCE also causes CNS dysfunction with altered mental status and ataxia. Chronic exposure has also been reported to cause cognitive dysfunction and peripheral neuropathy.

Diagnostic considerations. Trigeminal somatosensory evoked potentials have been used to measure the effects of TCE exposure. Abnormalities are reported in asymptomatic individuals exposed to TCE. Slowing of nerve conduction velocity in facial, trigeminal (blink) and extremity peripheral nerves has been reported. Pathologically, axon degeneration, cell loss in the cranial nerve nuclei, and myelin degeneration have been reported in autopsy studies.

Treatment. Removal of the individual from the exposure source is the first step. If ingested, lavage should be performed. The mental status changes usually resolve rapidly but facial numbness tends to persist. In one case, long-term follow-up 18 years later revealed continued facial sensory disturbance.

Allyl chloride

Allyl chloride is a reactive halogenated hydrocarbon that is used in the manufacture of glycerin and epoxy resin. Exposure to high levels for long duration results in a distal symmetric neuropathy. This is gradual in onset and presents with distal numbness and weakness along with reduced ankle reflexes.⁴⁵ Nerve conduction studies reveal prolonged distal latencies. EMG demonstrates active and chronic denervation in distal muscles. Cessation of exposure usually results in good recovery. Animal studies reveal abnormal accumulation of neurofilaments. There is also degeneration in the distal terminals of both peripheral and central axons.

Mixed solvents

A variety of solvent mixtures, including toluene, have been associated with electrophysiologic changes in peripheral (particularly autonomic) nerve function. Further research is required to assess the clinical and pathological impact of solvents on the peripheral nervous system. Electrophysiologic studies and trial removal from exposure should be considered in exposed individuals with persistent neuropathic symptoms.

Plastics

Acrylamide

Acrylamide is used in grouting agents for soil and sealing applications, and polyacrylamide is used as a flocculator in waste water treatment plants. Although acrylamide monomer is the toxic form, polyacrylamide (which is innocuous) may be contaminated by up to 2% monomer and therefore may be a source of toxicity. Absorption takes place by dermal contact, inhalation or ingestion. Acrylamide neuropathy is a popular experimental animal model for studying the processes of axonal transport, dying-back neuropathy and axonal swelling. Acrylamide appears to interfere with axonal transport^{46,47} resulting in an accumulation of neurofilaments and axonal swelling.^{48,49} The swelling is most prominent in the paranodal region, possibly due to the constriction of the axon at that point.

Clinical considerations. The manifestations of acrylamide toxicity depend on the degree and duration of exposure. The usual route of exposure is through the skin and thus a contact dermatitis is usually present prior to the clinical symptoms of neuropathy. In the setting of acute exposure, malaise, dizziness, anorexia and headache are often present. With high-level acute exposure, the neurologic picture includes encephalopathy with seizures and truncal ataxia followed by peripheral neuropathy. Early behavioral changes may be less apparent to the patient than others. In chronic, low-level exposure, the dermatitis persists but the CNS effects are not as prominent.

The neuropathy resulting from acrylamide is a classic example of a central-peripheral distal axonopathy.⁵⁰ Initial clinical manifestations include toe numbness and widespread hyporeflexia. Large fiber sensory dysfunction with loss of vibration and proprioception is common while pain and paresthesias are rare. Acute, high-level exposure often results in widespread autonomic dysfunction such as impairment of reflex changes in heart rate and blood pressure, vasomotor changes in fingers and toes, and excessive sweating. Overt autonomic dysfunction rarely occurs in chronic exposure and may be limited to excessive sweating of the hands and feet. Although sensory complaints dominate, motor and cerebellar deficits may be evident on physical examination. Cranial nerve function is unaffected.

Diagnostic considerations. Neurophysiologic testing reveals reduced amplitude sensory responses with preservation of motor amplitude and conduction velocity.⁵¹

These findings are characteristic of a distal axonopathy and in some instances the electrophysiologic abnormalities may precede the development of symptoms. The sural nerve biopsy correlates with the physiologic and clinical manifestations, showing reduced numbers of large diameter, thickly myelinated fibers.

Treatment. Preventing further exposure to acrylamide is the primary treatment modality. Acute ingestion should prompt gastric lavage to reduce levels of intoxication. Liver and renal failure may complicate recovery. Removal from exposure usually results in recovery if the neuropathy is mild. Some residual loss of vibratory sensation may be apparent. However, in the case of severe neuropathy, spasticity, ataxia, more profound sensory dysfunction and memory problems may remain. Central nervous system dysfunction, such as spasticity and upper motor neuron weakness may be obscured initially by peripheral nerve dysfunction. As nerve recovery ensues, clinical dysfunction may remain due to unresolved central nervous system dysfunction. Coasting, the worsening of symptoms after termination of exposure, may occur.

Dimethylaminopropionitrile (DMAPN)

DMAPN had been used as a catalyst in polymerization reactions until 1978. It was found to be responsible for an outbreak of toxic axonopathy in the production of polyurethane foams. Since that time, it is no longer used and no additional cases have been reported.

Clinical considerations. The peripheral neuropathy associated with DMAPN is very distinct in that there are prominent urinary symptoms that manifest prior to the onset of sensory or motor complaints.⁵² The degree of exposure determines the rapidity of onset of symptoms. The exposed individual often complains initially of urinary hesitancy and abdominal pain. This progresses to reduced frequency of urination, decreased urinary stream and incontinence. Sexual dysfunction follows with partial or complete impotence. About the same time, sensory symptoms develop in the feet. The sensory symptoms progress to involve the proximal legs and the hands while weakness develops in the distal legs. Abnormality of sensation to pain, temperature and touch in the sacral dermatomes is characteristic of DMAPN neuropathy. There is also loss of distal vibratory sensation but the reflexes are surprisingly well preserved. The preservation of reflexes, autonomic features and preferential loss of pain and temperature sensation suggest more prominent involvement of the small nerve fibers. However, the available morphologic data have not borne this out. Other than bladder and sexual abnormalities, other autonomic function is preserved. The cranial nerves are not affected. The differential diagnosis is primarily that of diabetic small-fiber neuropathy or amyloid neuropathy.

Diagnostic considerations. Urodynamic studies reveal hypocontractility of the bladder, consistent with autonomic nerve dysfunction. In mild cases of DMAPN neuropathy, electrodiagnostic testing may be normal. In

most cases, the sensory potential amplitudes are reduced in the lower extremities. Severe cases may demonstrate slowing of motor conduction velocity.

Treatment. Removal from exposure is the only form of treatment. The prognosis for recovery is good in young patients. Older individuals tend to have more persistent bladder and sexual dysfunction.

Gases

Methyl bromide

Methyl bromide is used in insecticides, fire extinguishers, refrigerants and fumigants. Acute, high-level exposure may be fatal. Chronic, high-level exposure to methyl bromide causes multifocal neurologic dysfunction involving the peripheral nerves, pyramidal tracts and cerebellum. The neuropathy usually appears after 3–7 months of exposure and is a distal sensorimotor polyneuropathy. Paresthesias in the distal extremities are the first symptoms. Pain and ataxia develop later. The optic nerves may be involved and color vision loss may reveal toxic exposure to methyl bromide at an early stage. Electrophysiologic testing reveals a distal, motor predominant neuropathy.⁵³ Sural nerve biopsy reveals loss of large myelinated axons. The cerebrospinal fluid is normal. The prognosis appears to be good in most cases, although recovery may take 6–8 months.

Ethylene oxide (EtO)

EtO is used in the sterilization of medical equipment, particularly that which is heat sensitive. After sterilization, the object must be allowed to aerate or residual EtO may be present. EtO is used in the production of ethylene glycol (antifreeze) and other chemical compounds, as well as the production of polyester fibers and polyethylene films. As this is a gaseous compound, the primary route of exposure is via inhalation.

Clinical considerations. Acute exposure causes respiratory tract and mucous membrane irritation as well as nausea, vomiting, headache, dizziness and anorexia. EtO exposure results in a distal sensorimotor axonopathy.⁵⁴ This may be seen after long duration, low-level exposure or with subacute, higher level exposure. Clinical symptoms include distal numbness and weakness, incoordination and ataxia. Sensory loss begins in the feet and, with continued exposure, begins to involve the hands. Weakness also begins distally and there is diffuse reduction of reflexes with the ankle jerks usually absent. Chronic exposure also causes CNS dysfunction including memory and concentration problems, as well as dysarthria and increased tone. Removal from exposure is the only therapy. There is usually a gradual recovery from the neuropathy once exposure is terminated.

Diagnostic considerations. Electrophysiologic testing is consistent with a distal axonopathy. EMG reveals active and chronic denervation changes in distal muscles. Nerve

conduction studies demonstrate reduced amplitude sensory and motor potentials with normal conduction velocity or only mild slowing. Nerve conduction abnormalities may appear prior to the onset of symptoms in exposed individuals. Sural nerve biopsy shows evidence of axon degeneration.

Polychlorinated biphenyls (PCBs)

PCBs have previously been used in electrical insulation as well as plasticizers (see Chapter 45). Although there is a lot of discussion about the toxicity of PCBs, neurotoxicity associated with specific congeners has not been well characterized. The use of PCBs was banned in the 1970s but contaminated products remain. Although PCB contamination of waterways and marine life is the most common source of exposure, there are no reported cases of toxicity as a result. Neuropathy caused by PCBs has been reported in an outbreak caused by contaminated cooking oil in Taiwan. Most cases reported more recently have been electrical workers involved in the removal of PCB contaminated transformers. PCBs are very lipid soluble and may remain in the tissues long after removal from exposure.

Clinical considerations. The peripheral neuropathy associated with PCB exposure is a distal symmetric sensorimotor neuropathy.⁵⁵ Encephalopathy is usually coexistent with neuropathy. Worsening of symptoms after termination of exposure has been described. Removal from exposure usually results in improvement. Most patients have some persistent deficit several years later.

Diagnostic considerations. Nerve conduction studies demonstrate significant slowing of sensory and motor nerves. Although PCB levels in the blood can be obtained, they do not correlate with the presence of neurologic symptoms.

FOCAL NERVE INJURIES

(See also Chapter 23.3)

Radial nerve

Source of injury

Most radial nerve injuries result from external trauma. The radial nerve may be damaged in the axilla by lacerations, crutch use, missile wounds, or pressure from the head of a sleeping person ('lover's Saturday night palsy'). Proximal nerve injury affects the triceps muscle and weakens forearm extension. The most frequent radial nerve lesion is compression of the nerve against the middle third of the humerus. These are usually Class I lesions with predominantly conduction block. Severe weakness with total paralysis of wrist and finger extensors may occur.

Radial nerve entrapment may result from a fibrous band derived from the lateral head of the triceps. This usually occurs in heavily muscled individuals involved in activities requiring prolonged and vigorous elbow extension.

Entrapment may also occur in the region of the supinator muscle by fibrous bands on the surface of the muscle (arcade of Frohse) or within the muscle itself by tumors, ganglia, or inflammatory conditions. A painful elbow may result from entrapment of the posterior interosseous nerve. The superficial radial nerve is vulnerable to a host of injuries, including lacerations or compression from tight wristwatches, handcuffs, or plaster casts, owing to its superficial position at the wrist.

Posterior interosseous nerve compression

The posterior interosseous nerve may be compressed as it enters the supinator muscle under a fibrous arch (arcade of Frohse) or within the substance of the muscle.⁵⁶ Common causes of injury include ganglia, tumors (especially lipomas), fibrous bands, fractures or dislocations of the radius. The condition may occur spontaneously without an identifiable cause. Many so-called idiopathic cases have been found to be the result of entrapment at the arcade of Frohse. The clinical syndrome of 'resistant' tennis elbow is, in many cases, a result of posterior interosseous nerve entrapment, most often by the arcade of Frohse. It often is misdiagnosed as tennis elbow caused by lateral epicondylitis because both conditions result in lateral elbow pain. Posterior interosseous nerve entrapment is characterized by pain on firm palpation of the extensor muscle mass distal to the radial head; in contrast, lateral epicondylitis has marked tenderness with palpation of the lateral epicondyle.

Posterior interosseous nerve lesions result in an inability to extend the fingers and abduct the thumb; wrist extension is usually less affected as a result of sparing of the extensor carpi radialis. Radial deviation may occur with wrist extension because of extensor carpi ulnaris weakness. Sensation is spared over the dorsum of the hand. The degree of weakness is variable and may not affect all distal radial muscles to the same extent. In patients with rheumatoid arthritis, posterior interosseous nerve lesions must be distinguished from rupture of the extensor tendons to the thumb and fingers.

Treatment and prognosis of specific radial nerve injuries

Radial nerve injuries in the upper arm. Most radial nerve lesions resulting in wrist drop should be treated with a cock-up wrist splint, described later, that maintains mild wrist extension. Mild cases, in which weakness is not complete, may need no specific therapy. Complete recovery, over weeks to a few months, generally occurs in most radial nerve lesions resulting from compression. The ultimate degree of recovery depends on the severity and duration of compression.

Patients with radial nerve entrapment within the triceps muscle usually recover spontaneously. Rarely, exploration and decompression may be needed in cases of progressive weakness or poor recovery.⁵⁷ Radial nerve injury secondary to fractures of the humerus have an excellent prognosis for spontaneous recovery. Mild cases of posterior interosseous nerve entrapment often recover spontaneously. A period

of observation ranging from 3 to 6 months is generally prescribed to allow spontaneous recovery. More severe cases, in which weakness is present or with poor recovery, may require surgical exploration and removal of identified masses (tumors, lipomas, or ganglia) or constricting bands. Entrapment under the arcade of Frohse, if present, is released. Nerve compression caused by radial fractures should be observed initially for 2–3 months.

Regardless of the cause of the radial nerve palsy, most cases of wrist and finger drop require a proper splint to protect against hyperextension of the paralyzed wrist extensor muscles and shortening of the flexor muscles.⁵⁸ A static cock-up splint, maintaining the wrist at about 15–30 degrees of extension, is usually all that is required in cases with mild wrist extensor muscle weakness. Palmar sensation should not be obscured by a palmar pad. The metacarpophalangeal (MCP) joints may need to be supported in extension, with the thumb extended and radially abducted. Finger joints must be regularly exercised because they rapidly become stiff when immobilized for even a short time. This type of splint supports the hand in a position of function, thereby encouraging continued use. If the hand is able to be opened sufficiently by interphalangeal (IP) joint extension, MCP joint support may be unnecessary. In more severe cases, dynamic splints are useful. Such splints utilize a finger slip around the proximal IP joint to support the MCP joints in slight extension, thereby allowing active finger flexion while offering protective positioning at rest.

During the stage of paralysis, daily passive exercises should be used to maintain adequate range of joint movement, including large arm excursion. After voluntary activity returns, specific exercises are employed to strengthen the wrist and finger extensors. Intrinsic hand muscles become weak and inefficient, owing to dependence on the synergistic action of the wrist extensors, and may need strengthening to restore adequate hand function.

Median nerve

Source of injury

The superficial position of the median nerve in the upper arm renders it vulnerable to missile wounds and lacerations. It is better protected in the forearm where it lies deep within the pronator teres muscle. Median nerve compression has been attributed to crutches pressing on the axilla, tourniquets, rifle sling palsy, and pressure from the head of a sleeping partner on the brachioaxillary angle or medial aspect of the arm.

Median nerve damage secondary to bony fracture is less common than with other upper limb nerves because it is protected by overlying arm muscles. Fractures of the elbow occasionally result in median nerve damage. The anterior interosseous nerve may be damaged by forearm fractures because the nerve is closely related to the radius and ulna as it descends on the interosseous membrane.

Chronic median nerve entrapment may result from chronic compression in well-defined fibro-osseous tunnels

or following repeated episodes of strenuous muscle activity.⁵⁹ The most common nerve entrapment in the upper limb is median nerve compression under the transverse carpal ligament (CTS). Other median nerve entrapments include the pronator syndrome, the anterior interosseous syndrome, and entrapment by the supracondylar ligament.

Carpal tunnel syndrome

CTS is by far the most common entrapment neuropathy in the arm. The usual presentation is with acroparesthesias, numbness, tingling, and burning sensations, usually in the lateral three fingers. Nocturnal exacerbation of pain and paresthesias is characteristic and may either wake the patient from sleep or be prominent on awakening in the morning. Although pain may involve the forearm and shoulder region, it is rare for patients to describe numbness or paresthesias radiating proximal to the wrist. Shaking the hand frequently relieves pain. Repetitive tasks, be they occupationally related or hobbies, such as knitting and sewing, often precipitate or aggravate symptoms.

Objective sensory loss most consistently involves the second and third fingers, occasionally there is splitting of the fourth finger with sensory loss on the lateral but not the medial aspect. The palm is usually spared. Raynaud's phenomenon may occasionally be present. If the condition is left untreated, weakness and wasting of median innervated thenar muscles eventually develops, particularly thumb abduction and opposition. Eventually, the thumb is unable to be maintained in the opposed and abducted position (post position). As a result, the thumb is restricted to the plane of the palm, precluding it from acting as a post against which the other fingers can push. Thenar atrophy may occasionally precede weakness. Percussion of the median nerve at the wrist may reproduce sensory symptoms in the median nerve distribution (Tinel's sign). Forced hand flexion (Phalen's test) or extension (reverse Phalen's test) may reproduce the sensory symptoms. Asymptomatic motor and sensory signs may rarely be discovered, particularly in older individuals.

A discussion of work-related factors, including forceful and repetitive hand use, in the development of CTS is provided in Chapter 23.3. CTS may develop acutely after a prolonged episode of unaccustomed hand use, such as house-painting. In patients with pre-existing CTS, vigorous hand activity can aggravate symptoms. Much of the original support for CTS as a repetitive movement injury can be traced to studies using poor case definition or workers' compensation claims, and the specific role of chronic repetitive hand use in CTS remains unsettled.⁶⁰ Two longitudinal studies of median nerve conductivity in workers engaged in a variety of industrial activities^{61,62} failed to demonstrate any deterioration of median nerve function over a period of greater than 5–10 years.

It has been suggested that a substantial increase in intracarpal pressure results from wrist flexion and extension. In addition, there is some evidence to suggest that patients with reduced cross-sectional diameters of their carpal bones may be at increased risk of CTS. However, in

at least one study, routine measurements of carpal tunnel dimensions did not predict the likelihood of developing CTS in an occupational setting. Although CTS most commonly involves the dominant hand, bilateral involvement is extremely common. In many cases, only one side is symptomatic, the asymptomatic lesion evident only by electrodiagnostic studies. Most cases of CTS are probably the result of non-specific tenosynovitis of the flexor tendons. Other causes include tuberculous tenosynovitis, rheumatoid arthritis, osteoarthritis of the carpus, pregnancy, hemodialysis, myxedema, acromegaly, and infiltration of the transverse carpal ligament in primary amyloidosis. CTS is common in patients with generalized peripheral neuropathies, such as uremia and diabetes. In such patients, it is believed that the generalized neuropathy predisposes the median nerve to compression. Acute CTS can be caused by hemorrhage or infection in the carpal tunnel and constitutes a medical emergency. CTS should be considered for any unexplained pain or sensory disturbance in the hand.

Electrodiagnostic studies. In many cases, the diagnosis is obvious from the clinical signs and symptoms. Diagnostic confirmation in atypical cases and an estimate of severity can be obtained by nerve conduction studies. Confirmatory electrodiagnostic studies should be obtained in all patients undergoing surgery. The most sensitive physiologic parameter is sensory and mixed nerve conduction across the carpal ligament. Median motor conduction is less often abnormal than sensory conduction, but may show prolonged distal latencies and reduced compound motor action potential amplitudes, the latter usually reflecting axonal degeneration. Comparison of distal motor latencies between the median innervated second lumbrical muscle and the ulnar interosseous muscle has proven to be sensitive and specific for mild CTS.

Treatment and prognosis. Conservative medical therapy is appropriate when there are mild sensory symptoms without weakness or atrophy, intermittent symptoms, or acute CTS related to a specific injury or overactivity.⁵⁸ Occupationally related symptoms often respond to a switch in jobs to one not requiring repetitive hand movements. Nocturnal immobilization, using a volar wrist splint that maintains the wrist in the neutral position, is usually the initial treatment. Splinting is most useful when symptoms are intermittent and nocturnally exacerbated. The splint should be worn for as long as it is effective; if symptoms recur, further splinting is usually not helpful. Occasionally, the splint may be worn during the day at work to prevent the wrist from assuming a potentially aggravating position. If possible, repetitive actions that aggravate symptoms should be avoided.

Splinting, in general, usually offers only temporary or minimal relief. In patients without marked sensory loss, thenar weakness, or muscle wasting, a local injection of a mixture of lidocaine (Xylocaine) and methylprednisolone (Solu-Medrol) can be tried. Low-dose oral prednisone or diuretics (especially in cases complicating pregnancy) may

occasionally be effective. Eventually, however, many patients require surgical release.

Carpal tunnel surgery is indicated when conservative therapy fails to alleviate abnormal sensations or when thenar weakness or atrophy (evidence of axonal injury) is present. Surgery may also be needed in patients with occupations that chronically aggravate the symptoms. In such cases, the patient is often faced with a surgical option or the necessity to find an alternative form of work. Surgery is usually effective in relieving pain and stopping the progression of weakness in almost all cases. The long-term prognosis on returning to the same exposure setting is guarded, and may result in aggravation of the condition.

Surgery is almost always successful in halting the progression of weakness. If the lesion is not too advanced, recovery of strength usually occurs. Most cases of failed carpal tunnel release result from either incomplete transection of the transverse carpal ligament or faulty initial diagnosis. As indicated previously, preoperative electrodiagnosis is essential to avoid this latter mistake. Reported complications of surgery include neuroma formation, a tender dysesthetic scar, transection of the palmar cutaneous branch, infection, incomplete release, development of a complex regional pain syndrome, and damage to the superficial palmar arch.

Median nerve entrapment at the elbow (pronator syndrome and anterior interosseous syndrome)

The pronator syndrome results from compression of the median nerve as it passes between the two heads of the pronator teres muscle and under the fibrous arch of the flexor digitorum superficialis muscle.^{56,59} The most frequent cause of entrapment is fibrous bands in the substance of the muscle or passage through a tight flexor superficialis arch. Repeated pronation-supination activity may precipitate symptoms in patients with hypertrophied volar forearm muscles. The nerve may occasionally be compressed under the lacertus fibrosus, a fascial band extending from the biceps tendon to the forearm fascia. The pronator syndrome is characterized by diffuse forearm aching and paresthesias in the median nerve distribution over the hand. The degree of weakness varies, ranging from no weakness, to mild involvement of thenar and forearm musculature.

Various tests have been advocated to localize the level of nerve entrapment within the pronator muscle mass. Pain in the proximal forearm induced by forced wrist supination and wrist extension suggests compression within the pronator teres. Pain with forced forearm pronation of the fully supinated and flexed forearm suggests entrapment under the lacertus fibrosus. Compression of the median nerve under the flexor superficialis arch is suggested by pain on forced flexion of the proximal interphalangeal joint of the middle finger.

Anterior interosseous nerve compression causes weakness of the flexor pollicis longus, pronator quadratus, and the median innervated flexor digitorum profundus muscles. The resulting clinical deficit is impaired flexion of

the terminal phalanx of the thumb and index finger. There is no associated sensory loss. The anterior interosseous nerve may be damaged by forearm lacerations or fractures, fibrous bands within the pronator teres, entrapment by the fibrous arch of the flexor superficialis, and as a manifestation of acute brachial neuritis. Occasionally, anterior interosseous nerve dysfunction may occur without precipitating events or follow vigorous forearm muscular activity.

Median nerve entrapment at the elbow may infrequently occur from an anomalous fibrous band that extends from the medial epicondyle to a bony spur on the anteromedial surface of the humerus (ligament of Struthers). The resultant weakness involves all median innervated muscles, including the pronator teres, and is accompanied by loss of the radial pulse when the arm is extended. Radiographs often demonstrate the anomalous bony spur.

Electrophysiologic studies. Nerve conduction studies in proximal median nerve compression syndromes are frequently normal. In more severe cases, the amplitudes of distal motor and sensory potentials may be reduced. Distal motor latencies may occasionally be prolonged with stimulation proximal to the elbow, but forearm median motor conduction velocities are usually normal. The most consistent and sensitive physiologic findings are neurogenic changes in median nerve innervated forearm and hand median muscles on needle EMG. In mild cases in which pain but not weakness is present, all electrophysiologic studies may be normal.

Treatment and prognosis. Conservative treatment of the pronator syndrome and spontaneous anterior interosseous nerve entrapment initially involves resting the arm by avoiding elbow flexion and pronation.⁵⁸ Gentle splinting of the arm in supination occasionally relieves symptoms but may also aggravate the condition. Corticosteroid injections into the pronator teres muscle may be of temporary benefit. In mild cases, non-steroidal anti-inflammatory medications may be useful. In both syndromes, persistent or progressive symptoms require exploratory surgery. Occasional cases are the result of schwannomas or other nerve tumors, which can sometimes be visualized by MRI imaging. Surgical excision of the spur and ligament in median nerve compression by the ligament of Struthers is usually successful.

Most entrapment injuries to the median nerve do not require splinting. Traumatic injury, however, frequently results in extensive and severe hand weakness for extended periods. In such cases, proper splinting of the thumb is essential to prevent deformity and preserve hand function. Regardless of the site of median nerve injury, thumb movement will be impaired. Loss of thumb abduction leaves it lying adjacent to the index finger, which predisposes to thumb web adductor contractures. A C-bar or wooden dowel, inserted between the thumb and second metacarpal, maintains thumb abduction, while an opponens bar on the proximal phalanx of the thumb stabilizes it in opposition to the index and middle fingers, thereby allowing full wrist movement and posting of the thumb.

Ulnar nerve

Source of injury^{56,59}

Ulnar nerve entrapment is second to CTS as the most common nerve entrapment in the arm. Ulnar compression may occur in the axilla or upper arm, elbow region (either ulnar groove or cubital tunnel), or distally at the wrist or hand. The nerve is relatively exposed as it passes around the elbow and at the wrist, making it vulnerable to mild compressive or penetrating injuries. In the forearm, the muscle mass of the flexor carpi ulnaris affords the nerve relatively safety, save for severe penetrating wounds. Most compression injuries of the ulnar nerve are Class I and II. Improper positioning during anesthesia may result in an ulnar palsy. Occasionally, forceful, repetitive, flexion-extension movements of the arm may precipitate symptoms of ulnar nerve dysfunction. It is not clear whether ulnar neuropathy can be caused by repetitive arm movements. The relative infrequency of occurrence, in contrast to CTS, has prevented there being a sufficient number of prospective studies, with electrophysiologic verification, to examine this issue.

Dislocations or fractures of the elbow or chronic compression resulting from habitual leaning against the elbows may damage the ulnar nerve. Entrapment may occur in the cubital tunnel, where the nerve lies under the aponeurotic band between the two heads of the flexor carpi ulnaris. Occasionally, ulnar nerve dysfunction becomes evident many years after a supracondylar fracture of the humerus, leading to an increased carrying angle at the elbows (tardy ulnar palsy).

Ulnar entrapment at the elbow

The exposed position of the ulnar nerve at the medial epicondyle leaves the nerve susceptible to minor trauma or chronic compression. The nerve enters the forearm through a narrow opening (cubital tunnel) formed by the epicondyle, the medial collateral ligament of the joint, and the firm aponeurotic band to which the flexor carpi ulnaris is attached. This entire structure, formerly known as the cubital tunnel, has recently been renamed the humero-ulnar aponeurotic arcade (HUA). It is estimated that up to one-half of normal individuals have thickened and enlarged ulnar nerves, predisposing to compression either in the ulnar groove or HUA. Elbow flexion reduces the size of the opening under the aponeurotic band while extension widens it. Ulnar nerve dysfunction may therefore occur secondary to HUA narrowing during elbow flexion, without additional external trauma or local pathologic changes, or may be the result of any condition that increases nerve size or reduces the space available for the nerve. Some patients give no history of recent ulnar injury but report a previous elbow fracture or traumatic injury. This tardy ulnar palsy is frequently insidious in onset and probably results from narrowing of the HUA secondary to osteoarthritis or an increased carrying angle at the elbow.

The clinical deficits resulting from ulnar nerve lesions at the elbow are variable. Sensory symptoms usually precede

weakness. Numbness, paresthesias, or pain in the fourth and fifth fingers are most common. Symptoms are occasionally positionally provoked, especially by prolonged elbow flexion, as during sleep or while talking on the phone. Although a chronic ache in the elbow is common, it is unusual for sensory symptoms and signs to extend proximal to the wrist. Cutaneous sensory appreciation is impaired in the fifth finger with occasional splitting of the fourth finger. Objective sensory impairment may involve the dorsum of the hand but does not extend proximal to the wrist crease. Because patients with ulnar neuropathies may not be bothered by paresthesias and pain, they may present with an advanced degree of weakness and wasting.

The first dorsal interossei are usually the earliest and most severely affected muscles; weakness and wasting of other ulnar hand and forearm muscles may follow. Severe weakness results in a claw hand deformity with variable flexion of the distal digits, depending on the degree of profundus muscle weakness. Ulnar neuropathy results in the loss of power grip and impaired precision movements.

Electrodiagnostic studies. Slowed motor or sensory nerve conduction across the elbow, relative to the forearm segment, is a clear localizing sign. Unfortunately, focal slowing of motor conduction is present in only 50–60% of cases. Absolute slowing of motor conduction across the elbow segment, regardless of forearm conduction, has been reported in 65–85% of patients with motor and sensory signs and about 50% of patients with only sensory impairment. Sensory potentials are frequently reduced in amplitude, including the dorsal cutaneous branch. Motor potential amplitudes are diminished in lesions resulting in motor axon degeneration. Nerve conduction studies may be normal in mild cases without weakness, but if axonal degeneration is present, needle EMG will demonstrate active and/or chronic denervation in ulnar-innervated muscles.

*Treatment and prognosis.*⁵⁸ Conservative therapy is reserved for three groups of patients: (1) those in whom symptoms are only posturally precipitated, (2) those mild cases in whom symptoms are aggravated by job-related activity, and (3) those who demonstrate only sensory symptoms without substantial progression. Therapy consists of avoiding aggravating movements, such as repeated elbow flexion and extension or habitually resting on the elbows. Splinting the elbow in extension for prolonged periods, especially during sleep, may occasionally be helpful. Elbow pads can be used in those who habitually rest on their elbows. Conservative therapy should be continued for at least 2–3 months or for as long as symptoms remain intermittent or mild, and weakness is absent. Careful follow-up is important to detect a progressive lesion that may result in substantial axonal degeneration. Non-steroidal anti-inflammatory agents are occasionally helpful.

Progressive sensory symptoms, new weakness, or worsening electrophysiologic deterioration dictates surgical inter-

vention. Most surgeons now recommend either simple decompression within the HUA, or anterior transposition of the ulnar nerve, deep to the flexor forearm muscle mass. Clinical improvement can be expected in about 75% of cases. The severity of the preoperative lesion is important in predicting recovery; earlier intervention results in better recovery than waiting until severe wasting has occurred. Complications include neuroma formation, recurrent scarring around the nerve, and persistent pain, possibly caused by interruption of the nerve's blood supply.

Splints for ulnar lesions are designed to prevent hyperextension of the ring and little finger's metacarpophalangeal (MCP) joints. A restraint on the dorsum of the proximal phalanx supports the MCP joint. Should IP joint flexion persist, a dynamic splint may be used to extend the distal IP joint.

Ulnar nerve lesion at the wrist

The ulnar nerve may be lacerated at the wrist or compressed either within Guyon's canal or more distally within the palm. The most common cause of distal ulnar compression is chronic repeated trauma to the palmar area, such as that which occurs among heavy laborers or cyclists. Other etiologies include ganglions that compress the nerve, either within Guyon's canal or distally along the deep terminal motor branch, fractures of the carpal bones, lipomas and other tumors, and rheumatoid arthritis. Acute trauma, such as a fall on the outstretched hand, may damage the nerve as it passes between the pisiform bone and the hook of the hamate.

Compression within Guyon's canal may result in any combination of weakness in hypothenar and thenar ulnar innervated muscles and sensory loss in the medial two fingers. Sensory innervation to the palmar and dorsal surfaces of the hand is spared. Distal ulnar compression should be suspected when ulnar innervated thenar muscles are weaker than hypothenar muscles. Other clinical scenarios include selective weakness of the hypothenar muscles and isolated sensory loss of the medial two fingers. Rarely, a more proximal wrist lesion may additionally affect the palmar sensory branch.

Electrodiagnostic studies. The most specific electrodiagnostic finding is a prolonged distal motor latency to the first dorsal interosseous muscle compared with the abductor digiti minimi muscle. The digital sensory potential to the fifth finger is of low amplitude or absent; dorsal cutaneous sensory potential is spared. Depending on the site of lesion, needle EMG may demonstrate active or chronic denervation in either hypothenar or thenar muscles with sparing of ulnar-innervated forearm muscles.

Treatment and prognosis. Conservative therapy is indicated when there are sensory symptoms alone. Maneuvers responsible for or aggravating the injury should be corrected. Surgery is indicated when conservative therapy has failed to relieve discomfort, when motor or sensory dysfunction progresses, or when the deficit has no clear cause and may be the result of a mass.

TOXIC NEUROMUSCULAR DISORDERS

The incidence of clinical neuromuscular transmission dysfunction resulting from toxins is infrequent compared with that of peripheral neuropathy. Recognition of a toxic etiology is vital, however, because complete function is usually returned after the offending agent(s) is(are) identified and eliminated. A discussion of the physiology of neuromuscular transmission is beyond the scope of this chapter, and the reader is referred to one of the many excellent texts dealing with this subject. The following is a brief description of the various toxins that have been identified to disrupt neuromuscular transmission.

Snake envenomation

The venom of certain poisonous snakes may produce acute, widespread weakness that clinically resembles a myasthenic crisis.⁶³ Two families of snakes have venom with a predilection for the neuromuscular junction, i.e., the Elapidae (coral snakes, cobras, mambas, and kraits) and the Hydrophiidae (sea snakes). Envenomation with cobra venom causes symptoms and signs within minutes to hours. The symptoms include ptosis, oculomotor paralysis, lower bulbar nerve dysfunction (resulting in lingual, laryngeal, and pharyngeal dysfunction), diffuse weakness, and eventually, respiratory compromise. In addition to neuromuscular blockage, local muscle necrosis may result. Impaired neuromuscular transmission from snake venom results from: (1) postsynaptic acetylcholine receptor blockade, which may be irreversible or partially reversible, and (2) presynaptic inhibition of acetylcholine release. Treatment of snake envenomation includes administration of anticholinesterases to antagonize postsynaptic receptor blockade, specific antivenom, debridement of necrotic muscle tissue, and mechanical respiration, when needed.

Arthropod envenomation

Impaired neuromuscular transmission may result from the toxins of black widow spiders, scorpions, female ticks, and wasps.⁶⁴ Black widow venom increases acetylcholine release and, probably, also prevents endocytosis of acetylcholine vesicles to nerve terminal membranes. The eventual result is depletion of such vesicles and impaired neuromuscular transmission. Clinical symptoms begin within 15–60 minutes of toxin injection and predominantly involve severe muscle cramps of the abdomen and limbs. Treatment is aimed at reducing muscle cramping by warming, infusing calcium gluconate, and administering magnesium sulfate to antagonize acetylcholine release. Atropine may help antagonize the cholinergic symptoms, and the administration of 2.5 mL of reconstituted antiserum is recommended.

Acute weakness may also be caused by the toxin from North American ticks (*Dermacentor andersoni* and *D. variabilis*). Tick paralysis may clinically resemble acute inflammatory demyelinating neuropathy (AIDP) and may result in

respiratory paralysis.⁶⁵ The exact site of the pathologic change remains uncertain; terminal motor nerve endings and neuromuscular junctions have both been implicated. Removal of the tick is curative, often leading to rapid clinical recovery. Anticholinesterase therapy is usually ineffective.

Scorpion toxin indirectly affects the neuromuscular junction by inducing AChE release, caused by repetitive nerve terminal impulses.⁶⁶ These repetitive action potentials are believed to result from a toxin-induced delay in the normal sodium channel inactivation, thereby prolonging the nerve action potential. Clinical neuromuscular junction dysfunction is usually minimal.

Weakness simulating ocular myasthenia may result from the stings of wasps, bees, and hornets. Ocular symptoms may persist for weeks and are responsive to anticholinesterases and prednisone. Generalized weakness is rare.

Toxic myopathies

A number of toxic chemicals may primarily affect muscle.⁶⁷ The most common is alcohol, which produces a number of clinical scenarios, resulting from a combination of a primary toxic effect on muscle, related nerve disease, and metabolite disturbances, especially potassium. Most other toxic myopathies result from pharmaceutical agents, rather than industrial or occupational exposure. In many cases, the relationship between toxin and muscle weakness is not initially apparent. Most toxic myopathies are generalized and symmetric in nature, affecting proximal muscles most severely. Cranial nerve musculature is usually spared. Focal myopathies are usually caused by the local injection of toxic agents.

Focal myopathies

Focal muscle dysfunction, secondary to toxins, usually results from intramuscular injections, either from a local effect of the needle or the administered drug. Drugs with a known local toxic effect include diazepam (Valium), lidocaine, digoxin (Lanoxin), chloroquine (Aralen), opiates, and chlorpromazine (Thorazine). Paraldehyde and cephalothin sodium (Keflin) produce local irritation and abscess formation. Clinical weakness is usually minimal. The most common manifestation is an elevated creatine kinase (CK) level. Occasionally, severe induration and contractures may result. This is especially common with intramuscular injections of antibiotics in children or with meperidine (Demerol) or pentazocine (Talwin).

Acute/subacute myopathies

Many drugs can cause rapid-onset, symmetric, proximal muscle weakness, which is often painful.⁶⁷ The underlying mechanism is usually related to either potassium deficiency or an inflammatory myopathy. Occasionally, as with L-tryptophan, inflammation may predominate in the fascial tissue rather than the muscle itself. The serum CK concentration is usually markedly elevated, and myoglobinuria may be present. Drugs implicated in such myopathies include clofibrate (Atromid-S), epsilon-aminocaproic acid (Amicar),

emetine hydrochloride, and vincristine (Oncoven). Clear inflammatory myopathies have been reported in patients taking procainamide (Provestyl), levodopa (Larodopa), and D-penicillamine. Patients ingesting certain brands of the amino acid L-tryptophan have developed severe myalgias and occasionally weakness. Pathologic changes have included a marked perimysial and perivascular inflammatory response with varying degrees of muscle necrosis. Recovery was often exceedingly prolonged and far outlasted the period of exposure. In most of these inflammatory myopathies, spontaneous recovery often accompanies removal of the drug, but steroids additionally may be needed.

Acute muscle weakness caused by hypokalemia is usually generalized and often painful. Frank muscle necrosis may result, and elevated CK levels and myoglobinuria may be present. Hypokalemia may result from diuretics, purgatives, amphotericin B (Fungizone), and carbenoxolone. Amphotericin B and carbenoxolone, along with amphetamines, have been implicated in producing a severe necrotizing myopathy with rhabdomyolysis.

Chronic myopathies

Many drugs produce a chronic painless myopathy presenting with limb-girdle weakness. Proximal leg and pelvic muscles are usually affected to a greater degree than are arm muscles. CK levels may be normal. The most commonly implicated drugs are corticosteroids, which produce weakness through their interference with oxidative metabolism and inhibition of protein synthesis. Other drugs include chloroquine, which can produce a clinical picture identical to that from steroids, heroin, and chronic hypokalemia. Muscle weakness has also been ascribed to perhexiline, colchicine, and rifampin (Rimectane).

Alcoholic myopathy

The deleterious effect of alcohol on muscle may be through a direct toxic effect or associated malnutrition and electrolyte disturbance. Alcohol may produce acute, subacute, and chronic weakness.⁶⁷ The acute variety usually follows binge drinking and is associated with painful swollen muscles and myoglobinuria. An acute but painless variety of muscle weakness may also occur, associated with marked hypokalemia, elevated CK levels, and muscle necrosis. Recovery proceeds over several weeks to months, but the problem may recur with subsequent drinking bouts.

28.3 Psychosocial Stressors and Psychiatric Disorders in the Workplace

Nancy Fiedler, Lawrence B Stein

Most adults spend a significant part of their daily life in the workplace and research has demonstrated that a stimulating job contributes to a more meaningful life, higher self-esteem, and opportunities to increase socioeconomic status. However, psychosocial and physical work stressors also contribute to a decrease in work function and to psychologic disturbances ranging from stress reactions to diagnosable psychiatric illnesses. For example, some occupations such as emergency workers may be more prone to stress-related illnesses due to the unrelenting demands that are a routine part of their occupation.

Psychiatric illness (e.g., depression and anxiety) is recognized as a leading occupational health problem by the National Institute of Occupational Safety and Health¹ and often occurs from the interaction of work and non-work related environmental stressors and individual predispositions. Therefore, to the extent that the occupational practitioner can identify work-related factors contributing to psychiatric illness and develop appropriate intervention strategies, the impact on the individual and the organization can be mitigated. This chapter offers an overview of the literature on work-related psychosocial and physical stressors and individual susceptibilities associated with psychiatric symptoms and illness. Following this overview and in the context of a public health prevention model, methods for identifying risks within the workplace and preventing the effects of psychiatric illness on the individual and the organization are presented.

OCCUPATIONS, PSYCHIATRIC DISORDERS, AND PRODUCTIVITY

Psychiatric disorders impair productivity through several avenues that include reduced labor supply, absenteeism, poor morale, and reduced quality of work. Statistics validating the overall economic impact of psychiatric disorders within the United States abound; depression is estimate to cost \$43.7 billion, while alcoholism costs approximately \$89 billion per year.² This amount includes costs of lost productivity, as well as healthcare. Aside from alcoholism, drinking behavior of undiagnosed employees, such as coming to work 'hung over', has also been associated with problems at work.^{3,4} In short, the costs of behavioral problems and psychiatric disorders affect not only workers and their families, but also managers, coworkers, employers and insurance companies.

As an initial step toward understanding occupational risk factors that contribute to psychiatric disorders, epidemiologic studies have compared prevalence rates across occupations. For example, the Epidemiologic Catchment Area (ECA) community survey of psychiatric disorders found, after controlling for demographic differences among 104

occupations, that lawyers, teachers, counselors (not college), and secretaries had elevated rates of major depression compared to the overall rate for employed individuals; movers (freight, stock, and material), transport and material moving occupations, handlers, equipment cleaners and laborers, janitors and cleaners, and waiters and waitresses had elevated rates of alcoholism.⁵ The ECA study also found, however, that the risk for a diagnosis of alcoholism increased for managers and construction laborers when they were unemployed, confirming the overall protective nature of being employed.

Comparisons of psychiatric disorders across occupations, while intriguing and heuristically valuable, do not specify what factors within these occupations contribute to risk. Thus, a significant literature has developed in which the behavioral consequences of psychosocial and physical risk factors have been explored.

WORK-RELATED PSYCHOSOCIAL RISKS FOR PSYCHIATRIC DISORDER

The mechanism for higher rates of psychiatric disorder among occupations varies with both health-enhancing and deleterious characteristics of the job and individual susceptibilities. Moreover, job characteristics may contribute to the type of psychiatric disorder. With regard to job qualities, evidence appears to be converging to support the significance of job demands and control over decisions as proposed by Karasek.⁶ For example, employees in lower status positions, who often experience little control over decisions, also have higher rates of psychiatric disorders than those in higher positions (i.e., more depression and anxiety). Although common sense suggests that high demands would cause increased illness, both Mandell et al.⁵ and Hemmingson & Lundberg⁷ reported greater risk of alcoholism with lower or no workload.

The latter is also consistent with the reported higher rates of alcoholism among unemployed workers and suggests that the relationship between job demands and psychiatric disorder may be curvilinear. That is, low work load (or unemployment) or working in an environment with strenuous demands and little or no control may have serious implications for an individual. In addition, moderators mitigate the negative effects of job demands. Stansfeld et al.⁸ reported that high social support and skill discretion were protective against absence due to psychiatric illness. Social support consisted of a high level of support from colleagues and supervisors coupled with clear and consistent information from supervisors, and skill discretion referred to job variety and the opportunity to use skills at work.

More recently, a nationwide study of Swedish males found that a combination of low work control, low work demands,

and low work social support was related to later alcoholism after controlling for other risk factors.⁷ This finding further supports the association between low work demands and alcoholism and incorporates other important psychosocial moderators. In a follow-up interview for the ECA study, Mausner-Dorsch & Eaton⁹ found support for the association between major depressive episode, depressive syndrome, and dysphoria and job strain defined as a combination of high demands and low control over decisions. Moreover, they found that women were at greater risk both because they were more susceptible to job strain and were probably more exposed to it in their work environment. The latter illustrates the interactive effect of individual susceptibility and work-related stressors on eventual psychiatric illness.

In summary, the relationship between job demands and psychiatric illness is moderated, particularly when demands are high, by perception of control over decisions. That is, if the individual has control, demands may not have the same negative impact on psychiatric function.

Work–family conflict

In addition to work stressors, pressures external to work also impact the incidence of psychiatric illness. For example, work–family conflicts, defined as the incompatibility between the role demands of a career and family (e.g., long work hours preventing time with spouse or other family members), have been associated with lower job, marital, and life satisfaction.⁷ More specific to the workplace, individuals who are experiencing high work–family conflict are more prone to job turnover and decreased job productivity. Some gender differences have been found; women show elevated risk of disability when they report both work and marital interpersonal conflict, whereas interpersonal conflict was not predictive of work disability for men.¹⁰ Instead, life dissatisfaction, neuroticism, monotonous work, and stress of daily activities predicted work disability for men. Duxbury & Higgins¹¹ report that men experience work–family conflict due to work expectations, while women experience more work–family conflicts due to family expectations.

This overview suggests that greater risk for psychiatric disorder occurs when the following work and non-work related conditions converge: (1) the employee is either insufficiently challenged (low job demands) or has too many demands with little control, (2) social support is low

at work, (3) work and family roles conflict, (4) the employee is female. Since women are more often in occupations with less control and simultaneously have more family responsibilities,¹² gender may be a surrogate for differences in exposure to stressors at work and in the home. Table 28.3.1 summarizes the work-related psychosocial risk factors and associated psychiatric symptoms.

PHYSICAL RISK FACTORS

Physical aspects of the work environment also contribute to the occurrence of stress and psychiatric disturbance. Exposure to toxic chemicals, poor indoor air quality, noise, shiftwork, and trauma are some of the physical stressors associated with psychiatric illness.

Neurotoxicant exposure

Numerous studies document psychiatric symptoms associated with exposure to lead, organic solvents, carbon monoxide, and mercury. Lead exposure, whether acute or chronic, may result in non-specific symptoms often found in psychiatric disorders, such as fatigue, decreased libido, restlessness and depression.^{13,14} Organic solvent exposure is well known to produce a variety of psychiatric symptoms ranging from mild mood disturbances to severe psychoses. Acute solvent exposure is most often followed by mood changes, transient euphoric reactions, or complaints of mental confusion.¹⁵ The organic affective syndrome, identified by the World Health Organization and by NIOSH, is associated with chronic solvent exposure and is characterized by symptoms such as irritability, poor concentration, and loss of interest, symptoms also seen in several psychiatric disorders.^{16,17} Post-traumatic stress disorder,¹⁸ somatoform disorder,¹⁹ schizophreniform disorder,²⁰ and panic disorder²¹ have been documented to occur following long-term exposure to organic solvents.

Similarly, carbon monoxide (CO) exposure from motor vehicle exhaust or malfunctioning heating systems can produce symptoms such as fatigue, apathy, emotional lability, lowered frustration tolerance, impulsivity, irritability, and at times, psychosis.²²⁻²⁵ The symptoms of CO exposure may be delayed and may occur from 3 to 240 days after recovery from acute intoxication;²⁶ 50–75% of exposed patients recover from this delayed syndrome within one

Psychosocial risk factors	Symptoms	Possible psychiatric illness
High job demands with low decision latitude ^{7,48}	Feelings of helplessness and hopelessness in both home and work environments; lack of sense of personal accomplishment; and irritability;	Depression and anxiety
Lack of social support ⁵³	emotional exhaustion; feelings of depersonalization	
Work–family conflict ⁹⁻¹¹	Increased conflict at home; decreased feelings of self-efficacy in decision making; decreased commitment to organization; increased absenteeism	Depression and anxiety
Interpersonal conflicts with coworkers and supervisors ⁴⁸	Decreased marital satisfaction; decreased job productivity; increased sense of guilt	Depression; anxiety; and heavy alcohol consumption
	Increased use of sick leave time; decreased self-esteem; emotional exhaustion; feelings of depersonalization	Depression; anxiety; somatic symptoms

Table 28.3.1 Psychosocial risk factors, symptoms associated with these factors, and possible psychiatric illness that may result from prolonged exposure to stressors

year.²⁷ Exposure to mercury, which occurred when hatmakers used mercury to process felt (hence the phrase, 'mad as a hatter'), has been found to result in both mania and chronic depressed mood with apathy and extreme shyness and withdrawal.²⁸ Chronic mild exposure may cause irritability, nervousness, fatigue, and depression.²⁹

Because the clinical presentation of neurotoxicant exposure has significant overlap with symptoms arising from many other factors to include work and non-work related psychosocial stressors, a good exposure history is essential to develop appropriate intervention. For example, if the health practitioner is presented with psychiatric symptoms without exploration of neurotoxicant exposures, behavioral therapy and psychotropic medications may be prescribed when removal or reduction of exposure is the appropriate intervention. Thus, inquiry about the chemicals used at work and at home is an important part of an evaluation for psychiatric disorder.

Indoor air quality

Sick building syndrome or non-specific building-related illness (NSBRI) presents as a constellation of symptoms that overlap to some extent with symptoms of stress and psychiatric illness. Symptoms include mucous membrane irritation, headache, fatigue, shortness of breath, rash and abnormal odor perception.^{30,31} In at least one cross-sectional study, workers in a sick versus control building reported an increased number of psychologic symptoms which did not account for NSBRI but appeared to be independent consequences of poor indoor air quality.³² Several work-site factors are hypothesized to account for the symptoms associated with poor indoor air quality to include direct toxic effects of the chemical mixtures, psychosocial job stress (e.g., poor supervision, high job demands) and noxious odors. Most studies suggest that symptoms likely result from an interaction of these chemical and psychosocial stressors, with each workplace presenting a unique combination of factors.

Noise and shiftwork

It has been noted that factory and construction workers exposed to high levels of noise have demonstrated a wide variety of complaints beyond hearing.³³ For example, individuals exposed to excessive noise have reported symptoms of depression, anxiety, insomnia, and weight loss.³⁴ Exposure to loud and unsystematic noise has also been demonstrated to create an uncomfortable workplace, decrease worker production, and is viewed by the worker as a significant physical, social, and cognitive stressor.³⁵ Shiftwork represents another source of physical and psychological stress for employees. Little evidence exists regarding a causal relationship between shiftwork and psychiatric disorders, with the exception of individuals with shift maladaptation syndrome (see Chapter 38).

Nonetheless, shiftworkers report lower subjective levels of physical health and wellbeing.³⁶⁻³⁸ In addition, they have higher rates of alcohol and substance abuse³⁹ as compared to daytime workers and high rates of neuroticism.^{40,41} It has

also been noted that the 'graveyard' shift (e.g., midnight to 8:00 am) is associated with the most problems (e.g., higher accident rates, lower performance quality); however, the swing shift has the most negative impact on social patterns and interpersonal interactions.⁴² At present, studies investigating the prevalence of depression in shiftworkers are contradictory and inconsistent, which reflects the necessity for further research to determine more thoroughly the potential psychological consequences of the worker's schedules on psychological functioning.

Workplace trauma

Workplace trauma can occur under several conditions: (1) physically hazardous working conditions where safety procedures are inadequate or not practiced, (2) the nature of the work is inherently traumatic (e.g., emergency response teams), and (3) work settings with risk for violence. The construction trades have a higher rate of injury and death than many other trades⁴³ and workers who are injured or who witness the injury or death of a coworker are at risk for post-traumatic stress disorder. Similarly, emergency response workers such as police, firefighters, and emergency medical technicians, by the nature of their work, encounter and manage violence, death, and injury on a routine basis.⁴⁴

Finally, employees in service positions may encounter violence under the following conditions: exchanging money, interacting with the public, working at night or in the early morning, delivering goods, and working alone. In work settings where trauma is likely to occur, preventive measures should be emphasized, and emergency procedures need to be implemented following a trauma to prevent psychiatric disorder and disability.

INDIVIDUAL SUSCEPTIBILITY

Risk factors for psychiatric disorders do not confine themselves to work stressors but also lie within the individual. Many of these factors may be psychosocial while others may be biologic or genetic. For example, compared to men, women are exposed to more job strain⁹ and may also be more sensitive to it and to interpersonal conflict than men.¹⁰ Gender is another well-known risk factor for specific psychiatric disturbance, with women being more vulnerable to depression and men abusing alcohol more than women.⁴⁵ Individuals who have a history of previous psychiatric disturbance or trauma are also at greater risk either for exacerbation of current psychiatric illness or recurrence with exposure to work-related stressors.

Similarly, individuals with lower socioeconomic status and those who are unemployed are more at risk for a wide variety of psychopathology including depression, anxiety, substance abuse, and schizophrenia. On the other hand, being employed in a job that is satisfying and productive may act as a buffer against these types of problems. Although in the early stages of investigation, genetic factors may contribute to risk particularly for susceptibility to neurotoxicant exposures.^{46,47}

RECOGNIZING AND ASSESSING STRESS, BURNOUT, AND PSYCHIATRIC ILLNESS IN THE WORKPLACE

Prevention of psychiatric disorder requires assessment of the job characteristics that contribute to symptoms and early diagnosis to reduce individual and organizational disabilities. The following section provides an overview of psychiatric disorders most frequently seen in the workplace and measures to screen for these symptoms (Table 28.3.2).

Stress symptoms and burnout

Stress-related problems often present as physical symptoms such as gastrointestinal distress, chronic headache, low back pain, and fatigue. Symptoms of anxiety and depressed mood that fall short of diagnostic criteria for depression and anxiety disorders, manifest themselves as stress syndromes. Job dissatisfaction and poor morale are organizational manifestations of stress. For example, machine-paced assembly work has been associated with somatic complaints, job dissatisfaction, anxiety, irritability, and depression.³⁵ Stress symptoms, while overlapping, can be distinguished from psychiatric disorders based on three criteria: number of symptoms, chronicity of symptoms, and effects on function.

Typically, to meet criteria for a psychiatric disorder, the individual must report a specified number and type of symptoms that have persisted over a given time period (e.g., 2 weeks) and that interfere in the performance of significant life functions at home and/or work. For example, feeling depressed and worried yet not reporting significant effects on interpersonal or work function such as conflicts with coworkers or impaired work performance would probably not meet criteria for a psychiatric disorder.

However, within the work environment, if these symptoms occur in several individuals, a net effect on productivity and morale may be observed. Thus, assessing job-related stress and intervening can prevent more serious individual and organizational disorder if these symptoms persist.

Job burnout is probably the extreme example of a stress-related syndrome. Although it is not an official medical or psychiatric diagnosis, it is often thought of as a precursor to psychiatric disorder. Maslach⁴⁸ proposed a tripartite model of burnout that encompasses both job and personal characteristics. Included in this model are emotional exhaustion, cynicism, and a lack of sense of personal accomplishment. It has been duly noted that increased levels of emotional exhaustion, which refers to feelings of 'being overextended, drained, or used up', is correlated with physical symptoms such as gastrointestinal disorders, chronic fatigue, hypertension, headaches, sleep disturbances, and flu/cold symptoms. On the other hand, chronic feelings of cynicism (i.e., negative or detached feelings concerning job and work-related behaviors) and ineffectiveness (i.e., decreased feelings of competency) are thought to contribute to other problems such as despondency, hopelessness, and, in extreme cases, depression and anxiety.

Workers experiencing high levels of burnout in any one of these three domains tend to have a higher rate of job turnover, higher rates of absenteeism, are more inflexible about work-related rules and procedures, and are more dissatisfied with their job when compared to their more engaged counterparts. Although burnout is seen across jobs and work settings, it is more likely when the job involves frequent contact with people who are in need of help (e.g., health and service fields) and when a job supervisor is perceived as being unresponsive to employee needs. When either the type of work or the supervisory climate promote burnout, assessment for burnout is the first step to prevent disability and high worker turnover (Table 28.3.2).

Measures	Description of measure	Administration time (minutes)	Psychometric properties
<i>Stressors</i>			
Job content questionnaire ⁷⁶	Assesses psychologic demands, decision latitude, social support and job insecurity.	30	Test-retest reliabilities ranging from .84 to .87
Hassles and uplifts scales ⁷⁴	Global measure of stressful life events. Helps to identify work and non-work related stressors along with positive aspects of work and personal life.	30	Test-retest reliabilities are .79 for frequency of uplifts and .60 for intensity of hassles
<i>Stress symptoms</i>			
Maslach burnout inventory ⁴⁸	Measures three aspects of burnout: (1) emotional exhaustion; (2) lack of sense of personal accomplishment; and (3) depersonalization.	30	Test-retest reliability ranging from .79 to .89
Symptom checklist-90-R ⁷³	A multidimensional measure of symptoms associated with psychologic distress and a wide variety of psychiatric disorders.	15	Internal consistency ranges from .77 to .90; test-retest reliability is .78 to .90
Beck depression inventory ⁷²	A unidimensional scale that measures severity of depression.	15	Test-retest reliability of .90, internal consistency of .86, and coefficient alpha of .94
Impact of event scale ⁷⁵	A multidimensional scale used to assess symptoms associated with post-traumatic stress disorder.	15	Coefficient alpha of .42 to .82
Michigan alcohol screening test ⁷⁷	A scale that measures past and present alcohol consumption.	15	Coefficient alpha of .95
Beck anxiety inventory ⁷¹	A unidimensional scale that measures severity of anxiety.	15	Test-retest reliability of .89, internal consistency of .85, and coefficient alpha of .87

Table 28.3.2 Instruments used to screen for stressors and psychiatric symptoms in the workplace

Psychiatric disorders

Depressive and anxiety disorders

Comparisons across occupations show that depressive disorders, in particular, are prevalent in the workplace. Diagnostic criteria common to all of the depressive disorders (major depression, dysthymia) include depressed mood and a loss of interest or pleasure in usual activities with symptoms of decreased or increased appetite, sleep disturbance, poor concentration, fatigue, and thoughts of death. Anxiety disorders include generalized anxiety disorder, panic disorder, and phobias and are characterized by excessive worry and a number of psychologic and physical symptoms such as shortness of breath, heart pounding, sweating, chest pain, nausea, and fear of losing control. Phobias can range from those that are specific to situations or things to a fear of being outside of the home (i.e., agoraphobia). The same screening tools suggested under stress disorders can also be useful to screen for depression and anxiety disorders with severity greater in the individual who has a diagnosable psychiatric disorder.

Post-traumatic stress disorder (PTSD) is an anxiety disorder specifically related to traumatic exposures. In the workplace, traumatic events include death or serious injury to self or others and workplace violence. For example, NIOSH data reveal that homicide is the second leading cause of occupational death, following work-related motor vehicle accidents, and surpassing machine-related deaths.⁴⁹ The individual's response to a traumatic event such as seeing a coworker seriously injured or killed involves intense fear, helplessness, and horror. Symptoms of PTSD include intrusive thoughts/dreams and recollections of the trauma, re-experiencing the trauma, and avoidance of stimuli that arouse recollection of the trauma. PTSD is not inevitable following a traumatic experience and can be prevented with debriefing and counseling immediately following an event.⁵⁰

Substance abuse and dependence

A vast literature documents the occurrence and deleterious effects of substance abuse in the workplace. Workers showing a pattern of poor performance that includes absenteeism, lateness, conflicts with coworkers, and frequent illness may alert the occupational health professional to a substance abuse problem. However, as is evident from the list, these work-related symptoms are not unique to substance abuse and may have numerous causes. Thus, diagnosing a substance abuse problem as a non-mental health professional, and in the absence of information about the individual's pattern of substance use, is difficult and potentially harmful. Denial is a major psychologic dimension of substance abuse and therefore, if the diagnosis is suggested to the individual with inadequate documentation, it may serve to reinforce denial.

Diagnosis of substance abuse includes an inability to control the use of a mood-altering substance and is not confined to alcohol or illicit drugs but also includes prescription and non-prescription medications. Abuse is

not determined by quantity of use but rather by the fact that the individual continues to use the substance despite adverse medical, social, family, or occupational consequences. Thus, the diagnosis is behavioral and does not depend on the amount or type of substance used. To make this point more clearly, virtually the same criteria are applied to diagnose pathologic gambling.⁴⁵

Psychoses

Psychotic disorders are characterized by delusions, hallucinations, incoherent speech, disorganized behavior, and flat or inappropriate affect. Since psychoses are frequently diagnosed in young adulthood, some individuals may have their first episode while employed. Psychotic individuals are often not employed, but with medication may be returned to a workplace with proper accommodations.

STRATEGIES FOR PREVENTION

Primary prevention

What can we do to make work less stressful and individuals less vulnerable to what may, to some extent, be an inevitable part of work? Jobs where workers have little control over decisions seem to produce greater risk for psychiatric disorder. Therefore, programs to enhance employee participation in decisions are interventions that may prove to reduce psychiatric morbidity. For example, Karasek recommended that specific Quality of Work Life programs (QWL) be used by organizations to ensure that employees feel a sense of empowerment. More specifically, this process enables workers to set their own goals, make decisions, and solve problems within their sphere of responsibility. Although QWL interventions have focused primarily on lower-level employees, Quality Circles (QC), which are often found within various organizational strata (e.g., middle management, blue-collar workers), include groups of volunteers who work together on a particular job, meet regularly, and discuss job-related problems and possible solutions. Porras and Silvers⁵¹ have noted that QCs have a positive impact on employee attitudes, which may decrease job strain and burnout. However, the effect of QCs on job productivity is more equivocal.⁵²

On an individual basis, wellness programs that enhance resilience through better diet, exercise, and relaxation may also improve mental health. These programs typically include stress management workshops, health risk assessments, exercise facilities, subsidized cafeterias, individual counseling, and seminars and lectures. Programs that reduce work-family conflict can also reduce the incidence of psychiatric disorder. For example, employee-sponsored daycare centers have been demonstrated to increase job satisfaction and decrease work-related stress on working mothers.⁵³

Other factors such as flexible work hours⁵⁴ and parental leave programs⁵⁵ have observed similar findings. Perhaps the existence of these programs helps the employer or organization to acknowledge and support the challenges that employees often face. Also, these programs help

employees feel more empowered and valued as individuals who make significant contributions at the workplace. Some preliminary research indicates that when upper level managers support wellness programs, and when employees have easy access to these services, notable decreases in medical expenses and increases in productivity⁵⁶ are typically seen.

Accurately assessing physical and psychosocial hazards within the workplace is an important step toward preventing psychiatric disorders. Reducing exposure to neurotoxins and to hazardous working conditions need to be considered when increased rates of symptoms and psychiatric disturbance are noted. For example, reducing exposure to neurotoxins through engineering controls and programs to train employees in the use of protective equipment will reduce exposure and disability. NIOSH has provided specific recommendations for shift workers to reduce the health effects of working non-daytime hours. Also, debriefing programs are standard operating procedures for emergency workers such as police following traumatic exposures. Such prevention programs are examples of proactive efforts to reduce psychiatric morbidity based on knowledge of the inherent risks of the work.

Secondary prevention

Employee Assistance Programs (EAP) are offered in over 20,000 US companies. The purpose of these programs is to detect and treat individuals with psychiatric disorders.⁵⁷ Initially, EAPs were developed in recognition of the impact substance abuse has on work productivity. However, it became apparent that other psychiatric disorders and psychosocial problems such as elder care, child care, and financial management also significantly impact work function. Therefore, EAPs broadened their scope to include evaluation and referral services for any personal problem. These 'broad brush' programs encourage employees to seek services on their own or as 'self-referrals' rather than wait until job performance suffers. Some investigators have reported significant improvement in absenteeism, lost time, warnings and supervisors ratings of performance⁵⁸⁻⁶² when comparing these indicators before and after EAP counseling. However, despite the proliferation of EAPs and widespread claims of their cost-effectiveness, more evaluation is needed.

Although EAPs have increased access to psychiatric services, there is a paucity of literature to document the effects of psychiatric treatment on work-related variables. Mintz et al.⁶³ reviewed the literature addressing the effect of psychiatric treatment on the capacity to work for those diagnosed with drug addiction, alcoholism, anxiety and affective disorders, gambling, and schizophrenia, and concluded that most attention has been given to work outcomes for substance abusers. The authors found that long-term treatment was not more beneficial than standard alcohol treatment regimens and that successful treatment aimed at reducing abusive drinking increased productivity.

In a separate review, data on occupational outcomes from 10 treatment studies for depression were analyzed.

Symptom improvements occurred more rapidly than improvements in work-related variables, such as missed time, lower productivity, and interpersonal problems, and were not affected by treatment duration. Work outcomes improved, however, as treatment duration increased, with maximum benefits achieved at 4–6 months. For schizophrenia, neuroleptic drugs reduce symptoms, but some studies suggest that they may also adversely affect work capacity by interfering with the learning process.⁶⁴ Overall, the most striking finding was the lack of attention in the psychiatric outcome research to the effects of treatment on functional work capacity, despite the stated importance of occupational impairment inherent in the DSM-IV criteria for most psychiatric disorders.⁴⁵

In sum, psychiatric disorders and associated behavioral problems, such as alcohol consumption, significantly impact productivity – regardless of their cause or relationship to worksite factors and stressors. From the data available, either through program evaluation of EAPs or in the general treatment outcome literature, it appears that when employed individuals are treated, their work improves. This finding is encouraging and further supports the importance of health insurance benefits that include psychiatric treatment.

Tertiary prevention – fitness for duty

When an employee has been out of work for psychiatric treatment (e.g., depression or anxiety) or a question arises about the employee's ability to function on the job, a fitness for duty evaluation may be requested. Fitness for duty is defined as the individual's ability to perform a job based on the specific job requirements. Therefore, this evaluation requires a detailed understanding of the job duties. Often this can be problematic since job descriptions are not necessarily informative or sufficiently behavioral in their descriptions (see Table 28.3.3 for guidelines). Ancillary materials such as interviews with workers in similar positions or with supervisors may be needed to understand the essential behaviors expected to perform the job.

Fitness for duty can never be based solely on psychiatric diagnosis but rather must be based on a behavioral analysis of the employee's abilities. Past job performance is the best predictor of future job performance. Further, determining a global assessment of functioning can be useful as a behavioral guide for the individual's current level of function and ability to perform daily tasks related to work.⁶⁵ Overall, matching an assessment of the employee's current behavioral function with the essential functions required to perform a job, along with consideration of the employee's premorbid level of function on the job, will give the best prediction of an employee's fitness for return to a job.

Accommodation in the workplace

Since the Americans with Disabilities Act of 1990 (ADA) was passed, employers have been under pressure to employ

Steps involved in constructing an observational and behavioral based performance analysis	Sample occupation: Executive Assistant	Sample occupation: Baker
Step 1: Observation: observe a worker complete job tasks from preparation to finish	Watch a sample of administrative assistants perform daily work duties	Watch a sample of bakers perform the duties involved in the production of bread
Step 2: Describe: develop a description of job tasks in observable and behaviorally oriented terms	Verbal fluency skills to communicate effectively on phone and face-to-face with coworkers; attention and concentration to organize complex schedule; motor skills needed to type, learn and remember software programs (e.g., word processors, spreadsheets, etc.)	Read recipe card; motor skills and coordination to handle oven and mixing; psychomotor speed to safely retrieve finished product from oven
Step 3: Rank-order: by consulting supervisors and workers, rank-order from highest to lowest the tasks that are most crucial to a job	Through both direct observation and through interviews with present workers and supervisors, determine the most important aspects of the job; determine if others are available to help if parts of job cannot be completed	Through both direct observation and interviews with present workers and supervisors, determine the most important aspects of the job; determine if others are available to help if parts of job cannot be completed
Step 4: Develop worksheet: construct a worksheet to be given to individuals conducting fitness for duty evaluations which include key components of performance analysis	Give list to the individual conducting the assessment to ensure that they have an understanding of duties required to work effectively as an administrative assistant	Give list to the individual conducting the assessment to ensure that they have an understanding of duties required to work effectively as a baker

Table 28.3.3 Observationally and behaviorally based performance

and accommodate individuals with disabilities, including psychiatric illness. The number of discrimination claims against employers based on emotional/psychiatric impairment has also increased since the passage of this legislation. For example, in 1997 the Equal Employment Opportunity Commission (EEOC) reported that 15% of discrimination claims were due to emotional/psychiatric impairment, which represented the largest category of claims in that year.

The ADA prohibits discrimination based on disability and provides that employers must make 'reasonable accommodations' to the disabilities of 'qualified' applicants so long as this does not impose 'undue hardship'. 'Qualified' means that the individual can perform the essential functions of the job, except for the disability. 'Reasonable accommodation' refers to any modification or adjustment to a job or work environment that will allow the qualified employee with the disability to perform the job functions. 'Undue hardship' refers to an action requiring significant difficulty or expense.⁶⁶ Employers are not allowed to inquire about a disability prior to employment, and the applicant does not have to reveal a psychiatric history at time of hire. Moreover, if a long-term employee who was previously performing the job develops a psychiatric disorder, the employer is obligated to make accommodations.⁶⁷

For people who are hospitalized for psychiatric diagnoses such as schizophrenia, employment rates have traditionally been low, with less than 20% of this group employed.⁶⁷ The best predictors of future work performance among the chronically mentally ill seem to be ratings of the individual's work adjustment in a sheltered job site, the ability to function socially with others, and prior employment history.^{68,69} Thus, diagnosis alone (e.g., psychotic vs. non-psychotic) is not as predictive of work capacity as is objective behavioral performance. While these findings apply

Management strategies

Review strengths and weaknesses with employees
Set behavioral goals for job performance
Deliver positive feedback and criticism in constructive manner
Meet regularly with employees
Be flexible in administrative policies (e.g., allow relaxation breaks for anxiety)
Accommodations for workers with psychiatric disabilities
Utilize flextime when needed
Consider job sharing
Arrange environment to reduce excess noise or visual distractions
Extend leave time
Allow workers to call supportive individual during day (e.g., family, friends)
Join meetings between employer, supervisor and employment service

* As noted at <http://janweb.icdi.wvu.edu/kinder/pages/psychiatric.html>

Table 28.3.4 Employing and accommodating workers with psychiatric disabilities*

specifically to the psychoses, the same guidelines are applicable for any physical or psychiatric illness.

The Mental Health Law Project's guidebook⁷⁰ on the ADA provides a helpful document outlining reasonable accommodations for individuals with psychiatric disabilities. Accommodations include analysis of the individual employee's behavioral problems, such as anxiety, and sensitivity to criticism, followed by the development of accommodations based on individual needs (see Table 28.3.4 for guidelines).

SUMMARY AND CONCLUSIONS

With increasing attention to psychiatric disorders in the workplace and growing concerns about how working conditions contribute to psychiatric illness, the occupational

health practitioner will be called upon to prevent, identify, and manage psychiatric disorders. Developing effective screening programs to identify stressful working conditions and early signs of psychiatric symptoms can help reduce lost productivity and disability. As for most occupational health programs, these efforts will require close coordination between the occupational health professional, management, and employees to develop meaningful programs that will succeed in reducing psychiatric disability. Although sometimes less apparent to the observer, the disabilities associated with psychiatric illness deserve accommodation and will require creative approaches to help managers overcome the biases toward mental illness that still exist in the greater community and the workplace.

Chapter 29

Dermatologic Diseases

29.1 Contact Dermatitis

Kalman L Watsky, Christina A Herrick, Elizabeth F Sherertz, Frances J Storrs

The types of contact dermatitis that may be associated with the workplace are listed in Table 29.1.1 and are the focus of this chapter. By far the most common type is irritant contact dermatitis (ICD), representing approximately 80% of occupational contact dermatitis, with the remaining 20% being allergic. Other occupational skin diseases are discussed in Chapters 20.2 and 21.9. The patient does not walk in with an established diagnosis, however, and one needs to start with a systematic approach to evaluate the individual with skin disease.

APPROACH TO THE WORKER WITH SKIN DISEASE

The key elements to consider in evaluating a patient with skin disease are summarized in Table 29.1.2. It is most useful to see the patient at a time when the dermatitis is active, but this is not always possible. Speaking directly to the patient rather than relying on the history gathered by the nurse, the physician, or the supervisor is helpful.

History of dermatitis

The patient's description of events at the onset of the skin problem can be very important to the ensuing investigation. The date of onset generally should be during employment at the job in question. However, a person may have worked at a previous job with similar tasks and exposures, and developed contact allergy or irritation that could recur or be aggravated by the current job. If the person had a previous dermatologic disease (e.g., atopic dermatitis, psoriasis), a history of the time course of worsening of the dermatitis should be sought. The rapidity with which symptoms and signs occurred can give important clues. Immediate (or within hours) onset of itching and swelling with hive-like lesions suggests contact urticaria. Burning, stinging, and a red, dried appearance at the time of an exposure suggest an acute irritant reaction. Chronic irritant dermatitis can take much longer to develop. Approximately 3 months of constant wetting and drying is the typical time course in wet-work jobs.¹ Allergic contact dermatitis (ACD) may occur in a less predictable manner; it may occur within weeks of exposure to a new material, or it may develop after months or years. Itching, blistering, and spreading of lesions are common at some time in the course of contact allergic dermatitis (see later).

The anatomic site of the lesions at the onset of dermatitis also is important. The hands are the most likely site, and it should

be noted which hand and which site on the hand (dorsum, fingers, palm) was first involved. In general, the *initial site* of involvement should correspond to sites exposed during a job task to provide evidence for occupational dermatitis. Later in the course of the condition, other body sites may become involved that may not clearly be related to direct exposure.

The course of the dermatitis related to time away from work is important in trying to establish evidence for work-relatedness. Documenting improvement away from the initial worksite is supportive evidence that work exposures are playing a role. It is important to note treatments undertaken during the time away from work, because some treatments (e.g., systemic corticosteroids) may suppress an ongoing problem and thus confuse the temporal relationship. Lack of improvement away from work is more difficult to assess: some chronic dermatoses may be very slow to improve even with time off from work, therapy, and protection. Activities undertaken away from work (household chores, hobbies) also may cloud the issue. At times, workers are moved to light duty or modified type of work after a skin problem develops. It is important to try to determine what differences there are between initial and modified duties, particularly with regard to the type and frequency of materials contacted, hand washing, and protective equipment. These differences also can give clues to which procedure may be contributing to the dermatitis.

The time course of recognition and treatment of the dermatitis also is important, as this may modify the appearance of the dermatitis even before a physician has seen the patient. Depending on the initial severity of a dermatitis, an employee may treat himself or herself for weeks or promptly seek medical evaluation. Encourage the patient to bring pharmacy printouts, bags of medications, notes from other physicians, or any other information to try to compile a history of topical and systemic medications. Topical treatments are of particular importance, because sometimes ingredients in these products can cause irritation or allergic reactions themselves, thus perpetuating what may have been a self-limited problem. Treatment with systemic corticosteroids that leads to clearing of the dermatitis and is followed by a subsequent flare of the dermatitis despite continued absence from work suggests that non-work factors may be playing a role. These issues further complicate assessment of the patient.

Occupational history

General principles for taking an occupational history are discussed in Chapter 1. When considering patients with

Irritant contact dermatitis

Single exposure dermatitis
Cumulative irritant dermatitis
Frictional irritant dermatitis
Psoriasiform dermatitis
Fiberglass dermatitis
Low humidity dermatitis
Post-traumatic eczema

Allergic contact dermatitis**Contact urticaria*****Contact photodermatitis**

Phototoxic
Photoallergic

*Urticaria appears on the list as it may eventuate into dermatitis (see text).

Table 29.1.2 Clinical evaluation of the worker with skin disease

skin problems, it is useful to *have patients explain their routine*, having them use their hands to demonstrate how they handle materials. Ask specifically about the amount of time spent each day with *wet exposure*, wearing protective clothing, and frequency of contact with *irritating chemicals*. If items or material safety data sheets (MSDS) are brought from the workplace, go over each item with the patient to determine the type of contact and the frequency of exposure. Repetitive motion tasks or handling materials that could cause *friction or trauma* to the skin should be noted. Information about the *physical environment* in the workplace, such as temperature, humidity, patterns of airflow, and exposure to ultraviolet light, should be sought.

It also is important to ask about other *intermittent job tasks* that may have a relationship to the onset of dermatitis, such as periodic cleaning routines, machinery maintenance, changing cutting oils, and overtime work. There may be a discrepancy between the specific type of protective clothing (e.g., gloves) recommended and the actual use of these items in the workplace. Does the worker follow the recommended use, is protection optional, or does the worker have problems with consistent usage because he or she perceives the protection as inadequate (e.g., gloves tear, get saturated, or hamper dexterity)?

Asking whether *other workers are affected* who work at the same job can be helpful, although a site visit or examination of the other workers, when feasible, is more valuable. The sudden development of dermatitis by many workers suggests a breakdown in housekeeping or the recent introduction of an irritant into the industrial process. It also is helpful to ask the worker what he or she believes is the cause. The question may narrow down the relevant part of the job task. Inquiring whether or not the patient likes the job and wants to continue (if the dermatitis can be improved) may be significant, because motivation may be a helpful factor in predicting prognosis, depending on the type of dermatitis involved. This question also may help uncover the rare malingerer. For example, if a diagnosis of

ICD is made and a specific glove is recommended, the motivated employee may be more likely to use the protective glove to reduce the dermatitis and stay on the job.

With regard to skin disease, it also is important to inquire about previous work descriptions, exposures, and episodes of dermatitis, as well as second jobs or combined schooling with a job. One of our patients was concerned that her hand dermatitis was due to her office job. She also was going to school to become a hairdresser, and the wet-work exposures in this setting were much more likely to be the cause of her dermatitis.

Personal history

Obtaining a *history of previous skin disease* should be a focal point in talking with the patient. This history may provide clues to the current skin problem and may have prognostic implications.

Atopic history

Childhood atopic dermatitis (atopic eczema) is fairly common (greater than 10% of children in the United States), and is characterized by dry, pruritic skin, usually appearing in flexural areas. The skin in an atopic individual is more susceptible to irritants, such as rough fibers, and to changes in the environment, such as wet-dry and hot-cold changes. Determining an atopic background most often is done by eliciting a personal and/or family history (in first-degree relatives) of atopic dermatitis (eczema), hay fever and allergic rhinitis, or childhood asthma. A history of one or more of these conditions may be elicited in up to 25% of individuals, indicating that atopy is common. A history of childhood eczema is a common factor in adults who develop hand dermatitis. In his study of compensated skin disease in South Carolina, Shmunes found that the relative odds of developing work-related skin disease were 13.5 times greater for an individual with a history of atopic skin disease.² Further, the course of work-related dermatitis may be more prolonged in an atopic patient.

Psoriasis is a common skin disorder that may have potential for aggravation or development of new lesions in response to occupational factors, especially friction or repeated trauma involving the hands. Psoriasis on the hands as a result of work-related trauma may appear to be dermatitis at first glance. The presence of psoriasis should not fool the physician because ACD may coexist with psoriasis.³ A history of *skin contact allergy* to jewelry, rubber articles, plants such as poison ivy, or other materials may provide a clue to the current dermatitis.

Other information in the personal history that should be sought is listed in Table 29.1.2. The patient's personal hygiene routine may give hints of other potential contact allergen exposure. Oral medications may predispose the person to special problems. For example, use of a medication that is potentially phototoxic (e.g., tetracycline) while continuing to work at a job with significant ultraviolet exposure could lead to severe sunburn. Hobbies are often sources of contact with potential allergens and irritants. Emphasis on pre-existing skin diseases as well as non-work

exposures is essential in that surveys of skin diseases occurring in the workplace have shown that a minority of them are fully related to the patient's work.⁴

Physical examination

The physical examination should encompass not only the affected area of skin but also hair, nails, and sites not directly affected by workplace exposure. Evidence of other skin disease, especially flexural eczema, psoriasis, dermatophyte fungal infection, acne, and acute or chronic sun damage, should be noted. The size, color, and type of primary lesion (macule, papule, vesicle, wheal, pustule), as well as the presence of secondary lesions, such as scales, crusts, fissures, erosions, or ulcerations, should be noted. The configuration of lesions, linear grouping, or cut-off at sun-exposed sites or sites of protective equipment such as gloves or facemasks should be noted. Patterns of localization of dermatitis on the hands can occasionally be useful. Primary web space involvement is usually, but not always, irritant. Vesicles localized on the fingertips often are associated with allergy. Note whether both dorsal and palmar surfaces are involved. Nail changes may indicate chronicity of lesions. See the discussion about specific disorders for more detail on clinical clues. Often, however, it is not possible to distinguish clinically the type of dermatitis without further diagnostic testing. Recording the distribution of lesions on a drawing of the body or hands is helpful.

Diagnostic techniques

A number of techniques can be helpful in the evaluation of a patient with possible occupational dermatitis. In general, an experienced physician (e.g., dermatologist) should perform and interpret these tests. If scaling is present, a *skin scraping* to which 10–20% *potassium hydroxide* (KOH) is applied may be examined under a microscope for evidence of fungal hyphal elements. The same technique may be used to look for irritating fibers (e.g., fiberglass).

Cultures should be considered if a primary or secondary infection is suspected. Bacterial superinfection (impetigo) is common in crusted eczematous dermatoses, and a cotton swab sample taken from beneath a crust or a ruptured pustule may be submitted for bacterial culture, in the search for *Staphylococcus aureus* or group A β -hemolytic *Streptococcus* in particular. Marginated scaling lesions that are suspected to be the result of dermatophyte or *Candida* infection may be cultured from scrapings of scale using fungal media. If herpetic viral infection is suspected, cultures can be obtained from vesicular lesions if the appropriate medium is available. Culture or typing for other viral infection, such as wart papilloma virus, can only be performed if special facilities are available.

At times, a *skin biopsy* may be helpful to characterize the microscopic inflammatory pattern, confirm the presence of neoplastic lesion, or establish a cutaneous diagnosis of a non-dermatitis type. Skin biopsy of dermatitis and eczema may be non-specific. The biopsy technique usually is performed with local anesthesia, a small punch biopsy, and suture closure.

The following diagnostic techniques can be especially useful in evaluating skin disease that may be wholly or partially occupational in origin. These techniques in particular should be reserved for physicians trained in their usefulness, pitfalls, methodology, and interpretation.

Patch testing

Diagnostic epicutaneous patch tests can help establish contact *allergy* (delayed contact hypersensitivity) to a given material. The concentration of the material to be tested should be standardized. Physicians with little experience

in patch testing should only test with *known* substances in concentrations that will not give an irritant reaction when applied to the skin. Commercially available patch tests that have been developed under Food and Drug Administration (FDA) guidelines are available in the United States for common cutaneous allergens such as rubber additives, formaldehyde and related preservatives, nickel, and neomycin. In Canada and Europe, a wider selection of allergens can be purchased. Common allergens in occupational ACD are listed in Table 29.1.3. Many of these allergens also are common outside the workplace. There

Allergen	Patch testing concentration**	Source examples
Acrylates	1–5%	Glues; paints, cosmetics (nails), dental appliances, artificial hips
Balsam of Peru	25%	Perfume screen, plastics, medications
Benzocaine‡	5%	Topical anesthetics, para-amino chemical cross-reactions
Benzoyl peroxide medication	1%	Catalyst for acrylic resins, bleaching agent foods, topical
Black rubber chemicals‡	0.6%	Mixture of <i>P</i> -phenylenediamine related chemicals used in black rubber
2-Bromo-2-nitropropane-1,3-diol (Bronopol)*†	0.5%	Cosmetic and industrial preservative
Carbamates‡	1%	Rubber, fungicides
Chloroxylenol (<i>P</i> -chloro-) m-xyleneol	1%	Photography, rubber, glues, photocopy, cosmetic and industrial preservative
Cinnamic aldehyde‡	1%	Plastics, flavoring, perfumes
Cobalt chloride‡	1%	Nickel co-reactor, animal feeds, photography, acrylates, paints, glazes
Diaminodiphenylmethane	0.5%	Epoxy and polyurethane curing agent, para-amino chemical cross-reactions
Diazolidinyl urea (Germall II)*†	1% petrolatum or water	Cosmetic and industrial preservative
Disperse yellow 3	1%	Nylon dyes
Epoxy resin‡	1%	Plastics, paints, glues
Ethylenediamine dihydrochloride‡	1%	Fluxes, stabilizer in topical medications
Formaldehyde‡	1% water	Preservative, fabric finishes, plastics
Fragrance mix	8%	Additive in many personal care products
Glutaraldehyde	1% water	Medical and dental sterilizing solutions, leather fixatives
Glyceryl monothioglycolate	1%	Permanent waving solutions
Imidazolidinyl urea*†‡	2% petrolatum or water	Cosmetic and industrial preservative
5-Chloro-2-methyl-4-isothiazolin-3-one and 2-methyl-4-isothiazolin-3-one (Kathon CG)*	0.1% water or petrolatum	Cosmetic and industrial preservative
Lanolin (wool wax alcohol)*	30%	Topical medications
Mercaptobenzothiazole‡	1%	Rubber accelerator (especially gloves), fungicide (veterinarians), anticorrosive
<i>P</i> -Methylaminophenol sulfate (Metol)	1%	Black and white photo developer
Neomycin‡	20%	Topical antibiotic preparations
Nickel sulfate‡	2.5%	Metal tools and devices, jewelry
Para-tertiary-butylphenol formaldehyde resin‡	1%	Neoprene plastics and glues (e.g., shoes)
Phenol formaldehyde resin	5%	Plastics, glues (e.g., plywood)
Para-phenylenediamine‡	1%	Hair dye (humans and animals), para-amino chemical cross-reactor
Potassium dichromate‡	0.25%	Leather fixative, anticorrosion chemical, paints
Propylene glycol	10% water	Topical medicaments, tattoos, foods, brake fluids, antifreeze, plastics
Quaternium 15*†‡ (Dowicil 200)	2%	Cosmetic and industrial preservative
Rosin (colophony)*‡	20%	Cosmetics, glues, soldering flux, anti-skid (violinists, athletes)
Sesquiterpene lactone mix	0.1%	Allergen in chrysanthemum and other weeds
Thimerosal (merthiolate)	0.1%	Preservative (e.g., vaccines), cross-reacts with some mercury compounds
Tetramethylthiuram disulfide‡	1%	Rubber accelerator (especially shoes and gloves), fungicides
Thioureas	1%	Rubber accelerator
Tixocortol-21-pivalate	1%	Marker for corticosteroid allergy

*CTFA (Cosmetic, Toiletory and Fragrance Association) name, appears on cosmetic labels. () is trade name and may be used in other industries.

†Formaldehyde-releasing preservatives.

‡Commercial allergens commonly available in the United States.

**Diluted in petrolatum unless otherwise designated.

Table 29.1.3 Common contact allergens

are several reference textbooks which discuss common allergens and irritants related to specific occupations.⁵⁻⁷ The tests usually are applied to the upper back on aluminum disc chambers or plastic chambers held in place with non-sensitizing tape. The tests are left in place for 2 days, and then removed and read. A second reading at 3, 4, or 7 days after patch test application is important for a final interpretation. An erythematous, spreading, indurated or vesicular response at an allergen site indicates a positive allergic response. At times, irritant and allergic reactions are indistinguishable.

Patch tests should be considered as a confirmatory test when an individual is exposed to a potential allergen or when the clinical presentation suggests that contact allergy is playing a role in the dermatitis. Test results require careful interpretation to discern allergic from irritant responses, as well as to determine the relevance of a positive result to the patient's dermatitis and exposures. There are nuances to the technique, including timing of testing related to systemic corticosteroid therapy, that dictate that patch testing should be performed only by physicians experienced in the method. These tests are used only to diagnose *allergy* and are one component of the total evaluation. False-negative and false-positive results can occur. Patch tests often are negative in occupational contact dermatitis. Standard textbooks offer details of patch testing methods.^{6,7} For many substances that have not been standardized, De Groot's book provides suggested concentrations and vehicles of patch testing.⁸

Contact urticaria testing

Contact urticaria should be considered when an immediate itching, edematous urticarial eruption or angioedema occurs at the site of contact with a substance. Occupationally, this has been seen mostly with food handlers, particularly meat and fish processors. With increasing use of latex gloves, contact urticarial reactions to latex gloves and other medical devices has been seen more commonly in medical and related personnel and certain patient populations. This has prompted a move to non-latex alternatives, especially in hospitals.⁹ General guidelines for this type of testing are available in reference texts,^{6,7} and Hausen and Hjorth give specific suggestions for testing foods.¹⁰

Testing for contact urticaria involves applying the substance in question (e.g., saline in which a piece of a latex glove or the glove itself has been soaked, or a piece of meat or fish flesh) to normal skin, previously affected skin, or skin adjacent to active dermatitis. Signs of itching, redness, and swelling should be sought within ½ to 2 hours of application. If no reaction is seen, a small scratch or prick that draws no blood with a sterile needle is induced on normal skin, and the substance is applied to this site, followed by observation. It is important that this testing be performed with positive (histamine) and negative (saline) controls and in an environment where resuscitation equipment is readily available because life-threatening anaphylaxis may occur. Delayed contact urticaria may occur, so patients should be followed up 1–2 days after testing.

Photopatch testing

When allergy to a substance in combination with ultraviolet exposure is being considered, phototesting and photopatch testing are indicated. Phototesting involves exposure of the patient's skin to measured doses of ultraviolet A (UVA), ultraviolet B (UVB), or both to determine whether or not a sunburn reaction occurs at less than the predicted dose of ultraviolet light. Photopatch tests are performed by applying two sets of allergens to a patient's back. After 1 day, one set is exposed to a measured dose (usually 10 joules) of ultraviolet A, and final readings are taken at 2 and 3 days to determine whether there is a reaction to any allergen, with or without the ultraviolet exposure.¹¹

Supplemental information and diagnostic criteria

The uses and limitations of MSDS are summarized elsewhere in this text. Medical records from the workplace and private physician can help with details of clinical description of the acute events, chronology of medication use, and diagnostic work-up previously performed. Combining the history, physical findings, and results of the diagnostic evaluation can be complicated. Criteria for determining occupational causation and aggravation for contact dermatitis are summarized in Table 29.1.4. An affirmative answer to at least four criteria strengthens the case for workplace exposure substantially contributing to the dermatitis. The level of diagnostic certainty required, as with any occupational illness, depends on the circumstances, the standard for most compensation systems being 'more probable than not'.

IRRITANT CONTACT DERMATITIS

Irritant contact dermatitis (ICD), an inflammatory disease caused by skin contact with material that inflicts damage through a non-immunologic mechanism, is the most common occupational skin disease. The material that

Questions*
<ol style="list-style-type: none"> 1. Is the clinical appearance consistent with contact dermatitis? 2. Are there workplace exposures to potential cutaneous irritants or allergens? 3. Is the anatomic distribution of dermatitis consistent with cutaneous exposure during the job task? 4. Is the temporal relationship between exposure and onset consistent with contact dermatitis? 5. Are non-occupational exposures excluded as possible causes? 6. Does dermatitis improve away from work exposure to the suspected irritant or allergen? 7. Do patch or provocation tests identify a probable causal agent?
<p>*Answering yes to at least four questions may provide adequate probability for workplace exposure. From Mathias CGT. Contact dermatitis and workers' compensation: criteria for establishing occupational causation and aggravation. J Am Acad Dermatol 1989; 20:842–8, with permission from The Association for Professionals in Infection Control and Epidemiology.</p>

Table 29.1.6 Occupations at high risk for irritant contact dermatitis

contacts the skin usually is a chemical that is toxic to the skin in single or in cumulative (repetitive or frequent) exposure. Examples of industrial irritants are listed in Table 29.1.5, and occupations at high risk for ICD are listed in Table 29.1.6. Lists of irritants associated with specific jobs are available from several sources.^{1,5} Physical factors such as mechanical forces (friction, repetitive motion) and ambient environment (heat, cold, humidity) also can lead to ICD.

Pathogenesis

The pathophysiology is not well understood. There is evidence that both external environmental factors and host-related factors contribute to the likelihood that an irritant skin reaction may occur, particularly when exposure to weak irritants is being considered.

Strong irritants elicit symptoms of burning and stinging as well as signs of redness and swelling in most exposed individuals within a short time period. The progression to blistering dermatitis or chemical burn depends on the concentration of the irritant and the duration of skin contact. Healing begins to occur after the irritant is removed from the skin, but during this healing phase there is a reduced threshold for developing dermatitis from the same or weaker irritants. *Weak irritants* tend to cause damage in a subtler manner. The stinging or burning sensation may not occur; thus, there may be no subjective signal that damage is being done. Repeated exposure to a weak

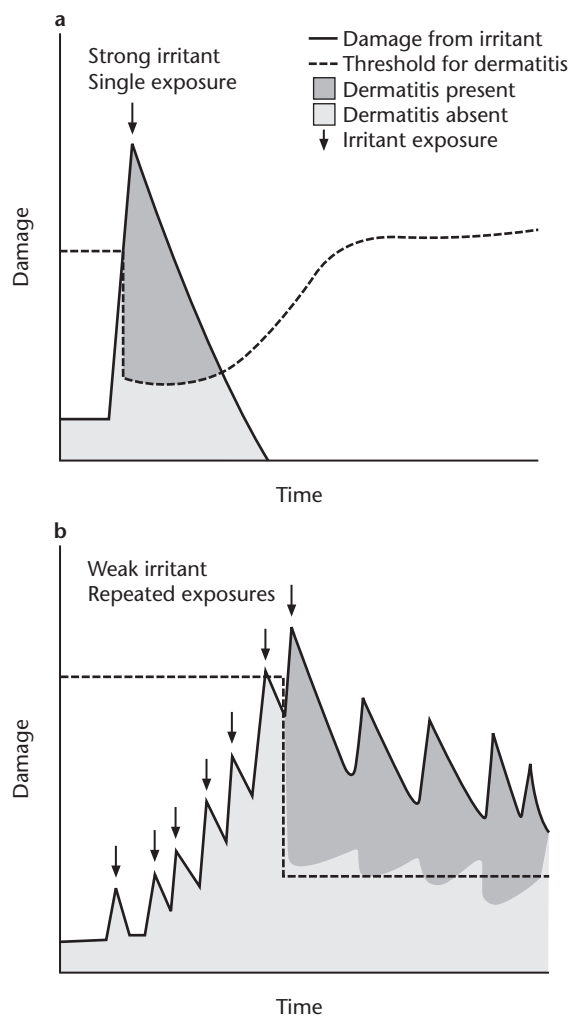

Figure 29.1.1: (a) Schematic for the time course of dermatitis with a single strong irritant exposure. Note rapid healing and recovery of threshold expected when exposure is stopped. (b) Time course of repeated insult with a weak irritant leading to dermatitis. The lowered threshold for dermatitis that results leads to perpetuation of dermatitis, even with less frequent damaging individual exposures. (Adapted from Malten KE. Thoughts on irritant contact dermatitis. *Contact Derm* 1981; 7:238–47; and from Dahl MV. Chronic irritant dermatitis: mechanisms, variables, and differentiation from other forms of contact dermatitis. *Adv Dermatol* 1988; 3:261–76. © 1988 Munksgaard International Publishers Ltd, Copenhagen, Denmark.)

irritant may be necessary to produce clinical evidence of dermatitis, so-called *cumulative insult* damage. The latency period for development of ICD of this type may vary from days, if contact with the weak irritant is constant, to years if contact is intermittent. Further complicating the picture is the fact that additional weak irritants, even water and soap, add further insult and contribute to the prolonged healing times necessary for dermatitis of this type. The schematic diagrams shown in Figure 29.1.1 contrast the time course of skin damage and dermatitis from strong versus weak irritants, and the effect on the threshold for developing dermatitis.^{12,13}

Environmental or exogenous factors that may predispose a person to the development of cutaneous irritation

from a given material include the type of irritant and the amount that penetrates the skin (which may depend on the concentration and vehicle for the irritant and time of contact with skin). The body site where contact occurs also makes a difference: eyelid skin is more prone to air-borne irritants than is palmar skin. Percutaneous penetration also varies with anatomic site; for example, the dorsal surfaces of the hands may be more likely to develop dermatitis than the palms due to differences in stratum corneum penetration by the irritant. Temperature and humidity also may be important. Working in a hot or cold, dry environment may cause chapping and water loss from the skin that could predispose the skin to penetration by some irritants, whereas heat, sweat, and occlusive clothing also could contribute to irritant effects of a material on skin.

Perhaps the single most important environmental factor in ICD is the role of water or *wet work*.^{14,15} Hydration of the skin increases the potential for the penetration of many substances. Intermittent wet and dry exposure leads to water loss, which can generate breaks in the skin barrier that solvents can traverse. The addition of soap or detergent to the water exposure, either in the hygiene routine or the industrial process itself, can lead to loss of superficial skin lipids, alkaline damage to the skin, or abrasive action on the stratum corneum that also contributes to irritant skin damage.¹⁶ Water exposure itself, or in combination with soap, can act as a weak irritant that lowers the threshold for dermatitis from other substances that might be otherwise tolerated, as shown in Figure 29.1.1(b).^{17,18} For this reason, avoidance of wet work is often recommended during the healing phase of contact dermatitis of any cause, and it also is recommended for individuals with endogenous factors (see later) that might make them more likely to develop ICD.

Atopic dermatitis has a strong association with the development of occupational ICD, as noted earlier. Individuals with atopic dermatitis have a low threshold for irritation and require a long time to heal. Individuals with a positive atopic history but no apparent dermatitis also may have a higher risk of hand dermatitis.^{17,19} Separating the endogenous atopic dermatitis from the relative importance of external irritants may be difficult. A history of new dermatitis at sites not previously involved but compatible with job-related exposure or a history of significantly more severe involvement (aggravation) at sites of pre-existent dermatitis suggests that the exogenous exposures are contributing to an ICD flare of atopic dermatitis. The link between atopy and potential for ICD is a powerful case for preplacement evaluation and job modifications, because preventative measures could have a significant impact on reducing the number of cases of occupational skin disease. Other host factors for ICD include skin care regimen and skin types.

The point of injury by irritants at the cellular level is variable. The stratum corneum barrier may be compromised or cell membranes may be disrupted, particularly by detergents. Damage to the epidermis can trigger the release of various cytokines and inflammatory mediators that potentiate the damage and inflammation. Some irritants have direct effects on blood vessels, causing vasodilatation,

and others may directly stimulate polymorphonuclear leukocyte chemotaxis or mast cell degranulation. The degree of inflammation seen clinically or histologically depends on the specific irritant involved, its concentration, and the type of exposure.²⁰

Clinical course

The clinical manifestations of ICD usually reflect the epidermal damage: a glazed look to the skin, with dryness of the surface ranging from a chapped scaling appearance to cracking or fissuring (Fig. 29.1.2). Erythema is variable and may be very faint when it is caused by weak irritants. Burning and stinging may be more prominent than itching. The web spaces of the fingers may be affected first, especially in ICD associated with wet work. In general, the presence of multiple small vesicles, especially around the nail fold, is not common in ICD and its presence should suggest the possibility of concomitant contact allergy to

Figure 29.1.2: Contact irritant dermatitis. Irritant contact dermatitis usually begins in the web spaces of the fingers and then spreads to involve the adjacent skin. The dorsum of the hand may be involved more than the palm. Redness, scaling, and itching without obvious vesiculation are most characteristic. This sort of dermatitis is common in people who do wet work, and is especially common in people who have a history of childhood eczema and who also do wet work.

the same or another offending agent.²¹ Large blisters of acute onset may occur with a strong irritant, causing the equivalent of a chemical burn, but these blisters usually resolve rapidly with removal of the irritant and wound care. With epidermal disruption, secondary infection may occur and lead to amber-colored crusting of the involved sites. With cumulative irritant dermatitis or chronic irritant exposure, the skin becomes hyperkeratotic. At sites like the hands, this thickened skin is prone to fissures.

Diagnosis

The major considerations in the differential diagnosis of ICD are atopic dermatitis (Fig. 29.1.3) and ACD, and it may be extremely difficult to distinguish among these conditions clinically. Table 29.1.7 contrasts features of irritant and ACD. In chronic cases, other disorders such as psoria-

Figure 29.1.3: Atopic hand eczema. This hairdresser is not allergic to anything in her workplace on patch testing. The frequent wetting and drying of her hands in her work has given her chronic dermatitis on both her palms and her dorsal hands. Notice the distal distribution, which is characteristic of irritant dermatitis caused by wet work exposures in atopics.

sis and acquired keratoderma also should be considered. There is no routine laboratory test to confirm a diagnosis of ICD: skin biopsy results are non-specific, and patch tests are used to confirm or exclude contact allergy. The history of exposures, job description, and clinical presentation lead to a clinical diagnosis of ICD.

Treatment and prognosis

Avoidance of strong irritants usually leads to prompt improvement of an acute case of ICD. Oral antibiotic treatment of secondary infection, soaks and debridement of crusts or bullae, and topical emollients often are adequate in this setting. If a chemical burn has occurred, specific emergency treatment should be instituted depending on the nature of the irritant chemical involved. For dermatitis due to weaker irritants or cumulative or multiple exposures, it is helpful to move the patient away from the job task associated with those or other irritants. As mentioned earlier, the threshold for further irritation is lowered, so that ideally all irritant exposures (occupational, domestic and hobby, and therapeutic) should be minimized. In the workplace, reducing exposure to the irritant through job modification or appropriate protective clothing may be helpful. If a similar problem has been seen among a number of workers at a given job, consideration should be given to replacement of the offending agent with a less irritating material. The proper glove may be helpful but barrier creams generally are not beneficial.^{22,23}

Skin cleaning should be performed as gently as possible, and abrasives, solvents, or harsh detergents should be avoided. If there is a marked inflammatory reaction, a topical corticosteroid in a simple ointment base (e.g., petrolatum) may be of benefit. Corticosteroid creams contain preservatives that can sensitize the skin. Ointments do not contain these additives or water in the base, which can be drying. Lack of response or worsening of symptoms with use of a topical corticosteroid may rarely indicate contact allergy to the steroid moiety itself.²⁴ Bland emollients such

Variables	Irritant	Allergic
Who	Many people	Few people
Where	Localized	Spreads
When	Soon with strong irritants (minutes to hours) Late with weak irritants (months)	24–72 hours
Job-relatedness	Improves with long (3 weeks) vacations	May improve even on weekends
Atopy	Predisposes	No predisposition
Morphology	Erythema, scale, fissures	Vesicles or inseparable from irritant
Distribution	Hands 90%	Hands 90%
Intermittent and frequent water exposure	May cause and perpetuate	May perpetuate
Immunology	Not known to be relevant (1991)	Type IV (cell-mediated immunity, delayed hypersensitivity)
Histology	Spongiosis or upper epidermal damage, some lymphocytes	Spongiosis with lymphocytic cellular infiltrate or inseparable from irritant
Chronicity	Often	If diagnosed early clears, can be chronic
Diagnosis	History and physical observation	History, physical, and patch testing
Examples	Hairdressers and machinists chronic hand dermatitis	Poison oak/ivy, nickel, chrome

Table 29.1.7 Generalizations about irritant versus allergic contact dermatitis

as white petrolatum are preferable to popular commercial moisturizing lotions, which can occasionally lead to further irritation.²⁵ Systemic corticosteroids may alleviate symptoms of inflamed ICD, but they should be reserved for short-term therapy of more severe cases. Oral antibiotics to cover *Staphylococcus aureus* and group A β -hemolytic streptococcal infection, in particular, should be used if crusted fissures are evident.

As the dermatitis improves, the strength and dosage interval of the topical corticosteroid should be tapered. The time course to improvement can be variable. As a general rule, the longer the duration of dermatitis, the longer the recovery time. The presence of atopy also prolongs healing time. The recommended length of time away from exposures or with modified duties is variable. Photographs of the dermatitis at the beginning and end of the time-off period may be of great value. If the dermatitis does not improve with the avoidance and treatment outlined, then other diagnoses should be considered and the therapeutic regimen should be scrutinized.

The prognosis of ICD depends on exogenous factors, such as the ability of the person to avoid irritants, and endogenous factors, such as the presence of atopy. For an isolated episode of an acute case of ICD to a strong irritant, the prognosis for recovery is good. Chronic ICD may not have such an optimistic prognosis. In fact, occupational contact dermatitis in general carries a poor prognosis, which is frustrating to the patient, employer, physicians, and insurance carriers.²⁶ For example, a follow-up study of patients with soluble-oil dermatitis (metal-working industry) indicated that the patients who experienced the resolution of their dermatitis after discontinuing oil contact did so within 3 months.²⁷ If there was no improvement within that time, the patients were not likely to improve whether they avoided soluble-oil contact or not. Overall, approximately 70% of these patients had not healed 2 years after being diagnosed.²⁷

Strides made in industrial hygiene and dermatologic diagnosis and treatment in the last 20 years have not led to an improvement of the prognosis. In long-term follow-up investigations of patients diagnosed with occupational contact dermatitis, 25% of patients have persistent dermatitis, 50% of patients had periodic flares of dermatitis, and only 25% completely healed. These percentages are similar for patients who change or leave their jobs owing to their skin disease; the majority continues to have dermatitis.²⁸ Factors to be considered in persistent occupational dermatitis are summarized in Table 29.1.8. Perhaps the most difficult of these factors to determine is the development of secondary dermatoses due to a lowered irritant threshold or other factors, or the concept that dermatitis begets dermatitis. It may not be possible to predict when and how much improvement will occur for a given patient with contact dermatitis.

Prevention

Given the poor prognosis of ICD, improved preventive strategies are essential.^{29,30} Prophylactic strategies should

Incorrect dermatologic diagnosis
 Proper diagnosis of occupational contact dermatitis, but
 Failure to establish specific cause
 Failure to eliminate exposure to causative agent(s)
 Improper therapeutic intervention
 Development of secondary dermatoses
 Infection
 Neurodermatitis/Lichen simplex chronicus
 Reactivation of atopic dermatitis
 Improper job modification or change
 Improper cleansing routines
 Development of
 Cross-sensitivities
 Multiple sensitivities
 New sensitivities
 Malingering

 Assess hand washing routine (avoid excess hand washing)
 Protective clothing
 Simple lubricants (e.g., petrolatum)

Table 29.1.9 Prevention of contact dermatitis

include those outlined in Table 29.1.9. Identification of workplace irritants, modification of work practices and

industrial processes, and worker education can reduce irritant exposures and incidence and severity of ICD. Early recognition and appropriate treatment are also essential. Workers with atopic dermatitis should be counseled as to the risks of wet-work careers such as housekeeping, medical fields, and hairdressing. Intermittent wetting and drying is particularly damaging (e.g., hand washing). Preplacement screening for atopy for wet-work or other high-risk occupations might reduce risk but is of unproven value and is ethically and legally problematic. Educational programs should also address possible irritant exposures outside the workplace, as in domestic chores or hobbies, because an accumulation of irritant insults may lead to dermatitis.

In the context of the job description, it is important to know which chemicals or other materials are irritating to human skin. Strong irritants may be identified on material safety data sheets, but weak irritants or those that may result in dermatitis from cumulative exposure may not be identified as such. Other sources of information on potential irritancy should be sought in the industrial literature. For new products likely to have significant exposure to human skin, predictive testing of irritant potential can be performed. There are a number of methods advocated for use in experimental animals or humans. These methods are widely used to evaluate skin care products and topical medications, but they could be adapted for evaluation of industrial compounds, if necessary. Further preventive strategies are similar to those discussed later under ACD and are summarized in Table 29.1.9.

LOW HUMIDITY DERMATOSES

Pathophysiology

At humidities of 50% and higher, the stratum corneum is at a steady state and remains pliable. In situations that are hot and dry and in which there is flowing air, the stratum corneum dries out and fissures, resulting in chapped skin.³¹ This mechanism plays a role in the development of some cases of allergic contact dermatitis and most irritant dermatitis associated with intermittent wetting and drying.³² It plays a primary role in explaining a dermatitis that is common in hot, dry, well-ventilated workplaces. As with most types of irritant dermatitis, this problem can affect many workers (Table 29.1.7).

Clinical course

Patients working in these environments, and especially those sitting exactly at points of maximum airflow, note itching on their exposed skin surfaces (especially the face and neck). This problem is followed by scaling and, finally, by the development of patches of asteatotic eczema (xerosis, erythema craquele, chapping). Although exposed surfaces are involved most often, covered skin may be included as well. Erythema or flushing and even urticaria (perhaps as a result of rubbing and scratching) also may be part of the syndrome. Individuals with a personal history

of atopic dermatitis are particularly vulnerable, and those who already have some sort of dermatitis will note that it worsens. Persons in whom this problem is likely to be prevalent include any workers in low humidity environments, which are common with current heating and air-conditioning systems.

Diagnosis

History and suspicion are most helpful initially, but inspection of the workplace, with documentation of low humidity and high temperature and airflow, as well as correction of the skin complaints after remediation of these factors, is diagnostic. Air-borne gaseous and particulate substances and other causes of dermatitis (allergic, contact, seborrheic) may complicate the diagnosis, and they should be sought as well.

Low humidity dermatitis may be the actual explanation for some skin diseases that have been attributed to visual display terminals, carbonless paper, and even the sick building syndrome (see Chapters 38 and 23.2), and thus its diagnosis and correction can improve the morale of an entire workforce.³³

Treatment and prognosis

Raising the humidity and lowering the temperature, when possible, solves most complaints. Moving a worker away from under or beside an air duct helps even more. Simple lubricants, devoid of common sensitizers that can complicate the problem, hasten the recovery of the xerotic skin. In some instances, topical corticosteroids are required briefly.

IRRITANT CONTACT DERMATITIS DUE TO FIBERGLASS

Pathophysiology

Fiberglass dermatitis is a specific type of ICD in which the mechanical effect of the sharp fiber spicules causes a sensation of itching and, at times, an inflammatory reaction.³⁴ The fiber size ($>4.5 \mu\text{m}$) is important in determining the likelihood of skin irritation. Textile glass and wool fibers that are used for insulation are the types most often implicated in skin irritation.

Clinical course

The skin lesions are small papules that are often crusted due to scratching. Hive-like lesions and linear excoriations may occur, and lesions have a predilection for exposed surfaces as well as areas of the skin where clothing is close to the skin (e.g., the waistline). Intense pruritus may be the chief complaint, and clinically apparent lesions may be absent. Fibers may be found on tape strippings of the skin or skin scrapings examined with potassium hydroxide preparation.

Diagnosis

The differential diagnosis includes infestations by scabies or body lice, irritation from dust exposure, neurodermatitis, and other types of contact dermatitis. A history of exposure such as working with fiberglass insulation or in indoor environments undergoing renovation should be sought.

Treatment and prognosis

In fiberglass workers, the symptoms of irritation often are relieved with gentle washing of exposed sites with non-abrasive soap and water. New workers tend to be more affected, and work hardening can occur over time in some workers. Topical corticosteroids are of limited benefit.

Prevention

To prevent fiberglass dermatitis, it is helpful for workers to wear loose clothing with long sleeves and pants, avoid rubbing the skin, and wash work clothes separately. Careful skin cleaning after working with fiberglass and use of skin emollients also may help.

POST-TRAUMATIC ECZEMA

Pathophysiology and clinical course

Post-traumatic eczema is a term used for the occurrence of dermatitis at a site of previous injury to the skin. The pathophysiology is not well understood and may be related to the lowered threshold for irritant dermatitis at sites of skin damage. Mathias has described an idiopathic type and an isomorphic reaction (i.e., the occurrence of a cutaneous lesion of a recognizable skin disease at a trauma site).³⁵ Patients with typical lesions of psoriasis, vitiligo, and lichen planus at other sites may develop new lesions at sites of trauma through the isomorphic reaction. Idiopathic post-traumatic eczema is an inflammatory, scaling reaction limited to the previous trauma site. The eruption usually begins within weeks of the injury and may persist for months to years after the initial injury.

Diagnosis

It is essential to exclude infection (bacterial, herpetic, fungal) at the injury site through appropriate laboratory techniques and culture. Contact dermatitis resulting from medications used to treat the wound (e.g., neomycin, adhesive, benzocaine) also should be excluded.

Treatment and prognosis

Topical corticosteroids may be helpful in the treatment of post-traumatic eczema, but patients may have intermittent active dermatitis at the trauma site. If the initial injury was occupational, this prolonged dermatitis at the injury site may be considered work related.

FRICTIONAL CONTACT DERMATITIS

Pathophysiology and clinical course

Frictional dermatitis results at points of chronic irritation and trauma. It is most easily recognized as calluses, and some occupations have distinctively distributed calluses.³⁶

Skin diseases that koebnerize (develop lesions typically at trauma sites [isomorphic phenomenon]) such as psoriasis or lichen planus may involve the palms and present a clinical picture that, at first glance, looks like frictional contact dermatitis and even may have foci of spongiosis histologically. Some people develop similar lesions clinically and histologically, although they do not have psoriasis or a family history. Clinicians may call frictional contact dermatitis psoriasiform dermatitis or hyperkeratotic dermatitis of the palms.³⁷ This entity does not vesiculate, seldom itches, and may involve the weight-bearing portions of the feet if heavy shoes are worn and if the patient is obese. The condition improves dramatically when the mechanical trauma is withdrawn, but it may take a month or longer to do so. Workers with impressive mechanical hand trauma are at greatest risk (e.g., construction workers, machinists, forest industry workers, and baggage handlers).

A more subtle but equally distinctive frictional dermatitis can occur in office workers who handle large volumes of papers, and especially carbonless copy paper. This dermatitis is found on the fingertips, where maximum paper contact occurs. It does not vesiculate or itch but rather is characterized by areas of redness, scaling, and painful fissuring. These patients may have no previous history of hand dermatitis and often are not atopic.³³

Diagnosis

This entity receives little mention in most comprehensive reviews of hand dermatitis. Exclusion of other entities such as irritant and allergic dermatitis, genuine psoriasis, and dermatophyte infection is important.

A biopsy can be of great help but will not absolutely exclude genuine psoriasis, which can be similar to frictional dermatitis histologically. Psoriasis may first begin on the palms in the setting of occupational trauma and only with the spread of the disease to distant sites can it be differentiated with confidence from the more nebulous frictional dermatoses. Clearing of the dermatitis with trauma avoidance is of the greatest diagnostic help.

Treatment and prognosis

Trauma avoidance, simple lubricants, and phototherapy are helpful.³⁸ Topical corticosteroids are of little help. Chronicity occurs, but clearing with a job change is more common.

Industry	Possible sensitizing agents
Textile	Azo dyes, formaldehyde, resins
Painting	Epoxy, acrylates
Printing	Acrylates, epoxy resins
Agriculture	Pesticides, plants, rubber
Food preparation	Flavorings and preservatives
Medical/dental/veterinary	Rubber, acrylates, medications
Hairdressers	Paraphenylenediamine, nickel, glyceryl monothioglycolate, rubber
Metal workers	Biocides in cutting fluids, metals
Rubber manufacture	Thiuram, carbamates, mercaptobenzothiazole
Leather tanning	Chromate, formaldehyde
Plastics manufacture	Formaldehyde, phenolic resins, epoxy resins

Table 29.1.10 Examples of occupations at risk for contact allergy

ALLERGIC CONTACT DERMATITIS

ACD is caused by skin contact with material that triggers an immunologic reaction, leading to inflammatory skin lesions. Approximately 20–25% of cases of occupational contact dermatitis are found to be allergic in origin, although some studies have reported up to 50%.³⁹ Certain occupational groups are at greater risk for developing contact allergy due to occupational exposure to common allergens (Table 29.1.10), with agricultural and manufacturing jobs being most often cited. In California and Oregon, for example, poison oak dermatitis is among the most commonly reported job-related illnesses. Common allergens in occupational ACD are summarized in Table 29.1.3, but these allergens represent only a small portion of known industrial allergens.

Pathophysiology

ACD is a type of delayed hypersensitivity reaction. A hapten for contact hypersensitivity usually is a low-molecular-weight, lipid-soluble material (to allow penetration through the stratum corneum to viable epidermis). The hapten then binds or complexes with cell surface or structural proteins on various cells, including Langerhans' cells (epidermal antigen-presenting cells) and keratinocytes. It appears that the Langerhans' cell processes and presents the antigen to T lymphocytes, and a cascade of events follows involving a number of interleukins and chemotactic factors that leads to a clonal proliferation of sensitized lymphocytes and to the inflammatory reaction seen clinically. There are several recent reviews of the mechanisms of ACD, and our understanding of the intricacies of the processes is still evolving.^{40–42} Recent data support the role of cutaneous irritancy as a necessary factor in the development of allergic contact dermatitis.^{43,44}

Clinical course

The clinical appearance of *acute* ACD usually is an erythematous, vesicular, edematous eruption at the sites of

contact with the allergenic substance (Table 29.1.7). The eruption is worse at sites with the most concentrated allergen exposure, and it may be milder (scattered erythematous papules) on areas where there was minimal exposure or where the allergen was washed off. The distribution of lesions may offer clues to the source of the allergen (e.g., gloves, clothing, air-borne) (Fig. 29.1.4). In severe, acute cases, the lesions may extend beyond sites of direct exposure because of the intensity of the inflammatory reaction and a phenomenon known as an auto-sensitization, or id, reaction. Because id reactions on the hands also are associated with fungal infections, the feet should be carefully examined. Inspecting the feet may provide clues to ACD because exposure may be originating from the person's

Figure 29.1.4: (a) and (b) Allergic contact dermatitis. Allergic contact dermatitis is characterized in its acute phase by vesicles with crusting and scaling. Erythema and edema are also features of this condition. The patient in (a) used neomycin-containing ointment on irritant dermatitis. The patient in (b) was a hairdresser who became allergic to the rubber gloves she was using to protect her hands from wet work.

footwear (e.g., rubber chemical). The lesions in acute ACD often occur 1–2 days after exposure, and may take 2 weeks to resolve. Thus, this time course differs from acute irritant exposure.

With repeated exposure to an allergen *chronic ACD* can develop. The clinical picture is variable, depending on the time interval between exposures (daily, weekly), and whether concomitant irritation is occurring with the same or other materials. In chronic ACD, the lesions generally are erythematous, scaling, and thickened. Vesicles may or may not be present, but they should be looked for very carefully. The hands are the most frequent site of involvement in ACD as well as in ICD. The dorsal surfaces may be more involved than the palms. However, the pattern of lesions on the hands cannot be reliably used to clinically distinguish ACD from ICD.⁴⁵

Diagnosis

The diagnosis of ACD is based on the occupational history and results of skin patch testing. A clinical impression alone can be incorrect, particularly with regard to the offending agent. Patch testing is summarized above, and as noted, there are several limitations to patch testing. There are limited commercially available allergens in the United States (Table 29.1.3), and both false-negative and false-positive results can occur. Adams' *Occupational skin disease*⁵ and other reviews^{39,46} offer valuable information about patch testing.

If patch testing gives a positive result, a determination should be made as to whether or not the allergen is present in the work environment. If so, avoidance of this allergen by the patient should be attempted by wearing adequate protective clothing, changing the industrial process to reduce worker exposure, or substituting a less allergenic material. If these measures are not feasible, then the worker may need to be removed from the job.

If patch testing is negative, the person's clinical history, examination, and exposures should be reviewed. If ACD is still suspected, one must question whether the proper allergens were tested and, if so, were they tested with the proper concentration and vehicle. A visit to the workplace to observe the patient performing his or her job may result in increasing the pool of suspected allergens. After an interval of several weeks, repeat patch testing might be performed with the same and additional allergens. It is preferable to have the patient tested when no systemic corticosteroids are being taken. Ultraviolet light can alter immune responsive cells in the skin; therefore it is best to avoid testing in the setting of recent ultraviolet exposure at the test site.⁴⁷ If contact allergy is suspected in such an individual (e.g., a brick mason who works shirtless in the summer), it may be worthwhile to repeat patch tests in the winter.

Other possibilities to be considered when faced with unexpected negative patch tests are contact urticaria or photocontact dermatitis. Eczematous dermatitis, for example, may result from scratching the area affected by contact urticaria induced by rubber gloves.

Treatment and prognosis

Avoidance of the allergen by one of the methods noted earlier is the first step in the management of ACD.⁴⁸ Unfortunately, these measures alone often do not solve the problem for several reasons. (1) The allergen (e.g., nickel) may be commonplace in both the workplace and the domestic environment, thereby making avoidance extremely difficult. (2) The allergen (e.g., glyceryl monothioglycolate in hairdressing) may be very common in the work environment, not only in direct contact in an industrial step but as residual in other steps of a process. In the example of glyceryl monothioglycolate, even if the affected hairdresser stops using the offending permanent wave solutions on his or her clients, there is still potential for the hairdresser to react to the product on other clients. Further, routine use of gloves may not protect the worker because the allergen can penetrate the gloves.⁴⁹ (3) In addition, ICD, atopic dermatitis, psoriasis, and another dermatosis may be part of a given patient's diagnosis, so that avoidance of the allergen alone does not solve the problem. When there is a reduced threshold for irritation, a recovery phase also may occur with ACD. Thus, general protective measures outlined for ICD are useful in treating ACD as well.

For acute ACD, removal of the affected individual from work and irritant exposures is indicated. Cool water or astringent agents such as aluminum acetate (Burow's solution) used as compresses are helpful in the treatment of weeping vesicular dermatitis. Topical corticosteroids applied once or twice daily also are useful. The strength of the corticosteroid chosen should depend on the body site involved and the severity of the reaction. Potent topical corticosteroids generally should not be used on the face or intertriginous sites, such as the groin, for prolonged periods (> 1 week). If medical treatment is sought early in the presentation of severe, acute ACD, systemic corticosteroids may be useful. A 2–3-week course of prednisone (0.5–0.75 mg/kg/day, with optional tapering) often is helpful. Shorter courses, or dose-packs, may result in rebound of signs and symptoms. Patch testing should be deferred until the systemic corticosteroids dose is lowered or completed. With vesicular dermatitis, secondary infection should be suspected and treated systemically, if present. It is prudent to avoid potentially complicating topical therapy of ACD with treatments such as neomycin-containing antibiotic ointments, medicated petroleum jelly, or even rubber gloves as such treatment could become part of the allergic problem if the patient also develops an allergy to one of these materials. Multiple contact allergies can develop. Systemic antihistamines can be useful for symptoms of ACD. Because most antihistamines are potentially sedating, caution should be used in prescribing them to workers who remain on the job. Newer low-sedating antihistamines may be potential alternatives that may not interfere with safety or job performance.

For chronic ACD, treatment measures are similar. Phototherapy with psoralens plus ultraviolet A (PUVA) may also be beneficial.⁵⁰

Prevention

Many of the preventive measures discussed under ICD are applicable to ACD as well (Table 29.1.9). With regard to *preplacement evaluation, eliciting a history of contact allergy* to nickel, gloves, or other allergens relevant to a specific job situation can be useful. For example, an individual may have a past history of nickel allergy that had manifested as a jewelry reaction. The associated rash may have long since resolved with avoidance of the offending jewelry. That individual could develop a new eruption if the new job involved frequent handling of nickel-plated metal parts. *Educating the potential worker about the nature of the job and potential allergen exposures* (e.g., poison ivy or oak in an outdoor job) also is useful in that this information may help an individual recall a past problem with that allergen. To educate the person effectively, however, the potential allergens in the workplace need to be identified. There are methods of predictive testing available to determine the sensitizing potential of chemicals in contact with human skin.

If a situation arises in which a potentially allergenic substance is to be introduced into the workplace, the question may arise regarding testing of employees to determine whether an individual is already allergic to that substance.⁵¹ This generally is not recommended for several reasons. An allergy may develop later even if the test is currently negative, and screening patch tests will not predict this possibility. Also, there is a risk of sensitizing the individual to the substance through the 2-day occlusive patch test, which may be a different exposure than might be encountered in the routine job activity. Predictive patch testing generally is limited to pre-marketing product evaluation and involves special techniques.

Protective clothing can be useful in minimizing skin contact with an allergen *if* (1) the clothing (such as gloves) is properly worn and (2) the clothing has been chosen so that it prevents penetration of the offending agent.⁵² Choosing specific gloves so that a hairdresser avoids contact with glyceryl monothioglycolate is a good example. Reference texts are available that detail penetration times for various gloves and chemicals.⁵³

In general, *barrier creams* have limited usefulness, but more recently, creams have been developed that aim at specific allergens. Products applied by outdoor workers prior to exposure to poison oak and ivy have been found to be effective in preventing or decreasing the occurrence of poison oak and ivy allergic dermatitis.^{54,55} Other barrier creams have been developed in an attempt to inactivate an allergen (e.g., chemical reduction of chromium) or to chelate metal allergens.⁵⁶

CONTACT URTICARIA

Immediate urticarial reactions to topical materials in the workplace, or so-called *contact urticaria*, has been recognized for many years, particularly in workers in the fish and meat industries. There is heightened awareness of contact urticaria in recent years due to the increased

recognition of immediate reactions to latex gloves and products in the healthcare field.^{9,57}

Pathogenesis

The wheal and flare reaction of contact urticaria can occur through either allergic (immunologic) or non-allergic (non-immunologic) mechanisms. Allergic contact urticaria usually is mediated by an IgE mechanism, and it is more common in atopic individuals (e.g., latex contact urticaria). As with delayed contact allergy, there may be a history of frequent exposure to an agent over time before symptoms occur, and a low proportion of individuals exposed to the agent develop an allergic reaction. In the non-immunologic type, many exposed individuals may be affected by the offending agent despite no prior exposure, paralleling what can occur with strong irritants. Atopic individuals are not predisposed to non-immunologic contact urticaria. There appears to be a direct effect on blood vessel walls through the release of vasoactive substances, leading to the wheal and flare.

Clinical course

The mechanism of contact urticaria (allergic versus non-allergic) may not be distinguished by the clinical presentation. There may be the onset of itching, stinging, or burning immediately or within minutes of contact with the agent. Preservatives (e.g., sorbic acid) or perfume ingredients (e.g., aldehydes) may explain the burning some people experience with cosmetics. This urticarial-like reaction is non-immunologic. The clinical lesions of contact urticaria may range from erythema to urticaria or angioedema, or all three (Fig. 29.1.5). Lesions usually are limited to sites of exposure, and again, the hands and forearms are the sites affected most often. Examples of materials that can cause contact urticaria in the occupational setting are listed in Table 29.1.11. Fish, foods, animal proteins, flavorings, and perfume ingredients are among the agents associated most often with contact urticaria.

With the institution of universal precautions in all allied health fields, contact urticaria is important to recognize because life-threatening anaphylactic reactions have occurred in healthcare workers (as well as in patients) exposed to latex products. Contact urticaria to latex (also called latex hypersensitivity) may present as asthma, hand dermatitis, or anaphylaxis depending on the source of exposure, e.g. air-borne latex protein in glove powder, gloves themselves, or mucosal contact with latex products. Groups at greatest risk include healthcare workers, patients with meningomyelocele, and those with atopic dermatitis.^{9,57}

A curious aspect of contact urticaria is that symptoms and signs may not occur with every exposure. In some cases, the reaction occurs only when the material is in contact with previously damaged skin (e.g., irritant dermatitis, atopic eczema), and if contact occurs when the underlying dermatitis is in remission, no urticaria or pruritus may be evident. Further, the clinical lesions of contact urticaria (erythematous wheals) may evolve into a vesicular

Foods	Medications	Flavorings/preservatives*	Miscellaneous
Apple Beer Carrot Egg Fish Lettuce Meat (poultry, beef) Milk Potato Spices	Bacitracin Benzocaine Chloramphenicol Neomycin Penicillin Promethazine Streptomycin	Balsam of Peru Benzoic acid Cinnamic acid/aldehyde Sodium benzoate Sorbic acid	Acrylic monomer Alcohol Aliphatic polyamine Diethyltoluamide Formaldehyde Lindane Latex Metals: nickel Platinum Xylene

* Usually cause non-immunologic contact urticaria.

Table 29.1.11 Sources of contact urticaria in the workplace

Figure 29.1.5: (a)–(c) Contact urticaria to latex. Wearing a latex glove, especially a wet one, for as short a time as 10 minutes can produce urticaria on the skin underneath the glove (a). Sometimes the urticaria is more conspicuous on the wrist than it is on the hand (b). An alternative way of producing contact urticaria is by tying a piece of the suspect glove onto the normal skin for 10–30 minutes and then observing the area of skin where the glove fabric has had contact (c).

dermatitis resembling typical ACD. For this reason, the time course of symptoms – itching at the time of or soon after contact – is a key point in suspecting the diagnosis of contact urticaria as the triggering factor for the subsequent evolution of the condition into eczematous dermatitis.

Diagnosis and differential diagnosis

Idiopathic urticaria usually can be distinguished from contact urticaria by its distribution. Physical urticarias, such as pressure or cold urticaria, may be more difficult to distinguish without contact urticaria testing or other test-

ing for physical urticarias. Dermographism, the most common physical urticaria, can be mistaken for type I allergy.⁵⁸ For example, a worker who cleans and packs fish on ice is exposed to the fish, the cold environment, rubber gloves, and the mechanical pressure of grasping the knife, any one of which could trigger urticarial lesions. Testing to demonstrate that the fish caused urticarial lesions could lead to intervention with protective vinyl gloves that might allow the worker to continue on the job. Irritants can cause immediate symptoms, usually burning more than itching, but there can be an overlap of irritant, allergic, and urticarial reactions triggered by certain agents

(e.g., formaldehyde, acrylates, ammonium persulfate in hair bleaches).

Testing for immediate reactions to latex proteins begins with a RAST (radio-allergosorbent test) for latex. If this is negative, having the patient wear a latex glove (or portion of glove) on a moistened hand is the next step. The risk of anaphylaxis is lower with this approach than with the skin prick test, still considered the gold standard.⁵⁷

ACD can be difficult to distinguish in the case of an eczematous reaction developing after immediate symptoms. Contact urticaria testing with a delayed eczematous reaction at the test site occasionally can demonstrate the problem, or performing both contact urticaria testing and standard patch testing at times may be useful. Latex protein can cause a type 4 delayed-type response as well as a type 1 reaction.^{59,60}

Treatment and prognosis

As with other types of contact dermatitis, avoidance of contact of the allergen with the skin is important. Oral antihistamines are useful to relieve itching. Systemic corticosteroids or epinephrine should be held in reserve for severe cases. Topical corticosteroids may be useful when eczematous lesions evolve. Protective gloves or sleeves can be useful if they are chosen carefully. As noted, the gloves themselves may be causing the problem. If glove-induced contact urticaria is suspected, it is most often due to the latex component, but immediate reactions to other components such as cornstarch or rubber additives have been reported. It may be important to analyze the situation before trying to recommend a substitute glove.

Prevention

Recognition that there are materials in the workplace that could cause both non-immunologic and immunologic contact urticaria is the first step. *Worker education* and *personal protection* are important. Because atopic individuals are more likely to develop immunologic contact urticaria, medical surveillance for early diagnosis and exposure modification may be helpful.

CONTACT PHOTODERMATITIS

Pathogenesis

Some naturally occurring and synthetic chemicals may cause contact dermatitis only in the presence of light, which may be sunlight or artificial light sources that emit specific wavelengths. This general reaction is known as contact photodermatitis, and there are two categories of reaction: phototoxic and photoallergic. Phototoxic reactions have non-immunologic mechanisms, in which a chemical, by the nature of its structure, absorbs a specific wavelength of light and produces a product that causes cellular damage. The mechanism may or may not involve production of reactive oxygen species. Photoallergic reactions involve conversion, by exposure to light, of a chem-

ical into an immunologically reactive hapten that leads to a delayed allergic hypersensitivity reaction. A recent review covers the spectrum of photosensitivity disorders.⁶¹

Clinical course

It can be difficult to distinguish clinically phototoxic from photo-ACD. In both, exposed areas of the skin such as the face, anterior V of the neck, backs of the hands, and uncovered sites on the arm (to the shirt sleeves) and legs frequently are involved. Hairy areas, upper eyelids, and below the chin may be spared. Phototoxic reactions may appear as a painful, exaggerated sunburn that may develop bullae and subsequent pigmentation. When the offending agent is avoided, the dermatitis usually disappears promptly. Photo-ACD may have many of the features outlined under ACD (itching, vesiculation).

Diagnosis and differential diagnosis

The distribution (on sun-exposed surfaces) of the reaction is an important clinical feature in suspecting the diagnosis, and the condition sometimes is difficult to distinguish from air-borne contact exposure. The method for photopatch testing is outlined in a previous section. Examples of substances that can cause contact photodermatitis with topical exposure and occupations at risk are given in Table 29.1.12.

Topical agent	Occupational example
Phototoxic	
Coal-tar derivatives	
Pitch, creosote	Railroad, construction
Acridine	Chemical/laboratory
Anthracene	
Dyes	
Anthraquinone	Textile, laboratory
Eosin	
Methylene blue	
Drugs	
Phenothiazines	Medical, pharmaceutical
Sulfonamides	
Plants and derivatives	
Compositae (yarrow)	Agricultural
Umbelliferae (celery, parsnip)	Vegetable workers
Rutaceae (lime, lemon)	Bartenders
Psoralen	Medical workers
8-Methoxypsoralen	
Photoallergic	
Antifungal agents	
Fentichlor	
Fragrances	Perfume/cosmetic industry
Methyl coumarin	
Musk ambrette	
Halogenated salicylanilide	Soap, cosmetic industry
Soap, deodorants	Usage exposure
Phenothiazines	Medical
Agricultural	
Sunscreens	Outdoor workers
PABA esters	
Benzophenones	
Whiteners	Textile workers

Table 29.1.12 Contact photodermatitis

Treatment and prognosis

Avoidance of contact with the offending agent is the most important measure in prevention and treatment. Protective measures such as clothing and topical sunscreens may be helpful, but it is important to be sure that the individual is not experiencing photodermatitis resulting from a chemical sunscreen ingredient (e.g., benzophenone). Other treatment measures are the same as those outlined under ACD. Prognostically, phototoxic eruptions usually resolve fairly quickly. Chronic photo-ACD may rarely eventuate into a marked and persistent photosensitivity reaction that continues despite avoidance of the triggering agent. Such persistent light reactivity (chronic actinic dermatitis) is difficult to manage and may require immunosuppressive agents.

29.2 Other Dermatoses

Christina A Herrick, Kalman L Watsky

The spectrum of occupational and environmental skin disease includes numerous other dermatoses in addition to the various forms of contact dermatitis. In this section of the chapter, we deal with non-malignant skin reactions to chemical, physical, and biologic agents. Skin cancer, the first recognized form of occupational skin disease, is discussed in Chapter 30.10. Acute skin injuries, including lacerations and punctures, account for a large proportion of all occupational injuries, but they are outside the scope of this chapter.

Skin disease continues to be the second most common form of occupational illness, with only repetitive trauma disorders accounting for more cases each year.¹ Data from the 2001 Bureau of Labor Statistics (BLS) annual survey shows that 12% of non-fatal occupational illnesses reported in 2000 in private industry were diseases of the skin. This represents an incidence of 46 cases per 100,000 full-time workers, although the true magnitude of occupational skin disease may be 10- to 50-fold higher than the annual survey suggests due to under-reporting and misclassification. Data from the United States and elsewhere estimate that contact dermatitis accounts for greater than 90% of cases of occupational skin disease.^{2,3} The remaining disorders represent a wide variety of cutaneous diseases whose prevalence is not well known. This section discusses the manifestations, pathogenesis, diagnosis, treatment, and prognosis of these dermatoses, organized by their causal agents.

Parasites

OCCUPATIONAL ACNE

Acne is a disorder of the pilosebaceous unit. Environmental and occupational acne can be divided into three types: oil folliculitis, acne vulgaris induced or exacerbated by environmental exposures, and chloracne. In each

instance, work-related acne is due to the action of chemical and mechanical factors on the follicular wall.

Oil acne (folliculitis)

Workers at risk include machinists; oil field workers; oil refiners; auto, truck, aircraft, and boat mechanics; rubber workers; roofers; and road maintenance workers.

Pathogenesis

The hair follicle is particularly susceptible to irritation from lipids, which disperse into sebum. Petroleum distillates such as non-synthetic cutting oils, pitch, and tar may alter the keratinization of the wall of the follicle, causing plugging of the follicle (comedo formation) or induce an inflammatory reaction by rupture of the follicular wall (folliculitis).

Clinical course

Oil acne presents as acneiform (follicular) lesions at the location of exposure, most commonly on the dorsae of the hands and forearms. Comedones as well as inflammatory folliculitis may occur in exposed sites. Covered areas of the body also may be involved due to saturation of clothing with oils. Pitch or coal tar acne is associated primarily with comedones across the malar area and periorbitally, with few inflammatory lesions.⁴

Diagnosis

The areas of involvement in oil acne are different from those seen in either acne vulgaris or chloracne (Table 29.2.1). The history usually is adequate to confirm the diagnosis.

Prevention

Protective clothing should be used, particularly aprons and arm shields. Mandatory daily laundering of work clothes and end-of-shift showers are helpful. If exposure cannot be prevented, then dilute synthetic water-based cutting fluids should be substituted for neat (i.e., straight petroleum-derived) oils.

Treatment and prognosis

Approaches to treatment are similar to those for routine acne.⁵ Oral antibiotics, especially tetracycline and erythromycin, reduce inflammation and treat secondary infection. Topical antibiotics (clindamycin; erythromycin) can also be useful. Comedones are more refractory to treatment but may respond to long-term topical retinoids (tretinoin; adapalene). Once the exposure has ended, the eruption gradually subsides.

Acne vulgaris

Persons at risk include workers in fast food restaurants, actors, actresses, models, and cosmeticians.

	Age	Distribution	Clinical features	Associated conditions
Oil acne (folliculitis) Acne vulgaris	Any age Peak incidence, ages 11 to 20	Exposed sites Face, neck, chest	Open comedones, pustules Open and closed back comedones, papules, pustules, cysts, scar	None None
Chloracne	Any age	Face, especially the malar crescent and auricular creases, axillae, groin; nose spared	Open and closed comedones, straw-colored cysts	Xerosis, conjunctivitis, actinic elastosis, peripheral neuritis, liver abnormalities

Table 29.2.1 Differential features of acne

Pathogenesis

Acne vulgaris can be induced or exacerbated by numerous environmental stimuli in addition to oil. Friction, heat, and sweating also play a role in the development of acne lesions.

Clinical course and diagnosis

The lesions typically involve the face, neck, upper chest and back (see Table 29.2.1). The history of exposure to oils and grease, oil-based make-up, or friction (e.g., from a head-band) usually is adequate to arrive at the diagnosis.

Prevention

Avoiding contact with the offending substance and adequate hygiene usually are helpful in preventing the condition.

Treatment and prognosis

Oral antibiotics, especially tetracycline and erythromycin, reduce inflammation and treat secondary infection. Topical antibiotics (clindamycin; erythromycin) can also be useful. Comedones are more refractory to treatment but may respond to long-term topical retinoids (tretinoin; adapalene).

Chloracne

Although originally described approximately 100 years ago by Von Bettman,⁶ chloracne more recently has entered the world's lexicon as a consequence of Agent Orange use during the Vietnam War and industrial accidents with dioxin and its related compounds.⁷ Chloracne is believed to be a sensitive indicator of systemic exposure to specific polyaromatic hydrocarbons. Persons at risk include workers in production of halogenated aromatic hydrocarbon-based pesticides and herbicides, electrical workers exposed to older polychlorinated biphenyl (PCB)-type transformer oils, and environmental workers engaged in cleaning up or disposing of previously produced agents. Table 29.2.2 lists the major chemicals that have been incriminated.

Pathogenesis

To a much greater extent than other petroleum products, agents that cause chloracne induce a marked dyskeratosis of the follicular epidermis, which causes a non-inflammatory keratin build-up in the follicle referred to as a comedo (Fig. 29.2.1). Comedo formation often progresses to a character-

Polyhalogenated naphthalenes*

Polychloronaphthalenes

Polybromonaphthalenes

Polyhalogenated biphenyls

Polychlorinated biphenyls (PCBs)

Polybrominated biphenyls (PBBs)†

Polyhalogenated dibenzofurans*

Polychlorodibenzofurans, especially tri-, tetra-, penta-, and hexachlorodibenzofuran

Polybromodibenzofuran, especially tetrabromodibenzofuran

Contaminants of polychlorophenol compounds, especially herbicides (2,4,5-T and pentachlorophenol) and herbicide intermediates (2,3,5-trichlorophenol)

2,3,7,8-Tetrachlorodibenzo-*p*-dioxin (TCDD)

Hexachlorodibenzo-*p*-dioxin

Tetrachlorodibenzofuran

Contaminants of 3,4-dichloroaniline and related herbicides (Propanil, Methazole)

3,4,3',4'-Tetrachloroazoxybenzene

3,3',3',4'-Tetrachloroazobenzene

Others‡

1,2,3,4'-Tetrachlorobenzene (experimental)

Dichlobenil (Casoron)—a herbicide (clinical only)

DDT (crude trichlorobenzene)

* Polychlorodibenzofurans and hexachloronaphthalenes may occur as contaminants in some PCBs.

† Polybromonaphthalenes may occur as contaminants in some PBBs.

‡ Not confirmed as chloracne-producing agents.

Table 29.2.2 Chloracne-producing chemicals.

istic straw-colored cystic lesion, the chloracne cyst. The development of chloracne can be generally correlated with serum levels of the chloracne-inducing agent, particularly with tetrachlorodibenzodioxin (TCDD).⁸ The experience with PCBs and pesticides has been less clear because the specific causal metabolite may differ from what is measured (see Chapters 45 and 48). Individual variation in follicles is clearly evident, with some individuals showing higher serum levels of TCDD without chloracne than others who have the cutaneous disease. The follicular level of the agent may be of greatest importance in producing clinical change.

Clinical course

Several clinical features distinguish chloracne from acne vulgaris (Table 29.2.1).^{3,7} The onset of chloracne is seen within 2–8 weeks of exposure to a chloracne-producing

Figure 29.2.1: Chloracne: comedones and scarring on the cheek and neck.

agent. The disease will continue to progress and subsequently regress over a 4–6-month period, presuming that there is no further exposure to the chloracne-producing agent. If the exposure has been intense, clinical lesions of chloracne may continue to appear many years after the exposure has ended. The primary lesion of chloracne is the comedo as well as the straw-colored cyst. The inflammatory papules and pustules of acne vulgaris are not evident. The distribution of lesions is also of primary importance (see Table 29.2.1). The most uniquely involved areas are the postauricular folds, the malar crescent, and the genitalia. The nose typically is spared. Associated cutaneous features include xerosis, pigmentation, conjunctivitis, and scarring.

Non-cutaneous findings are varied following exposure to the chemicals that cause chloracne.^{3,7} Hepatomegaly may occur, as may liver damage. Liver damage is associated more commonly with chloronaphthalenes than with PCBs. Porphyria cutanea tarda has been associated with exposure to chloracne-producing agents in some cases, but the causal link remains weak. Hepatic porphyria has been attributed to TCDD exposure. Peripheral neuropathy also has been reported.

The chloracne-causing agents (Table 29.2.2) vary in their potency, with TCDD causing chloracne at the lowest concentrations. Microgram concentrations of TCDD applied directly to the skin over a period of time induce chloracne.

Diagnosis

A history of exposure to a chloracne-producing agent and lesions consistent with chloracne suggest the diagnosis. Serum lipid and adipose levels of suspect compounds and metabolites should be obtained for confirmation of exposure; this measurement must be performed by an experienced laboratory with gas chromatography/mass spectroscopy (GC/MS) capabilities and carefully controlled comparisons. Biopsy may be useful for diagnosis because chloracne-producing agents cause loss of follicular sebaceous glands. It may be difficult to distinguish actinic elastotic comedones from mild cases of chloracne.

Treatment

The treatment of chloracne is difficult, although some success has been seen with oral antibiotics, topical retinoic acid, and oral isotretinoin.⁹ Cyst formation may be prevented by early institution of retinoid therapy.

Prevention

Chloracne-producing agents are unwanted byproducts of industrial processes. Even minute exposures must be avoided. Therefore, the following guidelines should be followed at any plant where chloracne-causing agents are produced or used: (1) clean locker room and shower facilities, (2) use disposable impervious clothing for workers with potential for direct contact, (3) routinely monitor for plant contamination using wipe samples, and (4) routinely educate and monitor workers.

PIGMENTARY DISORDERS

Occupational and environmental causes of cutaneous dyspigmentation are varied and may be exhibited as hyperpigmentation or hypopigmentation. The differential diagnosis should always include inherited or idiopathic conditions, and thus, a thorough investigation should be undertaken in each case.

Hyperpigmentation

Workers at risk include those exposed to heavy metals and those working with organic nitrogen compounds and dyes. Compounds that may cause hyperpigmentation are listed in Tables 29.2.3 and 29.2.4.

Pathogenesis

Mechanisms of hyperpigmentation include: (1) exogenous pigment deposition, (2) deposition in skin systemically, (3)

Chemical	Color
Aniline dyes	Pigmented contact dermatitis
Azo dyes	Pigmented contact dermatitis
Danthron	Red-brown
Dihydroxyacetone	Yellow-orange
2,4-Dinitrophenol	Yellow
Dinitrosalicylic acid	Yellow
Henna (2,4-dihydroxynaphthoquinone)	Reddish orange
Nitrazepam	Yellow
Phenazopyridine (Pyridium)	Yellow
Picric acid	Jaundiced appearance
Sodium nitrite	Yellow
Tetryl (Tetra-nitromethylaniline)	Canary yellow

Adapted from Lerner EA, Sober AJ. Chemical and pharmacologic agents which cause hyperpigmentation of the skin. In: Fitzpatrick TB, Wick MM, Toda K, eds. Brown melanoderma: biology and disease of epidermal pigmentation. Tokyo: University of Tokyo Press, 1986: 215–227.

Table 29.2.3 Hyperpigmentation: nitro compounds and dyes that stain skin

Substance	Color	Location
Arsenic	Bronze	Diffuse, especially trunk and proximal extremities
Bismuth (chromium)	Blue-gray	Diffuse
Copper	Greenish	Hair
Gold (chrysiasis)	Blue-gray	Sun-exposed areas, especially periorbitally
Iron	Brown	Tattoo
Lead	Pallor and vividity	Generalized, gingival leadline
Mercury	Slate gray	Skin folds
Silver (argyria)	Slate gray	Sun-exposed areas

Adapted from Lerner EA, Sober AJ. Chemical and pharmacologic agents which cause hyperpigmentation of the skin. In Fitzpatrick TB, Wick MM, Toda K, eds. *Brown Melanoderma: Biology and Disease of Epidural Pigmentation*. Tokyo, University of Tokyo Press, 1986 pp 215–227.

Table 29.2.4 Hyperpigmentation: metals that may be systemically or locally deposited in skin

Figure 29.2.2: Argyria: silver tattoos in a silver worker.

Figure 29.2.3: Postinflammatory hyperpigmentation and hypopigmentation following irritant contact dermatitis.

photoeruptions, and (4) postinflammatory hyperpigmentation.¹⁰ Exogenous pigment deposition is typically due to a tattoo (e.g., silver shavings in a jewelry worker) or superficial staining by dye-like compounds. The most important of these factors are listed in Tables 29.2.3 and 29.2.4. Systemic toxicity with a variety of heavy metals can lead to cutaneous dyspigmentation. The most striking form of dyspigmentation is argyria due to systemic deposition of silver (Fig. 29.2.2).

The most common forms of occupational and environmental hyperpigmentation are photoeruption and postinflammatory hyperpigmentation (Fig. 29.2.3). Photoeruptions include sunburn as well as the exacerbated sunburn response (phototoxic dermatosis) that results from exposure of the skin to furocoumarins and light in the UVA spectrum.¹¹ Postinflammatory hyperpigmentation is typically dermal and can follow any skin injury. Dermal pigment results from deposition of melanin, hemosiderin, or both.

Clinical course

The pattern of pigmentation varies depending on the etiology (Tables 29.2.3 and 29.2.4). With photodermatoses, the pigmentary changes are usually noted in sun-exposed sites: the face, the V of the neck, and the dorsa of the

hands. Pigmentation resulting from heavy metal toxicity may be exacerbated by exposure to the sun. Postinflammatory hyperpigmentation occurs at the sites of skin injury. Hyperpigmentation may be epidermal, dermal, or mixed. The type often can be distinguished by a Wood's lamp examination, which shows epidermal hyperpigmentation to be accentuated and dermal pigmentation to be diminished.

Diagnosis

The pattern of pigmentary change often suggests the diagnosis. Wood's lamp examination may be helpful. Biopsy may give important information in cases of dermal tattoos or systemic toxicity from heavy metals (Tables 29.2.3 and 29.2.4).

Prevention

Sunscreens can be effective in limiting photoeruptions. Protective clothing is needed to prevent exogenous pigment deposition. This protection is doubly important in working with organic dye-like compounds because many of these compounds are toxic and are absorbed through intact skin (see Chapter 42). Prevention of systemic absorption of metals requires the range of industrial hygiene practices.

Treatment and prognosis

The hyperpigmentation that results from tattoos and systemic heavy metal toxicity may be irreversible. Exogenous staining of the stratum corneum resolves without treatment within a period of a few weeks. Postinflammatory hyperpigmentation may persist for months, especially in those who are more darkly pigmented. Epidermal hyperpigmentation may respond to treatment with agents containing hydroquinone and retinoic acid. Side effects of hydroquinone include contact dermatitis as well as exogenous ochronosis. Dermal pigmentation has no effective therapy.

Hypopigmentation

Hypopigmentation of the skin due to occupational or environmental causes has two principal etiologies: chemical leukoderma and postinflammatory hypopigmentation (Figs 29.2.4 and 29.2.5). Chemical leukoderma can result from skin contact with substances containing hydroquinone or derivatives of alkyl phenols and catechols (Table 29.2.5). Those at risk include rubber workers, photographic developers, hospital housekeepers, printers, and workers in the oil, paint and plastics industries.³ Cutaneous injury, from inflammation or trauma, may also produce a focal loss of skin pigment (Fig. 29.2.5).

Clinical course

Chemical leukoderma was first described in 1939 as an epidemic of depigmentation at a tannery due to the use of rubber gloves containing monobenzyl ether of hydroquinone.^{12,13} Pigment was lost in areas exposed to the compound but also at sites distant from exposed skin. This pattern of pigment loss may be difficult to distinguish clinically from idiopathic vitiligo. Postinflammatory hypopigmentation occurs at the location of previous skin injury, either from trauma or dermatitis.

Pathogenesis

The compounds known to cause chemical leukoderma are very similar in structure to that of melanin and its precursors, and they are known to have a direct cytotoxic effect

Hydroquinone
 Monobenzyl ether of hydroquinone
 Monoethyl ether of hydroquinone (hydroxyanisole)
 p-Isopropylcatechol
 p-Methylcatechol
 p-tert-Butylcatechol
 p-tert-Butylphenol
 p-tert-Butylphenol
 p-tert-Amylphenol
 Mercaptoamines
 N-(2-Mercaptoethyl)-dimethylamine hydrochloride
 2-Mercaptoethylamine hydrochloride
 N, N', N''-Triethylenethiophosphoramide (thiotepa)

Table 29.2.5 Compounds known to produce chemical leukoderma.

Figure 29.2.4: Chemical leukoderma in a worker exposed to phenolic compounds.

Figure 29.2.5: Postinflammatory hypopigmentation following a chemical burn due to ethylene oxide.

on melanocytes. The effects possibly are due to the formation of free radicals, leading to damage of cellular membranes and formation of antigens, which activate lymphocytes.¹⁴ This theory would explain why the loss of pigment cells may occur at sites distant from the sites of exposure. Postinflammatory hypopigmentation likely is due to a defect in the transfer of pigment from melanocytes to keratinocytes.

Diagnosis

Wood's lamp examination is helpful in distinguishing postinflammatory hypopigmentation from chemical leukoderma. Chemical leukoderma typically demonstrates complete depigmentation. Skin biopsy with special stains for melanocytes also may be helpful. It can be difficult to distinguish idiopathic vitiligo from chemical leukoderma, and therefore, a complete history of chemical exposures needs to be obtained in all instances.

Prevention

Melanocytotoxic agents should be used only with caution and with strict adherence to protective safety measures. Worker education regarding the effects of these chemicals is essential.

Treatment

Chemical leukoderma can respond to long-term treatment with psoralen plus UVA light (PUVA).¹⁵ Localized areas of pigment loss also may be treated with epidermal allografts.¹⁶ Postinflammatory hypopigmentation usually resolves over time. Permanent postinflammatory pigment loss may require cosmetic cover-up.

RADIODERMATITIS

Workers at risk are numerous and include all those involved with radioactive substances. Medical and industrial workers exposed to x-ray-emitting devices and isotopes, workers in uranium mining in the field of nuclear energy, and nuclear waste management personnel are particularly at risk.

Clinical course

Cutaneous findings of acute, intense radiation damage include early blistering, with eventual loss of skin and skin appendages in the exposed area. Chronic radiation damage results in epidermal atrophy, enlarged blood vessels, and pigmentary changes (poikiloderma). The clinical appearance is that of a burn scar. Cutaneous carcinoma may develop in irradiated skin many years later.

Other effects include dryness and cracking of irradiated skin, alopecia, and chronic skin ulcers. If extensive areas of the body are exposed, the skin changes become a small part of the acute radiation syndrome, with its three phases of early nausea and prostration, followed in 1–2 days by a general feeling of wellbeing, and a third phase in about a week of fever, weight loss, gastrointestinal symptoms, and possible death from bone marrow suppression and infection (see Chapter 33.1).

Pathogenesis

Radiodermatitis commonly refers to alterations in the skin produced by ionizing radiation. Radioactive particles pass through and damage cell structures, including chromosomes, particularly in rapidly dividing tissue layers. Lethal damage to basal cells results in initiation of a classic inflammatory response. Death of melanosomes may result in subsequent pigmentary alteration. Non-lethal damage enhances the possibility of cell transformation and subsequent neoplasia (see Chapter 30.10).

Diagnosis

A history of radiation exposure and a compatible clinical picture are suggestive. A biopsy may be useful to confirm the diagnosis.

Prevention

Radiation can be measured, and routine monitoring is needed for any worker with potential exposure. Protective

shielding, based on the form of exposure, should prevent radiation damage and should be required for workers with radiation exposures.

Treatment and prognosis

Treatment of acute radiation exposure is supportive. Because radiation exposure is irreversible and produces effects many years later, monitoring of exposed individuals for the development of cutaneous malignancies and premalignancies is needed; early diagnosis and treatment may alter the natural history of the condition. Routine use of sunscreens may prevent augmentation of x-ray-induced sequelae by radiation with the longer wavelengths of ultraviolet light.

PHYSICAL URTICARIA

Urticaria, also known as hives, is a common condition that may affect up to 20% of the population at some time during the course of their lives. Urticaria may result from occupational or environmental exposures. Contact urticaria (see Chapter 29.1) has been increasingly recognized as an important and potentially serious entity. The physical urticarias may be exacerbated by environmental exposures.

Clinical course

Physical urticarias have been divided into several subgroups.¹⁷ Dermographism usually presents as hives, which are elicited by stroking or scratching. Pressure urticaria may be seen at localized points of skin pressure. Cholinergic urticaria presents as small wheals surrounded by wide areas of erythema in response to heat and sweating. Cold urticaria develops at sites of contact with cold and may be familial. Solar urticaria develops in response to light of varying wavelengths. All of these physical forms of urticaria may be accompanied by systemic complaints such as headache, wheezing, or syncope. Rare forms of physical urticarias include heat contact urticaria, aquagenic urticaria, vibratory angioedema, and exercise anaphylaxis.^{18,19}

Pathogenesis

Urticaria can represent an IgE-mediated response to a variety of stimuli. Acute urticaria usually is due to exposure to various foods or medications. A specific cause of chronic urticaria, arbitrarily defined as urticaria lasting more than 6 weeks, is rarely discovered. Many of these cases may represent patients with autoreactive anti-IgE receptor antibodies.²⁰ In evaluating any patient with urticaria, it is important to exclude physical urticarias as a possible cause to avoid unnecessary testing.

Diagnosis

Clinical history and appearance usually are adequate to make a diagnosis of physical urticaria. Firm stroking of the skin leads to hives in patients with dermographism. Cholinergic urticaria may be induced by physical exercise or a hot shower. The diagnosis of cold urticaria may be made by using a 3–5-minute skin exposure to ice, a

5–15-minute exposure to cold water, or a 5–10-minute exposure to cold air. Solar urticaria may be induced by phototesting the skin at the appropriate wavelengths, whereas pressure urticaria requires local application of weights.

Prevention

The various forms of physical urticaria require specific preventive measures according to the nature of the eliciting stimulus. Job reassignment may be necessary.

Treatment and prognosis

The treatment of physical urticaria primarily is preventive, although antihistamines and mast cell stabilizers also are used.²¹ Accurate diagnosis in the workplace setting is critical to avoid unnecessary evaluation. The prognosis for the various forms of physical urticarias is variable, although most patients improve over a period of months to years. A recent study showed that only 16% of patients with physical urticaria were symptom free one year after diagnosis, compared with 47% of those with other forms of chronic urticaria.²²

PHOTODERMATOSES

Photoeruptions related to occupational and environmental exposures are of several types. Excessive exposure to the sun is a risk for a number of outdoor occupations. Phototoxic reactions are an exaggerated sunburn response and occur in association with a variety of chemical exposures. Photoallergic eruptions require light and a photoallergen in order to fully develop. This last topic is discussed at greater length in Chapter 29.1. Persons at risk include farm workers, roofers, commercial fisherman, and other outdoor workers.

Clinical course

Sunburn typically presents as a first-degree burn, characterized by erythema in sun-exposed sites followed in 1–2 days by desquamation. Phototoxic dermatoses represent an exaggerated sunburn response that occurs at sites that are exposed to both the sun's rays and photoactive agents. Second-degree burns may result, characterized by intense erythema and bullae formation. The postinflammatory hyperpigmentation that results may persist for several weeks.

Pathogenesis

Sunburn is primarily due to light in the UVB spectrum. Occupational phototoxic dermatoses are principally the result of exposure to light in the UVA spectrum in combination with furocoumarins (Table 29.2.6) and tar products.^{11,23} UVA is believed to be the wavelength of light primarily responsible for skin aging, although both UVA and UVB have been implicated in photocarcinogenesis.

Diagnosis

A history of sun exposure, combined with a typical photodistribution, usually is adequate to make the diagnosis.

Bergamot	Giant hogweed
Bitter orange	Lemon
Carrot	Lime
Celery	Masterwort
Citron	Parsnip
Cow parsley	Persian lime
Dill	Rue

Adapted from Fisher AA. Contact dermatitis, 3rd edn. Philadelphia: Lea and Febiger, 1986.

Table 29.2.6 Some common plants containing furocoumarins

sis. Exposure to photoactive substances is further evidence in support of the diagnosis. A biopsy may be helpful. It is important to exclude other causes of photosensitivity (e.g., lupus erythematosus, medications) in the evaluation of a patient with a photodermatosis.

Prevention

Sunscreens are helpful in the prevention of sunburn. It is important to use those with a sun protection factor (SPF) rating of #15 or better. These compounds are less effective in preventing damage from UVA, and therefore, physical sunblocks are more useful in these cases. Use of protective clothing when working with photoactive substances is important in the prevention of phototoxic dermatoses.

Treatment and prognosis

Treatment of photoeruptions includes open-wet dressings and bland emollients. Rarely, a course of systemic steroids is necessary for severe cases. Postinflammatory hyperpigmentation resolves over a period of several months. Workers with clinical signs of chronic sun exposure are at risk for cutaneous malignancies and should be followed closely.

ERYTHEMA AB IGNE

This condition may occur in workers exposed to furnaces, such as cooks, stokers, glass blowers, and kiln operators. In addition, long-term exposure to a heating pad, stove, or heater is a risk factor.

Clinical course

The early changes are an asymptomatic reticulated pattern of the cutaneous blood vessels (livedo reticularis), which proceeds to reticulated pigmentation. Localized poikiloderma (epidermal atrophy, telangiectasia, and pigment alteration) develops later. The area usually is regional, corresponding to the site of repeated applications of heat. Both squamous cell and Merkel cell carcinomas have been reported to occur in the poikilodermatous area.^{24,25}

Pathogenesis

Radiant energy applied to the same area over time produces this change. Persistent vasodilation of the dermal-subcutaneous vasculature is the likely cause of the early changes (Fig. 29.2.6).

Figure 29.2.6: Erythema ab igne due to prolonged use of a heating pad for a back injury.

Diagnosis

The local nature of the condition, along with a history of exposure to heat, is suggestive. A biopsy of the affected area may be useful to exclude other conditions associated with livedo reticularis.

Prevention

Repeated exposure to intense radiant energy must be avoided. Education of workers at risk is the key to prevention.

Treatment

Cessation of exposure may bring regression of early changes. Once permanent change has occurred, the area must be monitored for future development of skin carcinoma, similar to the monitoring of skin damaged by ionizing radiation.

MILIARIA

Bakers, foundry workers, cooks, coke oven operators, and workers with similar exposure to excessive heat that causes sweating are at particular risk for developing this condition.

Clinical course

This condition results from blockage of the sweat ducts. Clinical lesions are on a spectrum encompassing clear vesicles if the blockage is in the superficial epidermis (miliaria crystallina), macules or papules if the blockage is in the lower epidermis (miliaria rubra), or flesh-colored to pale white papules if the obstruction is in the dermis (miliaria profunda). The trunk is the most commonly affected location, especially the chest, back, submammary, and axillary areas. The palms and groin also may be involved. Symptoms usually are absent with miliaria crystallina, while miliaria rubra and miliaria profunda may be pruritic or painful.

Scaling results from the superficial vesicles, whereas deeper plugging, if extensive, may lead to inadequate body

thermoregulation with accompanying heat exhaustion. If the condition progresses due to continued heat exposure, the lesions of miliaria profunda, which are indicative of loss of sweating mechanisms, may result in extreme susceptibility to systemic illness resulting from heat stress (see Chapter 34).

Pathogenesis

Sweating and maceration cause plugging of the eccrine sweat duct with ductal keratin. Microbial organisms may invade the macerated keratin and cause further plugging of the duct.

Diagnosis

Diagnosis is made by the clinical picture, symptoms, and the history of onset after excessive heat exposure and sweating. Excessive sweating also may exacerbate an underlying skin disease.

Prevention

Repeated heat exposures should be avoided in workers prone to miliaria. Hexachlorophene soap may be useful to decrease the skin's bacterial population. Maceration of the skin should be avoided by frequent clothing changes when sweating is profuse.

Treatment and prognosis

Removal of the worker from the hot working environment cures the disease, although the lesions and symptoms may persist for several days. A period of a week or more should elapse before re-exposure of the individual to the hot environment is attempted, particularly if the eruption is severe enough to cause a decrease in systemic heat tolerance. Some individuals are very susceptible to this condition and may need to avoid occupational heat stress altogether.

FROSTBITE, IMMERSION FOOT, AND CHILBLAINS

These conditions caused by local tissue exposure to cold may affect a wide range of workers (see also Chapter 34). Persons at risk for frostbite include those who work in refrigerated environments, fire fighters, sailors, pipeline maintenance workers, and military personnel in frigid northern areas. Sewer and construction workers, as well as military personnel working in extremely cold weather, are at risk for immersion foot. Chilblains affect primarily northern European workers exposed to cold, damp conditions.

Clinical course

Frostbite results from exposure to extreme cold, which initially causes blanching of exposed skin, especially on acral areas (Fig. 29.2.7). Dysesthesia accompanies this early cutaneous alteration. As exposure continues, the skin becomes frozen and appears white or waxy and becomes anesthetic. On rewarming, the extent of injury emerges over several days with an initial bluish appearance, then redness, edema, and blistering. Severe pain accompanies

Figure 29.2.7: Frostbite of the distal fingers in a bridge worker. The yellow discoloration is due to povidone-iodine (Betadine).

the rewarming. Lines of necrosis develop, and recovery is often prolonged.

Immersion foot is cold injury in conjunction with water.²⁶ Continuous exposure for as few as 19 hours may cause an extremity to become pale bluish, edematous, and numb. The clinical course then progresses to erythema, further swelling, and extreme pain as the foot is warmed. This phase may last for weeks to months. Paresthesias, vasomotor instability, and joint stiffness may persist for years.

Chilblains are characterized by red to bluish plaques accompanied by burning or itching, with an occasional vesicular component that may occur within 24 hours of exposure to a cold damp climate. Pressure eliminates the color of the plaque, which may progress to swelling and ulceration. These plaques may become chronic nodules, which tend to develop bullae and ulcerate, leading to fibrosis. They may disappear in warm weather and reappear in cold weather. Children frequently are affected.

Pathogenesis

During intense cold exposure, there is channeling of blood from superficial vessels to conserve core body heat. Skin tissue can become cold enough for ice crystals to form in cells, leading to tissue death. Immersion foot results from constriction of cutaneous blood vessels by footwear and prolonged low temperatures of the skin not sufficient to cause freezing of the cells. Chilblains result from localized vascular injury due to exposure of the skin to cold and damp areas. Genetic factors that allow vasomotor instability in this type of environment are probably relevant.

Diagnosis

Characteristic signs and symptoms following extreme cold exposure are diagnostic of frostbite, although the extent of tissue injury may not be known for days to weeks.

Chilblains and immersion foot also have characteristic histories of cold exposure preceding the cutaneous findings. However, the cold exposure is less severe with these conditions, the clinical appearance is different, and a wet-work environment is essential in the diagnosis of immersion foot. A skin biopsy may be needed to differentiate

chilblains from vasculitis, connective tissue disease, and cryoglobulinemia.

Treatment and prognosis

Immediate and rapid rewarming of the affected area, usually by immersion in warm water, is recommended for frostbite and immersion foot. Warm drinks and warm food raise core body temperature, increasing cutaneous blood flow. Analgesics for pain and vigorous surveillance for and treatment of infection are required.

For frostbite, the depth and extent of tissue necrosis dictate the long-term prognosis. Surgical debridement or amputation of gangrenous tissue may be required. Infection can greatly increase the damage from frostbite. Even when gangrene is absent, long-term effects may include vascular and neurologic alterations of the affected area such as episodic vasoconstriction, increased sweating, and paresthesias of the injured part.

Long-term sequelae from immersion foot are similar to those of frostbite and may persist for years.

Chilblains are treated symptomatically and do not require rapid rewarming. Vasodilating agents (e.g., calcium channel blockers) have proved effective when symptoms resist or recur.²⁷ Moving to a warm climate is helpful in some instances, but some cases become progressive and chronic despite the use of therapeutic measures.

Prevention

Cold injury may be prevented by using protective clothing, which prevents chilling of skin tissues. It is important that the clothing is not tight fitting, so as not to compromise cutaneous circulation. Education of workers regarding the early changes of these conditions and potential problems associated with prolonged cold exposure is essential.

VIBRATION-INDUCED WHITE FINGER DISEASE (HAND-ARM VIBRATION SYNDROME)

Workers at risk for vibration-induced white finger disease, or hand-arm vibration syndrome (HAVS), include operators of vibrating tools, piston-operated compressed air tools, and tools that are turned by electric motors or air-driven turbines. Most recently, HAVS has been reported in workers operating high pressure hoses.²⁸ This condition may be exacerbated by occupational activities in cold weather.

Clinical course

HAVS, characterized by blanching of the fingers when operating vibrating tools, is accompanied in its early stages by mild numbness and tingling. With continued operation, the fingers may develop loss of sensation and decreased dexterity. The blanching may be followed by cyanosis and hyperemia as in classic Raynaud's phenomenon, although it tends to be asymmetric. Vascular changes are more prominent when vibrating tools are handled in

cold weather. The number of occurrences and the severity of symptoms may be exacerbated by continued work with vibrating tools. Although at first a single digit may be affected, the condition eventually may involve all the fingers on both hands, although the thumbs often are spared (see also Chapter 23.3).

Cold exposure or emotional stimuli leading to pallor of the fingers followed by bluish cyanosis and subsequently erythematous hyperemia, known as Raynaud's phenomenon, may be idiopathic or familial, but it also may be a cutaneous sign of an underlying connective tissue disease.

Pathogenesis

Skin, vascular and nerve changes are seen in skin biopsies of patients with vibration-induced white finger disease.²⁹ Vascular abnormalities in these patients include microangiopathic, vasospastic and thrombotic changes. HAVS has been associated with vibrating frequencies between 30 and 300 Hz. The effects of vibration are probably exacerbated by the pressure required to hold and guide a vibrating tool, which leads to vasoconstriction.

Diagnosis

A history of exposure to vibrating tools is necessary to make a diagnosis of HAVS. A thorough investigation for possible underlying connective tissue disease should be undertaken in every case.

Prevention

Insulation from vibrations, combined with tools designed to decrease the pressure needed for tool guidance, is useful. Operators of vibrating tools should be made aware of the risk of vibration injury to the hand and instructed to report the early changes. All workers with Raynaud's phenomenon, whether or not the condition is job related, should have protection of their hands from cold weather to avoid exacerbation of the disorder.

Treatment and prognosis

Treatment of Raynaud's phenomenon involves both physical and pharmacologic therapies that are beyond the scope of this text. Avoidance of vibrating tools and protection from cold are important factors. The prognosis depends on the cause and extent of vascular injury. In general, early vibration changes will stabilize or revert if the trauma is discontinued.

OCCUPATIONAL ACRO-OSTEOLYSIS AND SCLERODERMA

Cleaners of vinyl chloride polymerization reactor tanks have been reported to develop Raynaud's phenomenon in association with osteolytic bone changes.³⁰ This association, however, has more recently come under question.³¹ Likewise, workers exposed to silica dust have been reported to be at risk for developing Raynaud's phenomenon and scleroderma, with the simultaneous use of vibrating tools

apparently contributing to development of disease.³² Exposure to organic solvents has also been associated with development of systemic sclerosis.³³

Clinical course

Occupational acro-osteolysis is the term used to define the triad of Raynaud's phenomenon, sclerodermatous skin changes, and lytic bone lesions reported in workers exposed to vinyl chloride.³⁴ Progressive systemic sclerosis associated with exposure to silica is difficult to distinguish from the idiopathic form of scleroderma. Prominent cutaneous features of this disorder include sclerodactyly, Raynaud's phenomenon, and digital necrosis.

Diagnosis

Patients presenting with Raynaud's phenomenon without a history of vibration exposure should be questioned regarding exposure to vinyl chloride, silica, organic solvents, and epoxy resins. A thorough investigation for possible underlying connective tissue disease should be undertaken in every case.

Prevention

Workers cleaning polymerization reactor tanks of vinyl chloride need complete skin and respiratory protection. Respiratory protection also is critical in those workers exposed to silica. All workers with Raynaud's phenomenon, whether or not the condition is job related, should have protection of their hands from cold weather to avoid exacerbation of the disorder.

Treatment and prognosis

Acro-osteolysis tends to stabilize after withdrawal from vinyl chloride monomer exposure. Scleroderma of any cause, however, tends to be progressive.

FOREIGN BODY REACTIONS

Workers in construction, electronics, metal working, and mining are at greatest risk for foreign body reactions, but these reactions occur throughout the workplace.

Clinical course

Foreign body reactions occur when the epidermal barrier is broken by various substances. The appearance of the reaction varies depending on whether it is acute or chronic. Acute reactions resemble irritant dermatitis. Chronic reactions typically are more papulonodular. Secondary bacterial infection may complicate the clinical picture. Common examples include reactions to metal filings and wood splinters. Fiberglass may cause an acute reaction that is extremely pruritic (see Chapter 29.1). Other specific causes of foreign body reactions in the occupational setting include beryllium and silica.^{35,36} An unusual occupational form of foreign body reaction is seen in the exposed skin of clam diggers as a result of exposure to avian schistosomes, so-called swimmer's itch.³⁷ Hairdressers may develop trichogranulomas following penetration of short hairs into the skin.³⁸

Pathogenesis

A granulomatous response is the consequence of a chronic foreign body reaction. This is typically a non-allergic response, but in the case of beryllium, the granulomatous response is due to delayed hypersensitivity. Acute reactions are eczematous and represent a form of irritant contact dermatitis.

Diagnosis

Biopsy may be helpful in arriving at a diagnosis of chronic foreign body reaction. In the case of systemic berylliosis with cutaneous granulomas, the lesions may be indistinguishable from sarcoidosis. In-vitro lymphocyte transformation testing with beryllium often is helpful (see Chapter 39.3).

Prevention

Awareness of the risks of foreign body reaction and protective clothing are the two most important factors in prevention.

Treatment and prognosis

Systemic berylliosis is only rarely a cause of cutaneous granulomas. Localized granulomas of any cause may be treated surgically. Topical therapies including open wet dressings and topical steroids are useful in the treatment of acute foreign body reactions. Fiberglass may be removed by using tape stripping of the skin.

BLISTERS AND CALLUSES

Repetitive tasks often lead to marks on the skin of workers in various industries. The most common of these are blisters and calluses.

Clinical course

Calluses appear over areas of trauma, especially on the hands and bony prominences. They are distinguished from warts by preservation of the skin markings throughout the lesion. They also may be associated with lichenification and fissures. Acute trauma to the skin, whether from friction or extremes of temperature, results in blisters. On thin skin, the overlying epidermis may be lost, resulting in an erosion.

Pathogenesis

The epidermal response to chronic trauma is thickening, resulting in calluses and lichenification. In patients who are prone to various skin disorders (e.g., psoriasis) trauma can lead to the development of new skin lesions (Koebner phenomenon) (Fig. 29.2.8). Blisters are created when the epidermis separates from the dermis.

Diagnosis

Collection of a patient history is essential. The Koebner phenomenon may complicate the diagnosis.

Prevention

Because calluses and lichenification are an adaptive response to chronic trauma, prevention is not necessarily

Figure 29.2.8: Psoriasis of the palm in a train conductor demonstrating the Koebner phenomenon due to friction from a ticket punch. Patch testing was negative.

desired. However, thickened lesions may fissure and become secondarily infected. Protective clothing often is useful in these cases, as is skin lubrication.

Treatment and prognosis

Calluses may be treated surgically, by paring, or chemically, by using keratolytics (e.g., salicylic acid, urea). Prevention of further trauma is necessary to allow healing. Blisters are best left intact to allow re-epithelialization, unless they are painful or secondarily infected. Erosions should be treated with an occlusive dressing because this approach enhances re-epithelialization.

BIOLOGIC CAUSES OF OCCUPATIONAL DISEASES

Occupational exposures are responsible for a wide variety of infectious skin diseases.² These can occur through direct skin contact, inoculation or inhalation. Up to 5% of all workers' compensation claims for skin diseases are due to infection, but data are not available to correlate the various agents with given occupations (see also Chapter 22).

It is important to recognize any potential case of infectious occupational skin disease as a sentinel health event.^{39,40} Action by the physician in consultation with public health authorities could prevent disease in other workers.

Bacterial diseases

Table 29.2.7 details the most common causes of occupational skin disease due to bacteria. In general, workers at greatest risk are those who work with animals (Fig. 29.2.9) and those in the construction trades.

Bacterial infections require identification of the pathogenic organism by a variety of techniques: culture, histology, and immunologic methods. Treatment is based on the definitive identification of a causative agent, and prognosis depends on early and effective treatment. Work-related

Disease	Causative agent	Workers at risk	Clinical findings
Anthrax	<i>Bacillus anthracis</i>	Abattoir workers, dock workers, hunters, workers with animal skin or hair	Ulcerated or bullous dark raised nodule; systemic signs of infection
Furuncles	<i>Staphylococcus aureus</i>	Military personnel, athletes, butchers	Red, tender fluctuant nodule; local symptoms unless severe
Brucellosis	<i>Brucella abortus</i> , <i>B. suis</i> , <i>B. melitensis</i>	Veterinarians, meat packers, abattoir workers	Maculopapular or petechial rash or skin ulcer, severe systemic signs of infection
Erysipeloid	<i>Erysipelothrix insidiosa</i>	Fishermen, butchers, workers with poultry, rabbits or pigs	Painful, erythematous plaques; lymphangitis
Mycobacterial infections, swimming pool granuloma	<i>Mycobacterium marinum</i>	Gulf fishermen, butchers, fish tank workers	Ulcerating papules and nodules along lymphatic drainage
Prosector's wart	<i>Mycobacterium tuberculosis</i>	Pathologists, morgue attendants, veterinarians, farmers	Warty nodular lesion
Tularemia	<i>Francisella tularensis</i>	Hunters, veterinarians, abattoir workers	Ulcer with deep eschar; systemic symptoms accompanied by maculopapular rash with purpura
Lyme disease	<i>Borrelia burgdorferi</i>	Outdoor workers in endemic areas	Erythema migrans
Impetigo	Group A streptococci, <i>S. aureus</i>	Construction workers, farmers	Crusted erosions

Table 29.2.7 Bacterial diseases

	Causative agent	Workers at risk	Clinical findings
Candidiasis	<i>C. albicans</i>	Bartenders, dishwashers	Chronic paronychia, intertrigo
Dermatophytes	Epidermophyton, Microsporum, and Trichophyton species	Veterinarians, agricultural workers	Tinea pedis, manum, corporis
Sporotrichosis	<i>Sporothrix schenckii</i>	Agricultural and forestry workers	Ulcerating papule with nodules following lymphatics
Mycetoma	Actinomycetes, <i>Pseudoallescheria boydii</i>	Agricultural workers	Chronic, indurated swelling with sinus tracts, usually on hands or feet
Chromomycosis	<i>Fonsecaea pedrosoi</i>	Agricultural workers	Verrucous plaques with scarring
T. versicolor	<i>Pityrosporum orbiculare</i>	Workers in hot, humid environments	Scaling hypopigmented or hyperpigmented macules in a shawl-like distribution

Table 29.2.8 Fungal diseases**Figure 29.2.9:** Infection with *Mycobacterium marinum* (fish tank granuloma), which demonstrates sporotrichoid spread in pet shop worker.

bacterial infections can be prevented by protective gear and awareness of the risks. Education of workers regarding the potential infectious agents in their work environment is an essential part of prevention.

Fungal diseases

A variety of superficial fungi are responsible for occupational disease. The most common of these are detailed in Table 29.2.8. In general, workers at greatest risk are those in the agricultural trades. Candida and dermatophyte infections are the most common superficial fungal infections seen in the occupational setting. Candida infection commonly presents as a chronic paronychia due to wet work (Fig. 29.2.10). Dermatophytosis may be acquired by exposure to species that are anthropophilic, zoophilic, or geophilic. An unusual variant of tinea pedis (one hand–two feet tinea) needs to be considered in the differential diagnosis of hand dermatitis (see Chapter 29.1). The specific diagnosis of Candida infection and dermatophytosis may be made by potassium hydroxide examination of scale and by fungal culture. Topical antifungal agents usually are adequate for treatment, although occasionally administration of oral antifungals (griseofulvin, ketoconazole, itraconazole, terbinafine) is necessary. As with other occupationally acquired infections, work-related fungal diseases may be prevented primarily through the use of protective gear and awareness of risks.

Causative agent		Workers at risk	Clinical findings
Herpetic whitlow	Herpes simplex type 1 > type 2	Hospital workers	Vesicles on an erythematous base
Farmyard pox	Orf-sheep, goats, milker's nodules-cows (paravaccinia viruses)	Farm workers	Painless papulovesicle, evolves over 6 weeks
Butcher's warts	Human papillomavirus, type 7	Meat handlers	Verrucous papules on the hands

Table 29.2.9 Viral diseases

Causative agent		Workers at risk	Clinical finding
Leishmaniasis	<i>L. tropica</i> , <i>L. brasiliensis</i>	Tropical forest workers	Mucocutaneous ulcers
Swimmer's itch	Avian schistosomes	Skin divers, dock workers	Urticarial papules on exposed skin
Larva migrans	<i>Ancylostoma braziliense</i>	Workers in subtropical and tropical beaches	Mobile, serpiginous plaque, especially on the feet

Table 29.2.10 Parasitic diseases

Figure 29.2.10: Chronic paronychia due to *Candida albicans* in a bartender, also known as bar rot.

Figure 29.2.11: Herpetic whitlow due to herpes simplex virus type 1 in a healthcare worker.

Viral diseases

The most significant occupationally acquired viral infection is herpes simplex infection of the finger (herpetic whitlow), which is usually seen in healthcare workers. Farm workers and meat handlers also are at risk for occupational viral diseases, as indicated in Table 29.2.9.

Herpetic whitlow can be due to herpes simplex virus type 1 or type 2. It presents as a recurrent, often painful vesicular eruption on an erythematous base (Fig. 29.2.11). Lesions occur at the site of contact, generally on a finger. Untreated infections last for 1 to 2 weeks, though therapy with oral antivirals (acyclovir, valacyclovir, famciclovir) is helpful in shortening the course. Diagnosis is made by a Tzanck smear, showing multinucleated giant cells, or by viral culture. Prevention is through use of adequate barrier methods.

Human immunodeficiency virus (HIV) may be transmitted in the occupational setting as well. The risk of percutaneous infection has led to the increased use of gloves, which, in turn, has led to an increased incidence of reactions to gloves in healthcare workers (see Chapter 29.1).

Parasitic diseases

Parasites are unusual causes of occupational disease in temperate climates. However, workers in developing countries are at particular risk. Several of the parasitic diseases reported in the occupational setting are included in Table 29.2.10.

Chapter 32

Mechanical Stressors

Thomas J Armstrong

INTRODUCTION

When work contributes significantly as a cause of musculoskeletal disorders (MSDs) or aggravates MSDs, regardless of their cause, the MSD is considered a work-related musculoskeletal disorder (WMSD). This chapter is intended to provide background to help healthcare providers assess work factors that may cause or aggravate MSDs. In particular it focuses on mechanical stressors, because there is significant literature supporting their contribution to WMSDs and to provide guidance for their assessment. It also focuses primarily on the upper limb, although many of the concepts are applicable to the back and other parts of the body. This chapter is not intended to make healthcare providers expert ergonomists or job analysts. Its goal is to help occupational physicians with: (1) walk-through inspections of worksites and (2) the clinical assessment of individual workers. In either case, the physician is likely to have limited time and resources. An understanding of these factors will enable the physician to work more closely with their working patients, managers, engineers, ergonomists, and occupational and physical therapists.

Mechanical stresses result from transfer of force between muscles and external work objects, e.g., equipment controls, parts and materials, and movements of the body to reach, grasp and move work objects. Within certain limits the body adapts to mechanical stress, and some stress is desirable to sustain physical fitness; however, there are limitations for adaptation. These limits may be influenced by chronic diseases, previous injuries, and other personal factors. As a result, susceptibility to MSDs varies from person to person and the 'dose-response' relationship between mechanical stresses and musculoskeletal disorders is modeled probabilistically. There is an established and growing body of literature that describes the relationship between work activities, mechanical stress, and musculoskeletal disorders. This literature provides guidance for the assessment of physical job demands and their contribution to WMSDs. The literature on WMSDs has been thoroughly reviewed by the Occupational Safety and Health administration for development of a standard¹⁻³ that was subsequently withdrawn by the Congress for political reasons. Proposed standards have also been withdrawn in the state of Washington. The strong scientific basis for work-related musculoskeletal disorders has also been reviewed in two separate reports by the National Academy of Sciences in 1999⁴ and 2001.⁵

WORK ACTIVITIES AND MECHANICAL STRESSORS

Figure 32.1 illustrates the relationship between job/task, the environment, and the internal loads on tendons, muscles and adjacent structures. It draws on models put forward by Armstrong et al⁶ and the NRC⁵ and NRC & IOM.⁴ Job task demands specify quantity of work and performance expectations. To achieve this goal the worker must perform: (1) mental actions to obtain and process information and (2) physical actions to hold and use work objects (parts, materials, and controls). The physical actions involve the activation of muscles and the production of forces in the musculoskeletal system to produce the desired effects. Aside from accomplishing the desired work task, these actions are associated with physiologic and mechanical responses.

Physiologic responses start with the release of ions to initiate contraction of muscles; they also include consumption of metabolic substrates and production of metabolites. Depletion of substrates, accumulation of metabolites, and ionic imbalance are all associated with transient fatigue response that is manifest by loss of strength, loss of motor control and discomfort. Localized muscle fatigue is a transient response that typically develops and recovers in periods of minutes or hours.⁷ Recovery begins with the cessation of work and, depending on its severity may require seconds to hours. As a practical matter, workers should not be experiencing effects of fatigue from one day to the next. Longer-term effects include tissue damage due to ischemia and free radical production. Tissue damage stimulates repair and adaptation of damaged tissue, which requires several weeks, assuming that the muscle is not re-injured.

Biomechanical responses include tissue stress and strain. Mechanical stress refers to force divided by the area over which it is distributed, and strain is the resulting deformation of the material divided by the unstressed dimensions of the material. Stress may also be used in broad reference to factors that disturb an individual's physical or mental state, and strain as a broad reference to the resulting disturbances. Tissue loads include the transmission of tensile forces from the muscles via tendons, and enable the body to maintain a mechanical equilibrium with the reaction forces associated with holding, using, and manipulating work objects. When the muscles pull on the tendons, tensile forces are produced in the direction of the long axis

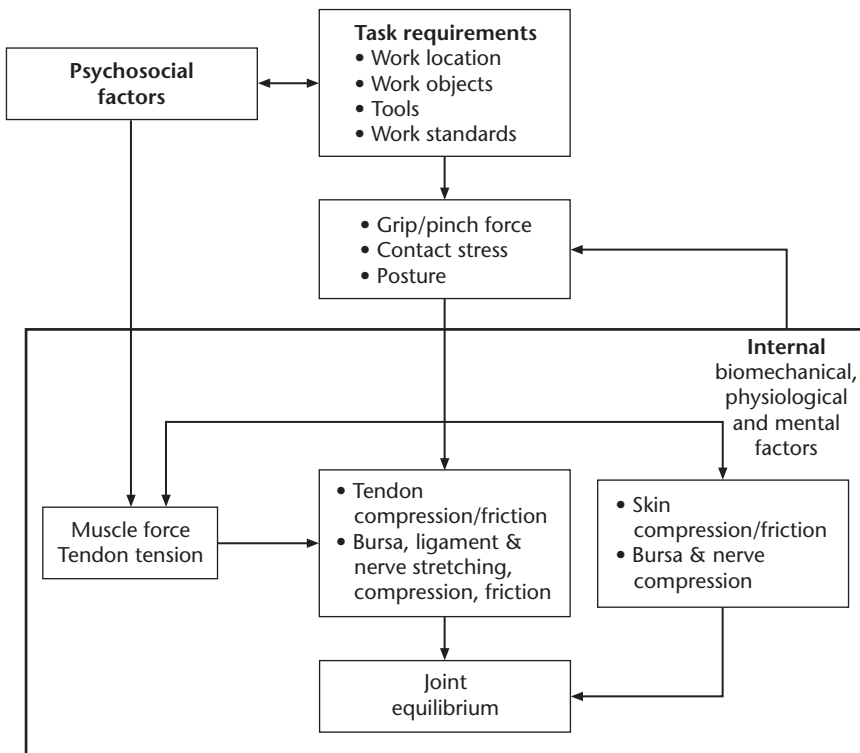

Figure 32.1: A conceptual model illustrating how external loads impose internal loads on the muscles, tendons, and nerves that may in turn cause or aggravate MSDs.

Figure 32.2: The wrist flexion or Phalen's test is widely used for diagnosis of carpal tunnel syndrome. Flexion of the wrist causes the finger flexor tendons to compress the median nerve against the flexor retinaculum.⁸ The test may be accelerated by pinching at the same time, which produces tension on the finger flexor tendons and additional pressure on the nerve.⁹

of the tendon and cause it to stretch. Compression forces are produced between the tendons and adjacent anatomical surfaces that intrude into the space between the point of a tendon's origin and its insertion, which occur when joints are flexed or extended.

This concept is exploited in the Phalen's wrist flexion test⁸ (Fig. 32.2) in which flexion of the wrist causes the median nerve to be compressed against the flexor retinaculum. Numbness and tingling in the areas innervated by the median nerve is a positive sign of carpal tunnel syndrome.

Smith et al⁹ proposed that the test could be improved if patients forcibly pinched at the same time they flexed their wrist, because of increased tension on the finger flexor tendons and pressure on the median nerve. In addition to its diagnostic value, the Phalen's test demonstrates how certain postures of the body impose secondary loads on tendons and nerves and can contribute to WMSDs. Flexion or extension of a joint also causes the shape of the tissues around the joint structure to change and can produce increased fluid pressure. These pressure changes have been measured around the median nerve in the wrist, and shown to be sufficient to interfere with microcirculation.

Tissues demonstrate viscoelastic properties; that is, they undergo both elastic and viscous deformations. Elastic deformations are essentially instantaneous with the application of force. Similarly, recovery is also instantaneous with the removal of the load. Viscous deformation continues to increase after the load is applied. Similarly, recovery requires some period of time following removal of the force. As a result, tendons may continue to stretch if there is insufficient recovery time between successive exertions. Touch and proprioception involve tissue deformation, but tissue deformation also produces pain. As with muscle fatigue, muscle deformation and associated pain will recover with the cessation of work. Elkus and Basmajian¹⁰ refer to intramuscular fatigue as the performance changes that occur as a result of changes inside the muscle, and extramuscular fatigue that occurs as a result of changes outside muscles.

Although tissue deformations are unlikely to result in acute tissue failure, e.g., tendon rupture, they may be sufficient to interfere with circulation and other physiologic functions. They may be sufficient to create micro tissue damage. In the short term, micro damage affects tissue and capillary permeability. This can lead to swelling following the cessation of work, and explains why many persons experience nocturnal numbness in their hands. Micro damage also stimulates degradation, repair, and adaptation of damaged tissues. This is a likely explanation for non-specific synovitis that results in proliferation of connective tissue and is commonly found inside the carpal tunnel. Thickening of the synovial membranes inside the carpal tunnel is a likely explanation of increased inter-carpal canal pressures in carpal tunnel patients^{8,11} and secondary carpal tunnel syndrome.

It can be seen that there are multiple primary and secondary mechanisms of musculoskeletal disorders, but that they share a common link to the patterns of exertions. Figure 32.3 depicts a general response function to varying exertion intensities and frequency. Figure 32.3a depicts a case where there is sufficient time in between exertions for complete recovery. Figure 32.3b depicts a case in which the response is increased either as a result of a primary factor like loading of the muscle tendon unit, or as a result of co-factors (e.g., posture or vibration). In this case the recovery time is insufficient, so that the response is increased with each successive exertion. Additional recovery time is required to arrest the growing response. Figure 32.3c depicts a case where there is adequate recovery time, but an irregular work element results in an extreme response that is then aggravated with each successive response, shown in Figure 32.3d.

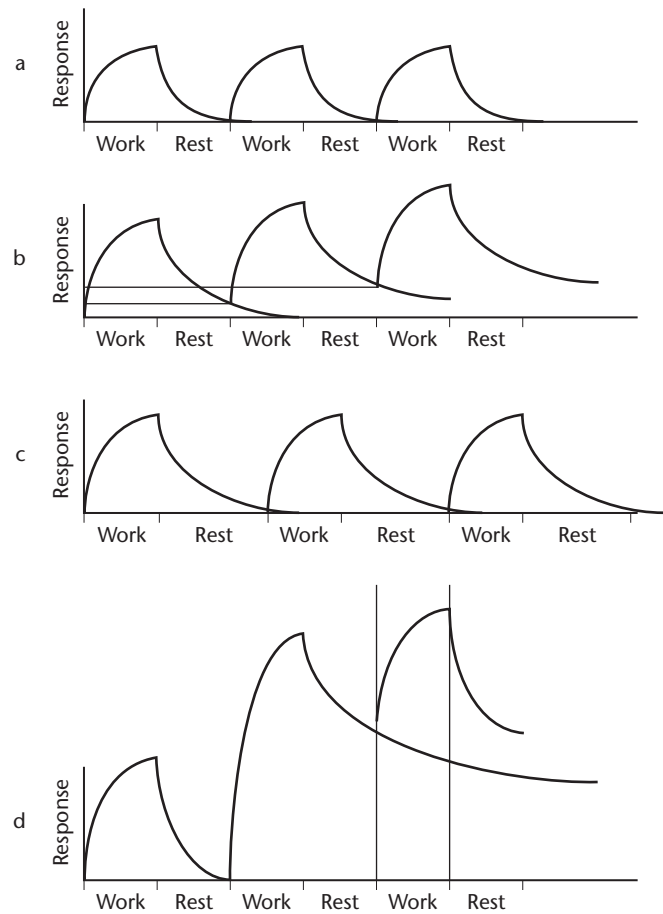

Figure 32.3: Four scenarios for repetitive work. In Case (a), the recovery periods are sufficient for complete recovery of biomechanical and physiologic disturbances that occur during the work periods. The work exposures to mechanical stresses have been increased in Case (b), such that the recovery periods are insufficient and the disturbances are cumulative. In Case (c), the recovery periods have been increased to compensate for the increased work levels in Case (b). In Case (d), the recovery periods are generally adequate until the worker is exposed to unusually high stresses as a result of an irregular work activity. Subsequent actions continue to aggravate the initial disturbance so that the worker is unable to achieve full recovery.

As shown in Figure 32.1, task demands are a primary determinant of the physical stressors that are placed on the worker's body and ultimately on the expression of symptoms. The load may be influenced by psychologic and sociologic factors.^{4,5,12} Some of these other factors are not explicitly part of the work requirements, but pertain to the workplace (e.g., manager and coworker). Other factors do not pertain to the job at all, but influence how the worker responds to mechanical stressors, e.g., family concerns, personal attitudes and beliefs, or coping and cognitive skills. These factors may be broadly referred to as psychosocial factors. There is a growing body of literature regarding psychosocial factors, but there is not yet broad consensus on how to evaluate and manage these factors. Management of psychosocial factors is complicated by the personal nature of many of the issues, which may be considered confidential.

The concept of biologic and mechanical response to physical exertion provides the foundation for an expo-

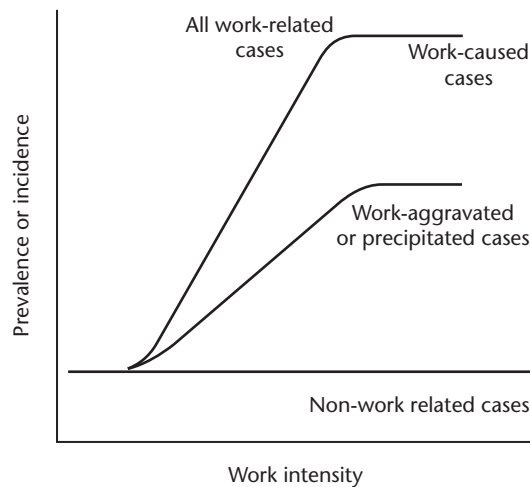

Figure 32.4: General dose–response curve for musculoskeletal disorders and exposure to various physical stressors. Some cases occur irrespective of work exposures. Other cases are due to aggravation of existing conditions and still others are primarily due to work exposures.

sure–response relationship. There is a growing body of epidemiological data that shows increased risk of MSDs with increasing intensity of handwork. Although there is not yet agreement on the best way to measure exposure or risk of MSDs, this is an important concept for those concerned with treatment. Figure 32.4 shows a general exposure–response relationship. Available literature demonstrates that: (1) there is a background risk of MSDs, even at the lowest level of exposure, and (2) the risk increases with increasing exposure. There is disagreement about the location of the inflection point where the risk of WMSDs begins to increase with increasing exposure. Part of the confusion can be attributed to different exposure and outcome metrics among investigators. It may be necessary for the healthcare providers and employers to aim for exposure levels that are below those that will cause an MSD in the absence of predisposing personal conditions.

A practitioner may elect to intervene with the onset of symptoms and in the absence of objective findings. Knowledge that the worker is experiencing persistent pain, and is exposed to a physical demanding job, will generally be more important to a practitioner than physiologic parameters such as intercarpal canal pressure, particularly since such physiologic data are not readily available. This approach is reflected in the current OSHA reporting regulations. Although there is a ‘temporary’ moratorium on the reporting of musculoskeletal disorders, the rules provide general guidelines for assessing the ‘work-relatedness’ of worker injuries and illnesses.

According to OSHA¹³ section 1904.5a: ‘Work-relatedness is presumed for injuries and illnesses resulting from events or exposures occurring in the work environment. . .’ The regulations include specific exemptions such as: it is clear the condition resulted from activities to exposures outside of the workplace, the worker was participating in a ‘voluntary’ company fitness program or it was due to motor vehicle accidents while commuting to work, to communicable diseases unrelated to work or to mental illness. Section 1904.5(b)(5)

states: ‘An injury or illness is a pre-existing condition if it resulted solely from a non-work-related event or exposure that occurred outside the work environment’. Section 1904.5(b) describes the meaning of significantly aggravated:

- One or more days away from work, or days of restricted work, or days of job transfer that otherwise would not have occurred but for the occupational event or exposure.
- Medical treatment in a case where no medical treatment was needed for the injury or illness before the workplace event or exposure, or a change in medical treatment was necessitated by the workplace event or exposure.

There is a high burden of proof on the employer and healthcare provider to show that a case is not work related. If there is a question about the contribution of work, Section 1904.5b says: ‘You must evaluate the employee’s work duties and environment to decide whether or not one or more events or exposures in the work environment either caused or contributed to the resulting condition or significantly aggravated a pre-existing condition’.

OSHA notwithstanding, many employers will want information about jobs performed by injured workers so that they can investigate factors that might affect other workers or, that would pose a barrier to employment by affected workers.

JOB ANALYSIS

As a practical matter, the time that a healthcare provider has to assess a worker’s exposure to mechanical stressors may be limited. This makes it important that the provider understand what a job analysis entails to effectively review the detailed analysis of others, to understand job factors that produce mechanical stress and to prescribe meaningful work restrictions.

It is important that the job analysis be systematic so that all possible stresses are identified. Several structured approaches have been proposed for assessing mechanical stressors. Selected systems are summarized in Table 32.1 along with the factors they include. These systems provide structured approaches for the analysis of jobs; however, systems developed in one setting are not necessarily applicable to others. For example, Keyserling et al¹⁴ describe a checklist developed for automotive manufacturing. The checklist used cycle time of less than 30 seconds as the threshold for high repetition work. Although a 30-second threshold works well for some types of manufacturing work, it does not work well for others, e.g., keyboard data entry. In some cases, healthcare providers may find that all of the information required to apply a given analysis system is not available, and that the action limit or threshold cannot be fully assessed. Finally, even though a threshold may protect most workers, it is likely that some fraction will be affected, and that a healthcare provider will be asked to manage that fraction.

An alternative to the structured systems listed in Table 32.1 is an open-ended structured approach in which each factor is considered, in so far as necessary or possible.¹⁵ The open-ended analyses require the user to recognize risk factors and exercise judgment about their severity and importance. They provide the user with the flexibility to increase the breadth and depth of the analysis as necessary

	Body parts	Repetition	Duty cycle	Dynamics	Work duration	Force	Posture	Contact stress	Low temp	Vibration
UAW-GM RFC Checklist developed & tested for automobile manufacturing	Upper limb & back	RFC I: Low >30s; Hi <30s RFCII: Low, Medium High ¹⁹	Included in repetition	Included in repetition	No	Selected factors yes/no	Wrist, elbow, shoulder	Selected factors yes/no	Selected factors yes/no	Yes; three categories

Table 32.1 Summary of selected job analysis systems for assessing upper limb physical stressors

for a given situation. The open-ended analysis can be supplemented as needed with some of the standardized procedures listed in Table 32.1. The following section presents a generic open-ended approach. The job analysis is divided into two steps: (1) documentation and (2) assessment of mechanical stressors:

Documentation

The first step of the job analysis is documentation. The documentation is descriptive information about the job,^{6,15-17} which is an aid to understanding what the worker does and determining his or her exposure to physical stressors. For example, repetitiveness may be related to a work standard that specifies a certain number of parts be assembled in a given amount of time, or that a certain amount of data be entered into a computer in a given amount of time. Posture stresses may result from the location of a work object or the shape of a tool. An understanding of what the worker does – even at a minimal level – will help the healthcare provider work more effectively with management to identify the causes of MSDs and to facilitate return to work. The following is a general outline of the necessary documentation information.

Table 32.2 provides a listing of the basic information that should be considered for documentation. How the documentation is performed will depend on the level of concern and available resources. Some organizations maintain a library of job information. Examples include job descriptions used by personnel for hiring and placement, work methods and standards data used by management for work allocation and production planning, and job safety analyses used by safety managers to identify unsafe work conditions. Often these data are not available in a form that healthcare providers can use.

Few healthcare providers have the luxury of visiting the worksite to observe or videotape jobs, to make direct measurements, or to interview workers and supervisors. They are most likely to perform the analysis when they see the worker/patient in their clinic, which may be offsite. As a result it may be necessary for someone to review the available documentation, observe and/or videotape the job, and to interview supervisors and workers. In the absence of this support, healthcare providers often have to obtain the needed information from workers at the same time they are evaluating or treating them. Table 32.3 provides a list of questions for obtaining descriptive job information from worker. These questions are intended as starting points. Additional questions may be required to achieve the desired level of detail. It will be helpful if the healthcare provider visits the worksites on a regular basis so that they have a background perspective for interpreting the worker's comments. Healthcare providers should understand that workplaces are highly dynamic, and work activities may vary from day to day or even hour to hour depending on the production demands, absenteeism and worker turnover.

The time required for completing documentation increases with job complexity. Complexity refers to the number of steps required to complete a job activity and how

1. Objective/purpose

The reasons the job is performed. These can be stated as simply as possible in list form.

2. Tasks

Groups or cycles of work elements that have a common objective. Tasks need not be performed in the same sequence, and one task may interrupt another. All jobs are composed of at least one task.

3. Production standards

The quantity of work that must be completed in a given amount of time. Standards may be stated as the number of parts per hour, the time per part, the line speed, or a work duration.

4. Work objects

Objects, such as parts and materials, on which work is performed. Work objects have attributes of size, shape, weight, hardness/softness, surface friction, location, orientation and temperature.

5. Tools and equipment

Objects or devices held or manipulated with the hands to do something to the work object, such as, insert fasteners, trim parts, or control. Tools and equipment have many of the same properties as work objects. Additionally they may require force to engage, activate or resist (reaction forces).

6. Workstation

The equipment that is used to hold or support work objects, equipment, or the worker, such as, the benches, chairs, and assembly lines. Workstations have important location, size and shape attributes.

7. Methods

A step-by-step description of the elements required to perform the task, such as, get part, inspect part, insert part, and drive screw. Steps can be listed for the right and left hand, but one list is sufficient if both hands do the same steps.

8. Environment

Where the work is performed and its physical characteristics, such as, inside, outside, and air temperature.

Table 32.2 Factors to include in job documentation. The level of detail may be adjusted according to the user's needs and resources

1. Does your job have an official name? Does it have a nickname (how do you refer to your job)?
2. In your own words, what is the purpose of your job?
3. How much are you expected to produce in a given minute, hour or shift – give averages and ranges?
4. Do you repeat the same work 'tasks' (e.g., get and assemble parts) over and over in the same way or do you perform different tasks (e.g., perform various maintenance, construction or office tasks as needed) in different ways from one time to the next? Please list the 'tasks' that you do. Indicate if they occur in the same or random order. Indicate approximately how many times per day and how long each is performed.
5. For each task list the things that you use: machines, hand tools, parts, and personal protective equipment (e.g., gloves). Also indicate if and how you interact with coworkers and clients.
6. Where is each task performed? Is it hot, cold or just right? Do your hands ever get cold?

* Detail may be added or removed depending on the needs and available resources

Table 32.3 Suggested questions for interview regarding work documentation* (can be modified as needed)

much those steps vary from one time to the next. At one extreme are simple mono-task jobs in which a few steps are completed in the same way in a few seconds, time after

time. Examples of these jobs include transcription on a computer or feeding a machine in a production manufacturing setting. At the other extreme are complex multitask jobs with high inter-task and inter-cycle variability. Examples of complex jobs might include maintenance jobs in which the workers must diagnose and fix equipment, or software under a variety of conditions, or utility workers who rotate from job to job. Even short cycle time mono-task jobs may require significant time to ascertain all of the material, process and worker variations. Long cycle time jobs, multi-task jobs and jobs with irregular schedules may require considerably more time. While it often is not possible to do a rigorous analysis, it is important that the analyst recognize the uncertainties associated with their assessment.

Some employers videotape jobs and send them with the patient to the healthcare provider. Videotapes can be very helpful if the healthcare provider has time to review them; however, videotapes can be misleading. Video recordings are only a sample of what the worker does in a much larger work shift, with potential variation from day to day. For example, a brief interruption in the supply of parts may leave the worker briefly idle and create the impression that there is a lot of recovery time built into the job. Similarly, an irregular part may require extra attention and make it look like the worker has to hurry to keep up with the process. Unless the person making the videotape understands the job and takes care to record sequences that are representative, the recording may provide an incorrect impression. Video recordings are a two-dimensional representation of a three-dimensional system. As a result, there will inevitably be distortions and it may not be clear if the worker is reaching towards or away from the camera. It may be necessary to record multiple views to see all of the hand actions.

The job documentation provides a framework for considering what the worker does and lays a foundation for assessing the physical stressors. Even if a thorough documentation is not possible, knowledge of these issues will help the healthcare provider with their assessment of physical stressors and interact with workers and supervisors to more effectively manage cases. Careful documentation provides a framework for assessing mechanical stressors.

Assessment of mechanical stressors

Physical stressors are identified and quantified from:

1. Interviews of workers and supervisors
2. Observations (direct or using videotape)
3. Computations based on job specific attributes, and
4. Instrumentation.

This chapter focuses primarily on interviews and observations because they are most readily available to healthcare providers. Computations are only introduced to help the healthcare provider understand the basis for the observational methods.

Repeated and static exertions (hand activity level)

Repeated and sustained exertions refer to the time qualities of the exertions of the hand or other body parts. An exer-

tion can be defined as an event during which the physiologic or biomechanical demand is placed on the musculoskeletal system at rate greater than at which recovery occurs. Exertions are depicted in Figure 32.3 as increasing response, and recovery is depicted as decreasing response. The rate of response and recovery will be related to force, posture, contact, vibration and other work factors, as well as personal factors. An exertion often corresponds to a work element or step, such as getting the screw, putting it on the bit, and driving the screw, but one work element and exertion may run into the next without intervening recovery periods. The result may be fewer but longer discrete exertions with reduced recovery time. Important time qualities include exertion frequency, exertion time, and recovery time. As a practical matter, few jobs entail repetition of a single exertion all day, such as shown in Figure 32.3, although some keyboard data entry, transcription, certain food processing, and packing jobs may approximate this. Most jobs entail one or more sequences of exertions. Exertion frequencies, durations and duty cycles are reported as average values and/or as ranges (minimum and maximum).

The ACGIH¹⁸ refers to repetition as hand activity level (HAL) and spells out the steps for calculating HAL for a detailed methods analysis. It also provides a scale for rating HAL from zero to ten, based on observations of the job or a video recording of the job, including six verbal anchor points based on work by Latko et al^{19,20} (see Table 32.4a). The ACGIH also includes a recommended exposure limit for various combinations of repetition and force.

Ebersole and Armstrong²¹ examined a procedure for applying the Latko scale in which two trained analysts

(a) Verbal anchor points used to rate repeated and sustained exertions of the hand*

- 0 Hands idle most of the time, no regular exertion
- 2 Consistent, conspicuous long pauses; or very slow motions
- 4 Slow steady motion/exertion, frequent brief pauses
- 6 Steady motion/ exertion; infrequent pauses
- 8 Rapid steady motion/ exertion; infrequent pauses
- 10 Rapid steady motion/ continuous exertion, difficulty keeping up

(b) The UAW-GM Risk Factor Checklist†

- Low: Hands/wrists pause to wait for equipment and/or parts
- Medium: Hands/wrists are in steady motion/pace. Infrequent opportunity for pauses
- High: Hands/wrists are in constant motion to keep up. No opportunity for pauses.

(c) The State of Washington Workplace Ergonomic Standard‡

The 'caution zone' is for an exposure to the following activity, occurring for more than one day per week and one week per year.

1. Repeating the same motion with the neck, shoulders, elbows, wrists, or hands (excluding keying activities) with little or no variation every few seconds more than 2 hours total per day
2. Performing intensive keying more than 4 hours total per day

* Hand activity level from 0 to 10.^{18,19}

† Keyserling et al 1993¹⁴ has been modified to include three ranges of repetition based on Latko et al.¹⁹

‡ Includes a checklist for assessing repetition.²²

Table 32.4 Repeated and static exertions (hand activity level)

observed and rated jobs in real time, and after discussion re-rated the jobs by consensus. Six raters working in random combinations of two rated a total of 410 automobile assembly jobs. Ninety-one percent of the HAL ratings were within one point on a 0–10 scale.

The UAW-GM Risk Factor Checklist initially characterized repetition as low (work cycle time greater than 30 seconds) and high (work cycle time less than 30 seconds).¹⁵ This checklist has subsequently been modified to include three levels of repetition: low, medium and high (see Table 32.4b). Medium and high risk are interpreted as having ‘potential risk to some workers’, further analysis is required for high exposures.

The State of Washington Workplace Ergonomic Standard includes a checklist for assessing job risk of musculoskeletal injuries.²² The criteria for assessing repetition are included in Table 32.4c. Their criteria ‘Repeating the same motion with the . . . wrists, or hands (excluding keying activities) with little or no variation every few seconds more than 2 hours total per day’ could correspond to the middle and upper parts of the Latko¹⁹ and ACGIH scales.¹⁸ ‘Performing intensive keying more than 4 hours total per day’ corresponds to the upper limit of Latko and ACGIH scales.

Worker self-assessments. Table 32.5 includes a list for questions that can be asked of the worker to assess their perception of physical stressors. Question 1 pertains to repetition and asks the worker if they can work at his or her own pace. It also addresses if the worker has trouble keeping up and would indicate if the worker is near the upper end of the ACGIH Hand Activity Scale.¹⁸ It may be

1. Is there adequate time for your hands to rest between work cycles, between tasks or during breaks, or do you have to use your hands continuously to keep up? (note: your hands may be resting while you are performing tasks such as reading documents, walking to parts, etc.)
2. Are you able to repeatedly exert the force required to get, put, or assemble parts, or to hold and use tools throughout the work shift without excessive fatigue? What, if any, parts of your job seem to require excessive force? How frequently do they occur?
3. Does your job require you to assume any unusual or uncomfortable postures? As appropriate demonstrate extreme: a. wrist flexion and extension, b. wrist deviation, c. forearm rotation, d. elbow flexion, e. reaching overhead, f. reaching forward, g. reaching side to side, h. reaching back, i. neck rotation, j. neck flexion/extension, k. bending, l. twisting and m. squatting. What work activities require these postures? How frequently?
4. Do you strike, press, or rest your body against any hard or sharp objects (e.g., pound parts together, rest wrists on sharp edge of desk or keyboard, lean on elbow? Where? Frequency?
5. Does anything you hold or touch vibrate or shake? What? Where? Frequency?
6. Do your hands get cold? Where? Frequency?

* For greater quantification, workers can also be asked to rate their exposures on a scale of 0 to 10 and to indicate exposure duration and frequency. Assessments may be performed for each task and the overall job depending on job complexity, needs and resources.

Table 32.5 Suggested questions for interview regarding exposure to physical stressors*

instructive to compare worker self-assessments of repetitions with those of a third party. Significant differences may indicate where the workers capacity is excessively challenged by the job demands.

Forceful exertion

Forces are exerted to hold or move the body or to hold or move work objects. Force is an important determinant of stresses on muscles, tendons and adjacent connective and nerve tissues. Force also is an important factor in muscle metabolic rates (Fig. 32.1). Tissue loads and metabolic rates may be influenced by posture. Recovery occurs when the hands are able to relax. The lowest force and greatest recovery occurs when workers are able to sit with their hands on their lap. A more likely scenario is sitting or standing waiting for a machine to cycle or respond; if the forearms are not supported, muscle activity to support the shoulder girdle may prevent recovery in the neck–shoulder region of the body. The mechanical relationship between external and internal loads is affected by the position of the body. As a result, greater muscle and tendon loads are required to work in some positions. For example, grip strength is typically four or five times greater than pinch strength. Force is also affected by work pace. Rapid or sudden motions will impose inertial loads and require higher muscle forces than for slow steady motions.

Force can be expressed on an absolute scale of newtons (kilograms or pounds). It also can be expressed on a relative scale of 0 to 10, where 10 corresponds to the greatest effort possible or 100%.

Using a relative scale of 0–10 makes it easier to compare the magnitude of force with other factors. If repetition is rated as 8 and force as 2, this would mean that it is a highly repetitive, but low force job. Physicians might focus more on the possible contribution of repetition than force to patient’s MSD, and an engineer would focus more on steps to reduce repetition than force.

A relative force value can be calculated as the required force divided by the strength of an individual or population percentile and multiplying by ten:

$$\text{Relative force (0–10)} = \text{Absolute force} / \text{Strength} * 10$$

A 0–10 scale was adopted by ACGIH so that it corresponded to the Hand Activity Level scale. Because strength varies from group to group, the relative force required for a given job will vary as well. For example, if a tool requires 350N of grip force to cycle, then the required force would be 10 for an average female, but only 5 for an average male. As a practical matter, the relative force will probably be one or two points greater for persons with high strength compared with low strength, because most people exert more than the minimum required force unless they are near their maximum.

A list of factors affecting hand force is included in Table 32.6. To understand the relationship between work requirements and force requirements, two examples are considered (Fig. 32.5a). In the first example, the worker is holding an object such as a toolbox or a suitcase. Flexing the fingers

Figure 32.5: (a) Holding a tool box requires the worker to flex his fingers against the weight of the tool box. The force requirements of holding the tool box will be equal to the gravity and inertial forces on the tool box. (b) To pull the files from the file drawer the worker must pinch the file hard enough to overcome the weight, friction and inertial forces on the file.

Weight of work object or tool
Center of gravity versus center of grip
Friction between hand and work object/tool
Size/shape of work object/tool
Glove fit/stiffness/friction
Force to activate controls for machines/tools
Force required to join parts and engage tools
Reaction forces of tools as they start and stop
Mechanical assists that are used to support and transfer materials and tools
Tool maintenance
Quality control

Table 32.6 Factors affecting hand force

against the handle supports the object. The force exerted by the fingers on the work object must be exactly equal to force exerted on the toolbox by gravity. In this case the force requirements to hold the toolbox will be equal to its weight. The relative workload required to hold the toolbox can be calculated by dividing the task force requirements by the strength of the worker.

Finger force = Weight of work object

The force required to pick up the toolbox will be greater than the force required to hold it because of the inertial

forces. As workers approach their maximum strength they will generally slow down. Thus a strong worker may end up exerting as much force as a weak worker because they lift the object more quickly.

The second example shown in Figure 32.5b involves pulling and holding a file. In this case the fingers must press against the sides of the file to produce enough friction to overcome the force of gravity and frictional forces from adjacent files. A mathematical expression that describes the relationship between the force exerted by the hand, the weight of an object, and the slipperiness or coefficient of friction of the skin can be written:

Finger force \geq File Weight / 2 x Friction Coefficient

This equation is written as an inequality because the worker can exert more than the minimum required force to hold the file. Friction is related to the object's material properties and moistness of the skin. Coefficients of friction for porous materials, such as paper and leather, are sensitive to moisture and range from 0.25 to 0.4 for dry skin and 0.4 to 0.7 for moist skin.²³ Coefficients of friction for non-porous materials such as aluminum, vinyl, and sandpaper are insensitive to moisture and range from 0.4 to 0.6.

The simplest case corresponds to holding the file at a stationary location in which the friction forces from adjacent files and inertial forces are zero. The required pinch force can therefore be expressed simply as:

$$\text{Finger force} = \text{File Weight} / 2 \times \text{Friction Coefficient}$$

As an example, if a file folder weighs 15N and the coefficient of friction for moist skin and paper is 0.5, the minimum pinch force required to overcome gravity is calculated as 15N; if the coefficient of friction is 0.25 for dry skin, the pinch force is 30N. The required pinch force to hold the folder if the skin is moist is approximately equal to the weight of the folder. Handling of paper folders results in the drying of the skin and decreasing the coefficient of friction. Thus, the required pinch force for the dry skin is nearly twice the weight of the file.

Other factors affecting force include the balance of the work object in the hand, the use mechanical assistance, glove fit, stiffness and friction, part quality, and fit and tool maintenance (Table 32.6). Many of these factors are addressed in the UAW-GM Risk Factor Checklist.¹⁴ Other systems such as the Strain Index,²⁴ the ACGIH,¹⁸ and the State of Washington²² leave it up to the user's professional judgment or the use of other methods.

The relative force can be calculated by dividing the force required by the strength of the hand in the position required to grip the work object. The file is held in pinch posture, so the pinch strength data from Table 32.7 are used to estimate strength. Approximately 99% of the males and 94% of the females with moist skin would be able to hold the folder and have a relative force less than 10. Only 89% of the males and 48% of the females with dry skin would be able to hold the folder and have a relative force less than 10. The relative force would range from 3 to 5 for average males and females with moist skin, and from 6 to 10 for average males and females with dry skin. Relative forces above 10 are not possible, which means persons with pinch strength less than that of a 5th percentile female would not be able to perform the task. Jobs that require 'pinching an unsupported object(s) weighing 2 or more pounds per hand, or pinching with a force of 4 or more pounds per hand, more than 2 hours total per day (comparable to pinching half a ream of paper) or 'gripping 10 or more pounds' would be designated by the State of Washington criteria as a caution zone job.²²

This simple example shows how hand force is related to weight and friction. Hand force is related to weight and friction of the work object for other postures in addition to pinch. The relationship between finger force and muscle

force varies significantly from one hand posture to another (Fig. 32.1). Generally, the lowest muscle forces for a given external load are found when the fingers can be closed around the object, such as holding a hammer or a suitcase. It can be seen from Table 32.7 that the hand is roughly 10 times stronger in power grip than in pinch. The finger flexor muscles have to work harder in pinch than in power grip to produce equivalent external forces.

It is possible to exert more than the required force. The pulps of the fingers are richly endowed with nerve endings, which provide feedback to the central nervous system when the object is slipping. The system does not provide perfect control, and the amount of force exerted will vary from person to person. As a practical matter, submaximal exertions will be greater than the minimum required. Armstrong et al²⁵ reported that subjects apply an average of three times the required force for keyboard jobs, at the low end of the scale. Westling and Johansson²⁶ refer to this excess force as a safety margin. Frederick and Armstrong²⁷ showed that the safety margin decreases with force as task strength requirements approach the maximum strength of the subject. Thus while strong subjects in theory do not have to exert as much force for a given task as weaker subjects, in practice stronger subjects tend to exert proportionally more effort than weaker subjects. As a result the relative workload difference between strong and weak subjects may vary from predicted. It has been suggested that the amount of force may be affected by psychological stressors, and provides a mechanism by which psychosocial stresses contribute to musculoskeletal disorders.²⁸ The sensitivity of the fingers and ability to control force may be altered by factors such as low temperatures and vibration, which alter the sensitivity of the fingers.

It should be apparent that the force required to perform a job typically varies from one work element to the next. It is possible to have a high maximum peak force while having a very low average force. The average force can be calculated as the sum of the average force times the time for each element, divided by the sum of the times. This is the same procedure that is used to calculate time-weighted averages for evaluating chemical TLVs. There is a debate about acceptable levels of average force. Physical endurance goes down precipitously when the average force increases above 15–20% (1.5–2.0 on a relative scale of 0–10), but workers may also experience adverse effects, such as acute and chronic muscle pain, as a result of prolonged and sustained exertions at lower levels. Some investigators argue that complete relaxation is necessary for a muscle to recover and avoid adverse effects of fatigue (see Bystrom and Fransson-Hall⁷ and NRC^{4,5} for a summary of this literature).

Posture	Population	5%tile	Male Average	95%tile	5%tile	Female Average	95%tile
Power grip ⁴⁶	Steel mill applicants	383.7	503 (72.5)	622.3	237.3	311 (44.8)	384.7
Power grip ⁴⁷	US Adults	333.8	487 (92.5)	639.2	186.4	308 (73.9)	429.6
Power grip ⁴⁸	Office workers	327.8	452 (75.5)	576.2		Not reported	
Pulp 3 pinch ⁴⁹	US Adults	23.5	48 (15.3)	73.8	15.0	30 (9.4)	45.9

* Values may vary greatly from one population to another. See text for discussion.

Table 32.7 Average, fifth percentile and ninety-fifth percentile grip and pinch strength data for adult males and females*

Observational methods do not have enough precision and accuracy to reliably rate absolute force levels between 1 and 2 on a scale of 0–10. However, it is often possible to determine which of two or more workers is exerting the most force within the low force range.²⁹

The UAW-GM Risk Factor Checklist and the State of Washington ergonomic standard checklist use weights in pinch and grip postures as criteria for forceful exertions.

Worker self-assessments. In Table 32.5, force is assessed by asking the worker if they perceive their job as fatiguing. While this is basically a yes/no question, it does take into consideration other factors, e.g., repetition and posture. Also, workers will add qualifications, e.g., ‘on days when we run a specific part’. The modified Borg³¹ scale is widely used to obtain worker assessments on a scale from 0 to 10, which correspond to the relative force ratings described above. Workers are shown the scale and simply asked to rate the effort required to perform their job using the verbal anchor points shown in Table 32.8. By dividing the Borg score by 10 and multiplying by the worker’s strength, the absolute force can be estimated. As a practical matter, we have found that a simple 10 cm horizontal line with 0 at one end and 10 at the other works as well as the Borg scale. Workers may be asked to rate the overall job or they may be asked to rate specific tasks or work elements, e.g., the insertion of a connector or use of a hand tool, etc.³⁰ In some cases it is instructive to obtain independent ratings from multiple workers. The Strain Index (Table 32.1) specifies five levels of force achieved on the Borg scale.²⁴

Mechanical stresses from localized contact

A localized mechanical stress is defined as a force distributed over some part of the body. For example, resting an arm on the edge of a workstation causes the weight of the arm to be distributed over the area of contact between the arm and armrest; or gripping a tool causes the force required to activate the tool to be distributed between the handle of the tool and the hand. Localized mechanical stresses can be quantified by dividing the contact force by the area of contact. For example, if an armrest, 2 cm × 5 cm, is in complete contact with the fleshy area of the forearm and if the forearm is resting on the armrest with a force of 20 N, the average contact stress is 20 kPa. As a second example, consider an arm resting against the edge

of a work surface holding a keyboard. In this case, the area of contact is 2 cm × 0.5 cm, again assuming a resting weight of 20 N, the contact stress is calculated as 200 kPa. (For comparison a 75 kg person with a 10 × 10 cm heel would produce about 75 kPa pressure if they were to step on your foot with their full weight.) These are average stress concentrations. When the load is distributed over large fleshy areas by a soft surface, these are reasonable approximations of the actual contact stresses. When the forces are exerted against bony areas of the body, such as the elbow or on hard surfaces, then the force is not uniformly distributed and there will be areas of much higher and much lower stress.

The level of insult and discomfort increases with the magnitude of contact stress. Some parts of the body are more tolerant to contact stresses than others. For example, a contact force may be tolerated longer if it is distributed in the thenar eminences than over the median nerve at the wrist and palm. Nerve response to even brief percussion over the median nerve is brisk, explaining its use as a diagnostic test (Tinel’s sign, Fig. 32.6). The steps for analyzing contact force are as follows.

Contact stresses can be rated on a scale of 0–10, as was described for repetition and force. One of the difficulties with rating contact stress is that the upper limit (i.e., scale designation of ‘10’) is not always clearly defined. Also, some parts of the body are more tolerant to contact stresses

Figure 32.6: The Tinel’s test in which percussion over the base of the palm demonstrates how contact stress at certain locations on the surface of the body can produce stress on underlying tissues.

0	Nothing at all

1	Very easy
2	Easy
3	Moderately hard
4	Somewhat hard
5	Hard
6	
7	Very hard
8	
9	
10	Very, very hard

Table 32.8 Ten-point Borg scale for worker assessment of task force requirements

than others.³² Even though a 10-point scale is used, it may be only possible to discriminate between high and low values or low, medium and high values.

Jobs that involve high contact stresses from pounding or exertions of connectors may still have low average values because the duration of the exertions is short as compared to the overall work cycle. High average values are sometimes observed where a worker rests his hand or forearms on hard or sharp surfaces.

The UAW-GM Risk Factor Checklist uses yes/no questions about contact with the fingers, palm, elbow and armpits with hard or sharp objects to identify contact stress hazards.¹⁴ The Washington State workplace ergonomic standard criteria for a 'caution zone job' is: '(9) Using the hand (heel/base of palm) or knee as a hammer more than 10 times per hour more than 2 hours total per day'.²²

Worker self assessments. In Table 32.5, contact stress is assessed by asking the worker if they strike, press or rest their body against any hard or sharp objects. The worker's hands often provide evidence of repeated contact via calluses, which can be observed in the clinic. In work settings, tape and packing materials on work equipment and on the worker's hands often provide evidence of contact stresses. Workers' bodies often show evidence of impact in the form of abrasions and calluses at specific locations contact with equipment (Fig. 32.7).

Posture stresses

All postures are stressful if they are maintained long enough. For example, lying in bed or sitting in an easy chair eventually becomes uncomfortable. Conversely, conspicuously stressful postures, such as stretching the arms above the head, may feel good for a brief period. Thus the question becomes: what makes one posture more stressful than another? First, some postures require more

effort than others. For example, the body must work harder to produce the same force with an outstretched arm or with a pinch grip than with the arms close to the body or with the hand in a power grip posture. Second, some postures result in greater internal stresses than others. The most common sites of these stresses are in tendons, nerves and blood vessels around joints. For example, exertion of the hand with a flexed wrist causes the flexor tendons to press against the median nerve (see Fig. 32.2). Precipitation of numbness and tingling in the median dermatome of the hand by this maneuver is considered a sign of carpal tunnel syndrome (Phalen's test).

Similarly, extreme extension of the wrist causes increased carpal canal pressure and stretching of the median nerve. Ulnar deviation of the wrist causes the extrinsic abductor and extensor tendons of the thumb to be stretched around the radial styloid process. Discomfort produced by forced deviation of the wrist with the fingers wrapped around the thumb is regarded as a positive sign of de Quervain's disease (Finkelstein's test). Stressful upper limb postures for repeated or sustained exertions include elevation of the elbows, reaching behind the torso, extreme elbow flexion, extreme forearm rotation, wrist deviation, flexion or hyperextension, and pinching. Joint angles can be measured in degrees and both peak and average values should be considered. Video methods have been proposed for assessing posture at fixed time intervals.^{33,34}

Corlett et al³⁵ proposed a graphical scheme for rating each major joint based on its degree of rotation. Armstrong et al³³ proposed an ordinal scheme for rating postures in which each major joint of the upper limb was divided into three or more zones. The Strain Index uses a system in which wrist posture is divided into five zones: very good (neutral), good, fair, bad and very bad (maximum deviation).²⁴ The UAW-GM risk factor checklist specifies acceptable ranges of postures for each joint. Postures that exceed those ranges are given a star if it occurs less than one-third of the time or a star if it occurs more than one-third of the time. Postures or joint positions can be rated from 0 to 10 where 0 is neutral and 10 is maximum deviation – as was described for repetition, force and contact stress. In most cases it is possible to achieve an extreme joint position in two or more directions. For example, the wrist can be flexed or extended or deviated in a radial or ulnar direction. The elbow can be flexed and the forearm can be rotated. The shoulder can be flexed or extended, it can be abducted or adducted, or it can be rotated. Rating can be performed for the most extreme position of a given joint or each degree of motion can be rated individually. Posture ratings should include both peak and average values.

Instrumental methods are generally beyond the scope of this discussion; however, the proliferation of commercially available equipment increases the likelihood that it will be encountered by an occupational health physician. Goniometers that can be attached externally to joints and connected to data loggers are commercially available. As was shown in the introduction to this chapter, there are important reasons why wrist postures and movements may contribute to specific MSDs. Indeed, Marras and

Figure 32.7: It is often possible to see evidence of contact stress on the surface of the body. For example, use of needle nose pliers can produce a major callus near the base of the palm.

Schonmarklin³⁶ have presented evidence that wrist velocity and acceleration measurements are associated with risk of cumulative trauma disorders. While these results are promising, further studies are needed to examine the relationship between joint postures and specific disorders before this equipment is widely used. Also, goniometers only measure posture and movement; they do not measure other factors such as force and contact stress. Presently this equipment is best used to answer narrowly defined questions about posture and as a research tool.

Worker self-assessments. In Table 32.5, posture stress is assessed by asking the worker if their job requires them to assume any unusual or uncomfortable postures. It is suggested that the physician demonstrate wrist flexion/extension and radial/ulnar deviation, extreme forearm rotation, extreme elbow flexion, extreme reaching, extreme neck motion, and, if appropriate, bending. Pictures can be used for greater standardization. The worker should then be asked where and how frequently the extreme postures are encountered. Workers also can be asked to rate posture comfort or discomfort for the overall job or specific tasks.³⁰

Low temperature

Strength, dexterity, and sensitivity are profoundly affected by skin temperatures below 18 degrees C. Most people have experienced the effect of cold fingers when working outside on a cold day. People normally exert just enough or slightly more force than is required to keep objects from slipping out of their hand, but cooling the skin results in reduced sensory function and excess force. Sources of cold exposure include ambient air, work materials, and the exhaust air from tools.

Worker self-assessments. In Table 32.5 the worker is asked if his or her hands get cold. If the answer is 'yes', subsequent questions would focus on the frequency and duration as well as the cause, e.g., is it due to low ambient temperatures or due to localized cooling from handling cold materials?

Vibration

Hand-arm vibration (HAV) has been shown to be associated with a number of soft tissue disorders of the upper limb, secondary Raynaud's phenomenon being the most notable.³⁷ It is important to remember that HAV occurs in combination with other mechanical stressors. Workers undergo vibration exposure by holding something that vibrates. Thus, vibration exposure inevitably occurs in combination with repeated or sustained exertions. Additionally, these exertions may involve high forces, localized mechanical stresses, posture stresses, and exposure to low temperatures.

Although quantitative vibration measurements require specialized instrumentation and trained technicians, it is possible to estimate the intensity of exposure from information about the job and the tools. There are several important considerations in estimating the intensity of HAV from tools. The first consideration is the action of the tool. Tool action can be classified as rotary, in which the tool turns something, such as a threaded fastener or a

grinder wheel, or as reciprocating, in which the tool moves something back and forth, such as a manual hammer, powered chipping hammer, or a rivet gun. Free running (not in contact with another object) industrial quality rotary tools that are well maintained should not exceed physiologic vibration limits; however, this may not be true for reciprocating tools. Some tools encompass both rotary and reciprocating parts. Examples include tools with internal combustion engines, such as lawn mowers and chain saws. Although these tools turn, they have reciprocating components such as pistons that may produce high vibration levels. Controls for machines and vehicles are another source of vibration exposure that should be considered. The State of Washington workplace ergonomics standard specifies maximum exposure duration limits for specified types of tools.²² For example, the limit for impact wrenches, chain saws and percussive tools is 30 minutes per day, while the limit for grinders and sanders is 2 hours per day.

Worker self-assessments. In Table 32.5 the worker is asked if anything he or she holds or touches vibrates or shakes. Subsequent questions would investigate how frequently and how long if the worker answers affirmatively.

PLANT VISIT/WALK-THROUGH

Many physicians find that walk-through inspections of workplaces provide important background information for evaluating workers they see in clinic. They also afford an excellent opportunity to learn about the attitudes of workers and employers. Table 32.9a includes a list of useful background information. Information about what the plant does, processes, equipment, materials and numbers of workers provides an overview of the operations and potential exposures. Often this information can be obtained in advance, and can be used to plan the visit. Table 32.9b is intended for collection of data about physical stress exposures for individual jobs and tasks at the time of the visit. It is important to recognize that exposures may change from job to job, hour to hour, day to day and season to season, and that the walk-through only

Table 32.9b Simple data collection forms for walk-through job surveys*

provides a sampling of some of the jobs at one point in time and may not be representative of the entire operation over the entire year or even the entire day. This can also be seen in a grocery store between the middle of the day and in the early evening or days immediately preceding holidays versus after holidays. Table 32.9a specifically asks for information on daily and seasonal variations. The walk-through should be designed to provide an overview, while allowing additional time to examine jobs with high exposures. Medical visit logs and OSHA records sometimes can be used to identify problem areas, but may be subject to statistical limitations due to small numbers, or variations in reporting.

An important source of information is from people at the plant – both workers and managers. It is helpful if both a management and worker representative accompany the physician on the walk-through. This is reinforced by a personal experience by the author during a walk-through inspection of a pork processing plant with a labor and a management representative. The management representative stated that he did not understand why people were having problems, because he himself had worked on the line for a number of years. The labor representative countered that they were previously running only 350 animals an hour through the plant, and now they were running 600. Also, the presence of the labor and management

representatives is usually reassuring to both workers and supervisors. A plant walk-through also provides an opportunity to involve others, e.g., other healthcare providers, engineers, and ergonomists who may be called upon to provide additional job information, develop job accommodations and treat patients.

Table 32.9b is intended for assessing exposures on individual jobs or job tasks, providing structure for the survey; it is not a definitive survey tool. The healthcare provider may want to request a detailed analysis using one or more of the tools listed in Table 32.1 as the need arises.

The walk-through survey should be documented in writing. It is likely that the healthcare provider will see workers from many plants and a written record will enable them to refresh their memory when they see a patient from that site. The written record also can be shared with the employer. This will help the healthcare provider and the employer reach a common understanding about the exposures. It also will give the employer feedback about exposures at that site so they can determine the feasibility of interventions.

The following examples illustrate how plant walk-through data can be used to supplement worker assessments in the clinic.

Office seating

By visiting an office worksite, the healthcare provider discovers to what degree jobs are clerical and involve keyboard and mouse work, filing, phoning, copying and meetings. It also might be discovered that some of the jobs entail repetitive handling of heavy files, while others involve prolonged interaction with the computer to compose documents with both text and graphical components. It may be determined that workers are using some new and some old furniture with varying degrees of adjustability. By inquiring about a patient's job title, job responsibilities and work equipment, the healthcare provider may be able to quickly assess the worker's exposure to mechanical stressors. Further discussion could focus on details unique to the case at hand. The following scenario illustrates the use of this job information.

A male worker from the office with persistent forearm, neck and shoulder pain visits a healthcare provider in his off-site clinic. It is quickly determined that the worker is an accounts manager who uses the computer and mouse to prepare financial reports and propose budgets. It is learned that the patient has a healthy lifestyle, with no evidence of chronic diseases, traumatic injuries, or excess recreation that might explain his symptoms. Finally it is learned that the worker had a recent deadline that required intense use of the computer and mouse and that he was working extended shifts and skipping breaks. It is also determined that the worker is 1.9 m tall (approximately 95th percentile), does not have an adjustable work surface for his keyboard, mouse, and monitor, and that his chair was difficult to adjust. By demonstrating the job, it appears that the worker has been spending 75% of his work shift, up to 12 hours a day, facing a computer monitor (non-adjustable)

with his neck flexed to highly flexed and his hands on the keyboard or mouse. The remaining time is spent handling documents and on the phone (often held between the neck and shoulder). A work restriction in this case might specify how much time the worker is permitted to key each day, and frequency of breaks. It might specify the use of a headset or speakerphone. An evaluation of the workstation to investigate modifications and to make sure the worker understands how to adjust the workstation and chair should also be initiated. Restrictions should be specified for a fixed period time, at which point the worker and restrictions would be reassessed.

Kitchen appliance manufacturer

A second example involves a manufacturer of small kitchen appliances. It is learned that the jobs include: 200 general utility workers who may be assigned to any job on the assembly line, 10 materials handlers who operate fork lifts and load and unload stock, 20 maintenance workers who set up and service equipment, six custodial workers who perform housekeeping activities, and 30 administrative/clerical workers who work in the office. From discussions with production supervisors and observations of the assembly line, it is determined that the assembly jobs have a 1-minute cycle time. The workers do not appear to be rushing, but there are no definable rest periods. Using Table 32.4 it is estimated that the repetition varies from 4 to 7 on the scale of 10.

Most of the parts handled by assemblers are small, with weights below 1 pound. While the overall force requirements are low, some jobs require nearly all of the worker's strength to install harnesses and join electrical connectors. The small size of the connectors forces assemblers to use their finger tips in awkward locations. It is also observed that about one-third of the workers use small in-line and pistol-shaped power tools. Tool use varied from one fastener per cycle to six per cycle. While most of the workers do not appear to have any trouble holding and controlling tools, many appear to jerk their wrist as the tool starts and stops. Using the methods described above, peak forces for assemblers were rated from 2 to 10 on a scale of 10. Average forces are generally below 2 on a 10 scale, but some jobs are of concern because the force never reaches zero, enabling the hands to rest. These cases occur where workers hold tools in their hand continuously – even while performing non-tool related work elements. As a result, these workers may never fully recover during work cycles (see Fig. 32.3).

Contact stress on the hand – particularly on the fingertips – results from grasping and handling of parts and tools. In some cases workers were observed joining parts by pressing and pounding on parts with the base of their palms. It was estimated peak finger and palm contact stresses are in the upper third of a 10-point scale (7–9 for some jobs), although the averages are all in the lower third of the scale 1–3.

Postures are observed to vary widely from one workstation to the next, as workers obtain and install parts and use

tools. Some notable examples include shoulder stresses associated with overhead reaching to get suspended tools, reaching for parts in tote pans, and installing parts in the moving assemblies. Some involve wrist flexion and deviation, and extreme forearm rotation to grasp and position parts and tools. Peak shoulder, forearm, and wrist postures are 7–9 on the 10-point scales as described above for repetition, force and contact stress. For most workers the average values are below 3, but for some workers the average shoulder stress is above 5. These workers were sitting down and had to keep their elbows up to reach their work.

The only source of vibration exposure is the power tools. It was observed that only about one-third of the workers use power tools. The most fasteners installed with a tool are six, which require less than 6 seconds of the 1-minute cycle time. Air-powered screw drivers generally have low vibration unless they use slip clutches to regulate torque.³⁸ The major stress associated with the hand tools is posture and force.

The assembly area is at room temperature. The only exposure to low temperature is from occasional batches of parts that are brought in from an unheated warehouse in the cold season.

Similar information would be compiled for other jobs at this worksite, e.g., materials handling, maintenance, custodial activities. These jobs will be much harder to characterize because they involve multiple and often irregular work tasks. Multiple visits or assistance from ergonomists or industrial hygienists may be required to get information about all jobs. Medical visit records and OSHA logs may be used to determine which jobs have a history of injuries and to set priorities for evaluation.

One of the first work questions for a patient with MSD symptoms from this plant would pertain to which area of the plant or which job he or she was employed in and for how long. How far back the exposures are traced would depend on the history and duration of symptoms. If the symptoms are new, it may be necessary to go back only a few months. If they are longstanding, it may be necessary to go back several years. Workplace rotations are becoming more and more common, which can increase the time required to get a full work history. At the same time, work rotations may provide an opportunity to compare jobs to see if there is anything about one position relative to another that makes symptoms worse.

For example, it may be that the worker's hand symptoms are worse when performing assembly jobs that require power tools. From the plant visit, the physician knows that hand tools are only used for a small part of any one work cycle, and that the tools do not weigh much or require high torque levels. By asking the worker to demonstrate how the tools are held and how they are used, it is learned that they are held in the hand continuously, even while other assembly operations are being performed, and that worker has to reach over the assembly and point the tool back towards himself to drive two screws. By watching the worker simulate this in the clinic, it is determined that the job requires elevation of the shoulder (7 on a scale of

10), inward rotation of the forearm (8 on a scale of 10) and extreme wrist flexion (9 on a scale of 10).

Rather than restrict the worker from the use of all power tools, the restriction is crafted to emphasize avoidance of continuous holding of tools or exertions that require flexion of the wrist or extreme forearm rotation. Further qualifications could be added depending on the severity of the case. The restrictions could be decreased over time. For example, the first week could specify that the worker should not perform any job that provides less than 20 seconds recovery time for each minute and no wrist flexion or forearm rotation more than two-thirds of their range of motion. It might still say 'no continuous holding of tools'. The following week might reduce the recovery time to 10 seconds, no wrist flexion, and no extreme forearm rotation, and still forbid continuous holding of tools. The physician would have to either instruct the employee on how to interpret wrist flexion and forearm rotation or meet with appropriate plant representatives. In many cases plants will designate someone to coordinate work restrictions between management, engineers, and healthcare providers.

These two scenarios illustrate the assessment of work exposures in both plant walk-through and clinical settings. Quality job information is essential for assessing the contribution of work to MSDs and for developing effective work restrictions. It is assumed that the work assessment also considers and prescribes for non-work factors, e.g., existing medical conditions and outside activities that can also cause MSDs. Even in cases where an MSD is due to non-work related factors, work exposures still need to be considered to avoid aggravating those conditions and facilitating return to work.

ANALYSIS OF JOBS FROM THE CLINIC

In the absence of first-hand information or summary information from the plant, the healthcare provider will have to rely on his or her interview of the worker. The information included in Tables 32.2 and 32.3 should serve as general guidelines. The healthcare provider will have to explore details as dictated by the needs of the worker and permitted by time.

Recognizing the limitations inherent in a clinical assessment of a job, many physicians will issue very conservative work restrictions, e.g., no hand tools, no gripping greater than 10 pounds, nor repetitive work. These may pose a challenge for the plant to accommodate. Physicians who issue such restrictions may want to add some qualifying language to indicate that the restriction was issued in the absence of a formal job analysis and that such an analysis should be performed to clarify the work restriction. Depending on the time or the service arrangement with the employer, the physician might want to arrange to visit the plant or for a trained job analyst to visit the plant and provide more detailed job analysis.

Worker assessments are sometimes criticized for not being objective. Studies by Homan and Armstrong³⁹ found that

workers in office settings tended to over-estimate their use of keyboards and mice by as much as 200% when compared with second party observations and electronic surveillance. The discrepancy between self-reports and external observations can be attributed to a difference in perspective and the analyst's failure to consider the worker's perspective. Most of the people were next to the computer and in some cases looking at the monitor. From their perspective they were using the keyboard. If the question is how much time they are using the keyboard, they should be asked that directly. They also should be asked what other activities they perform and how much time they devote to those tasks. Discrepancies can then be noted and discussed. It is important that the person asking the questions be perceived as neutral, and not express approval or disapproval.⁴⁰

CAUSALITY

As mentioned above, present and proposed OSHA regulations presume that injuries are work related and place a high burden on employers to prove otherwise. Healthcare providers frequently are called upon to decide if specific MSD cases are related to a specific job or, in some cases, a specific activity or tool. Determining causality goes beyond the scope of this chapter; however, information about exposure to mechanical stressors is an important consideration in determining causality. Most musculoskeletal disorders can be caused by one or more factors. The available data may be insufficient to assign exact probabilities to any one or combination of factors with a high degree of certainty; however, the data may effectively address 'more probable than not' criteria for causation. It is possible to determine if and how much a given worker was exposed to a mechanical stressor or group of stressors. This information must be weighed against knowledge of other physical and mental factors that may affect a worker's risk. This issue is likely to remain within the realm of expert medical opinion and be subject to much controversy over workers' compensation claims for the foreseeable future. This controversy must not dissuade healthcare providers from assessing mechanical stressors and treating both the cause and the consequences of musculoskeletal disorders.

SUMMARY

Musculoskeletal disorders may be caused or aggravated by certain types of work activities. Recognized risk factors include: repetitive or prolonged force, contact stresses, postures, vibration, and low temperatures. The healthcare provider should consider, along with health and personal information, information about the workers' exposure to mechanical stresses. In most cases, healthcare providers do not have time to visit the worksite each time a worker with symptoms reports to them. Thus they often have to obtain information about the job from the worker. It is helpful if the healthcare provider conducts regular walk-through inspections of workplaces so that they have a background for interviewing the worker and interpreting their responses. It is helpful if the healthcare provider under-

stands how work contributes to musculoskeletal disorders, and uses a structured approach in obtaining and interpreting clinical and workplace data.

Chapter 31

Occupational Injuries

Bruce H Alexander, Frederick P Rivara

BACKGROUND

Injuries are a leading cause of work-related morbidity and mortality among persons in the labor force, and are responsible for substantial financial loss and decreased productivity. The US Department of Labor estimated that from 1997 to 2001 an average of 6036 fatal work-related injuries occurred annually in the US, with 5915 being reported in 2001.¹ These numbers exclude losses due to the terrorist attacks of September 11, 2001, which accounted for an additional 2886 work-related fatalities. In the same time period, 4.9 million non-fatal injuries were reported by the Bureau of Labor Statistics.² The long-term and economic burden of work-related injuries is substantial. The National Safety Council (NSC) estimates that 3.9 million disabling occupational injuries occurred in the United States in 2001.³ The total estimated costs for these injuries were \$132.1 billion, which included \$24.6 billion in medical costs alone.³ Work-related injuries also result in enormous losses in worker productivity. Injuries sustained in 2001 caused an estimated 85 million lost workdays, and another 45 million lost workdays were attributed to injuries from previous years. The cumulative economic effect of these lost workdays totaled \$69.2 billion in lost wages and productivity. On an individual basis, approximately \$970 of every worker's annual productivity is absorbed by the costs of occupational injury. The true number and costs of work-related injuries are unknown, and the NSC estimates are subject to debate. However, there is little debate on the importance of work-related injuries and the need to improve injury prevention measures.

THE SCIENCE OF INJURY CONTROL

Over the last three decades, the field of injury control has developed a solid scientific basis by which a substantial reduction in the morbidity and mortality from trauma can be expected. Injuries are viewed as preventable problems, not as 'accidents' that occur without pattern, predictability or reason. Viewing injuries as 'accidents' fosters a sense of fatalism, in which a certain number of deaths and permanently disabling injuries are believed to be inevitable.

One of the basic premises of this approach to trauma is conceptually separating the injury (i.e., the trauma to the individual) from the events leading to the injury. A motor vehicle collision is separate from the injuries that may or may not occur in the collision; the injuries are not

an inevitable outcome of such an event. Even if the collision cannot be prevented, the chance of injury may be substantially decreased through the use of seat restraints and vehicle design to protect the occupants. Likewise, a slip from a roof does not need to lead to a fall and injury, if the person is restrained with a safety harness.

Once injuries occur, the outcome (recovery, temporary or permanent disability, or death) is also influenced by the availability of adequate pre-hospital care at the scene, rapid transport to an appropriately equipped trauma center, and the provision of rehabilitation care to return the individual back to his or her level of functioning before the injury. The emphasis is on injury control, a more comprehensive concept than the more traditional approach, which encompasses only injury prevention. The paradigm of injury control incorporates etiologic research, interventions, and outcomes (Fig. 31.1).⁴ Etiologic research explores not only the causes of injury and the factors that reduce the frequency and severity of injury, but also how the body responds to energy transfer during an injury event and the healing process. The intervention phase of injury control focuses on modifying risk factors to prevent an injury from occurring and ameliorating the negative effects of injury events and any injuries that occur. The final aspect of injury control is to change the outcomes of hazardous situations by reducing the rate and severity of injury, decreasing the costs of injury and their impact on productivity, improving trauma care, and the overall quality of life of injured workers.

A useful tool for examining injury problems and determining potential avenues for intervention is the matrix developed by Haddon (Table 31.1).⁵ This takes the classic epidemiologic paradigm of agent, host, and environment and applies it to the pre-event, event, and post-event factors associated with the occurrence of injury. The matrix also separates the physical environment from the sociocultural environment of laws, expectations, and norms that affect injuries and prevention strategies.

A large body of research conducted over the last two decades has established that injury prevention strategies are likely to be most successful if they operate automatically, without needing repeated behavioral change on the part of the individual.⁶ Thus, modification of the environment or of the product and vehicle to reduce the hazards associated with their use are likely to have the greatest impact on injuries. Examples of these successes are airbags, anti-lock brakes, interstate highways, rollover protection devices on tractors, and bulletproof partitions in taxicabs. Legislation and regulation have also proved to be effective

Table 31.1 Haddon matrix*

adjuncts to decreasing the toll from injury. Mandatory seat belt use and motorcycle helmet laws have resulted in a substantial reduction of fatalities on the nation's highways. Gun control laws may help to curb the epidemic of homicides that occur both at home and at work.

The effectiveness of educational programs to change behavior is difficult to establish. Training workers in the proper use of equipment is a key safety measure in many industries. The fact that injuries are often associated with unsafe behavior attests to the difficulties inherent in this approach. Since its inception in 1971, OSHA has required engineering changes and workplace controls as the primary means of reducing hazards in the workplace.

The severity of an injury will vary depending on the mechanism and the underlying causal force. When evaluating the effectiveness of control programs or prioritizing prevention efforts, an understanding of the severity of injuries is necessary. Several algorithms for scoring the severity of injuries have been developed, although they have traditionally been directed toward predicting the survival and functional outcome of victims of very severe injuries. Some essential injury severity scoring systems include: the Abbreviated Injury Score (AIS), developed by the Association for the Advancement of Automotive Medicine,⁷ that is primarily based on the diagnostic classification and location of injury, and the Injury Severity Score (ISS),^{8,9} which is directly calculated from the most severe AIS scores of each body region and was developed as a method to characterize multiple injuries. Limitations of these scoring systems have led to the proposal of potential alternatives, including the New Injury Severity Score (NISS)¹⁰ and the Anatomic Profile Score (APS),¹¹ that are intended to more accurately describe severity due to multiple injuries. More complex injury severity rating systems, which include physiologic parameters, have been specifically developed for evaluating patients in trauma centers.^{12–14}

The above scoring systems, and several other proposed algorithms, are directed at the most severe injuries and often require substantial clinical information. A majority of the work-related injury burden may result in a range of

Indicators

- *Death*
- *Permanent total disability*: loss of functions necessary for work or routine life skills.
- *Permanent partial disability*: limits work or normal activities.
- *Time-loss injuries*: injuries that meet a minimum amount of time away from work, allowing the injured worker to collect worker compensation wage replacement. The criteria vary by state.
- *Return to work*: return to work or return to normal tasks. This may be influenced by the occupation and usual job tasks.
